About the Authors

Joanne M. Willey has been a professor at Hofstra University on Long Island, New York, since 1993, where she is Professor of Microbiology; she holds a joint appointment with the Hofstra University School of Medicine. Dr. Willey received her B.A. in Biology from the University of Pennsylvania, where her interest in microbiology began with work on cyanobacterial growth in eutrophic streams. She earned her Ph.D. in biological oceanography (specializing in marine microbiology) from the Massachusetts Institute of Technology–Woods Hole Oceanographic Institution Joint Program in 1987. She then went to Harvard University, where she spent her postdoctoral fellowship studying the filamentous soil bacterium *Streptomyces coelicolor*. Dr. Willey continues to investigate this fascinating microbe and has coauthored a number of publications that focus on its complex developmental cycle. She is an active member of the American Society for Microbiology (ASM), and served on the editorial board of the journal *Applied and Environmental Microbiology* for nine years and as Chair of the Division of General Microbiology. Dr. Willey regularly teaches microbiology to biology majors as well as medical students. She also teaches courses in cell biology, marine microbiology, and laboratory techniques in molecular genetics. Dr. Willey lives on the north shore of Long Island with her husband and two sons. She is an avid runner and enjoys skiing, hiking, sailing, and reading. She can be reached at joanne.m.willey@hofstra.edu.

Linda M. Sherwood is a member of the Department of Microbiology at Montana State University. Her interest in microbiology was sparked by the last course she took to complete a B.S. degree in Psychology at Western Illinois University. She went on to complete an M.S. degree in Microbiology at the University of Alabama, where she studied histidine utilization by *Pseudomonas acidovorans*. She subsequently earned a Ph.D. in Genetics at Michigan State University, where she studied sporulation in *Saccharomyces cerevisiae*. She briefly left the microbial world to study the molecular biology of *dunce* fruit flies at Michigan State University before moving to Montana State University. Dr. Sherwood has always had a keen interest in teaching, and her psychology training has helped her to understand current models of cognition and learning and their implications for teaching. Over the years, she has taught courses in general microbiology, genetics, biology, microbial genetics, and microbial physiology. She has served as the editor for ASM's *Focus on Microbiology Education* and has participated in and contributed to numerous ASM Conferences for Undergraduate Educators (ASMCUE). She also has worked with K–12 teachers to develop a kit-based unit to introduce microbiology into the elementary school curriculum and has coauthored with Barbara Hudson a general microbiology laboratory manual, *Explorations in Microbiology: A Discovery Approach*, published by Prentice-Hall. Her association with McGraw-Hill began when she prepared the study guides for the fifth and sixth editions of *Microbiology*. Her non-academic interests focus primarily on her family. She also enjoys reading, hiking, gardening, and traveling. She can be reached at lsherwood@montana.edu.

Christopher J. Woolverton is founding professor of Environmental Health Science, College of Public Health at Kent State University (Kent, OH), and is the Director of the Kent State University (KSU) Center for Public Health Preparedness, overseeing its BSL-3 Training Facility. Dr. Woolverton serves on the KSU graduate faculty of the College of Public Health, the School of Biomedical Sciences, and the Department of Biological Sciences. He holds a joint appointment at Akron Children's Hospital (Akron, OH). He earned his B.S. in Biology from Wilkes College (PA), and his M.S. and Ph.D. in Medical Microbiology from West Virginia University, School of Medicine. He spent two years as a postdoctoral fellow at UNC-Chapel-Hill. Dr. Woolverton's current research is focused on real-time detection and identification of pathogens using a liquid crystal (LC) biosensor that he patented in 2001. Dr. Woolverton has published and lectured widely on the mechanisms by which LCs act as biosensors and on the LC characteristics of microbial proteins. Professor Woolverton teaches microbiology, communicable diseases, immunology, prevention and control of disease, and microbial physiology. He is on the faculty of the National Institutes of Health National Biosafety and Biocontainment Training Program, teaching laboratory safety, risk assessment, decontamination strategies, and bioterrorism readiness. An active member of the American Society for Microbiology, Woolverton serves on its Board of Education and as the editor-in-chief of its *Journal of Microbiology and Biology Education*. Woolverton and his wife, Nancy, have three daughters, a son-in-law, and a grandson. He enjoys time with his family, ultra-light hiking and camping, and is an avid cyclist. His e-mail address is cwoolver@kent.edu.

Digital Tools for Your Success

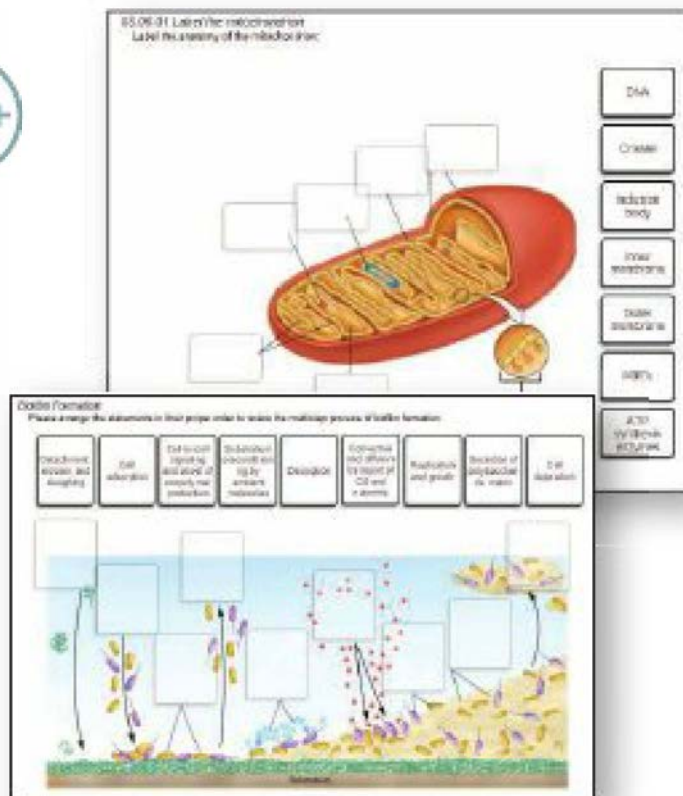

**Save time with auto-graded assessments
Gather powerful performance data.**

McGraw-Hill ConnectPlus® Microbiology provides online presentation, assignment, and assessment solutions, connecting your students with the tools and resources they'll need to achieve success.

Homework and Assessment

With **ConnectPlus Microbiology**, you can deliver auto-graded assignments, quizzes, and tests online. A robust set of interactive questions and activities using high-quality art from the textbook and animations is presented. Assignable content is available for every Learning Outcome in the book and is categorized according to the **ASM Curriculum Guidelines**. As an instructor, you can edit existing questions and author entirely new problems.

INSTRUCTOR RESOURCES

Customize your lecture with tools such as PowerPoint® presentations, animations, and editable art from the textbook. An instructor's manual for the text and lab manual as well as answer keys to in-text questions save you time in developing your course.

EBOOK

ConnectPlus Microbiology provides students 24/7 online access to a media-rich version of the book, allowing seamless integration of text, media, and assessments.

Detailed Reports

Track individual student performance—by question, assignment, or in relation to the class overall—with detailed grade reports. Integrate grade reports easily with Learning Management Systems (LMS), such as WebCT and Blackboard—and much more.

Lecture Capture

McGraw-Hill Tegrity® records and distributes your class lecture with just a click of a button. Students can view anytime, anywhere via computer or mobile device. Indexed as you record, students can use keywords to find exactly what they want to study.

Learn more at www.mcgrawhillconnect.com.

Digital Tools for Your Success

A diagnostic, adaptive learning system to increase preparedness.

Now Available for the Ninth Edition!

McGraw-Hill LearnSmart™ is an adaptive learning system designed to help students learn faster, study more efficiently, and retain more knowledge for greater success. LearnSmart assesses a student's knowledge of course content through a series of adaptive questions. It pinpoints concepts the student does not understand and maps out a **personalized study plan** for success. This innovative study tool also has features that allow instructors to see exactly what students have accomplished and a built-in assessment tool for graded assignments.

Visit www.mhlearnsmart.com for a demonstration.

Laboratory Exercises in Microbiology, Ninth Edition

John P. Harley has revised this laboratory manual to accompany the ninth edition of *Prescott's Microbiology*. The class-tested exercises are modular to allow instructors to easily incorporate them into their course. This balanced introduction to each area of microbiology now also has accompanying Connect content for additional homework

and assessment opportunities. In addition, all artwork from the lab manual is now available through the Instructor Resources in Connect for incorporation into lectures.

With McGraw-Hill Create™, you can easily rearrange chapters, combine material from other content sources, and quickly upload content you have written, such as your course syllabus or teaching notes. Find the content you need in Create by searching through thousands of leading McGraw-Hill textbooks. Arrange your book to fit your teaching style. Create even allows you to personalize your book's appearance by selecting the cover and adding your name, school, and course information. Order a Create book and you'll receive a complimentary print review copy in three to five business days or a complimentary electronic review copy (eComp) via e-mail in minutes. Go to www.mcgrawhillcreate.com today and register to experience how McGraw-Hill Create empowers you to teach your students your way.

A Modern Approach to Microbiology

Evolution as a Framework

Introduced immediately in chapter 1 and used as an overarching theme throughout, evolution helps unite microbiological concepts and provides a framework upon which students can build their knowledge.

Separate Chapters on Bacteria and Archaea

In recognition of the importance and prevalence of archaea, the structure, genetics, and taxonomic and physiologic diversity of these microbes are now covered in chapters that are separate from those about bacteria.

An Introduction to the Entire Microbial World

Now covered in chapters 3–6, the separate chapters on the structure and function of bacteria and archaea are followed by the discussion of eukaryotic cells preceding viruses.

Brief Contents

About the Authors iii
Preface iv

Part One Introduction to Microbiology

- 1 The Evolution of Microorganisms and Microbiology 1
- 2 Microscopy 22
- 3 Bacterial Cell Structure 42
- 4 Archaeal Cell Structure 82
- 5 Eukaryotic Cell Structure 92
- 6 Viruses and Other Acellular Infectious Agents 112

Part Two Microbial Nutrition, Growth, and Control

- 7 Microbial Growth 133
- 8 Control of Microorganisms in the Environment 172
- 9 Antimicrobial Chemotherapy 189

Part Three Microbial Metabolism

- 10 Introduction to Metabolism 210
- 11 Catabolism: Energy Release and Conservation 230
- 12 Anabolism: The Use of Energy in Biosynthesis 266

Part Four Microbial Molecular Biology and Genetics

- 13 Bacterial Genome Replication and Expression 287
- 14 Regulation of Bacterial Cellular Processes 325
- 15 Eukaryotic and Archaeal Genome Replication and Expression 353
- 16 Mechanisms of Genetic Variation 372
- 17 Recombinant DNA Technology 404
- 18 Microbial Genomics 424

Part Five The Diversity of the Microbial World

- 19 Microbial Taxonomy and the Evolution of Diversity 447
- 20 The Archaea 469
- 21 The Bacteria, Mollicutes, and Nonproteobacterial Gram-Negative Bacteria 489
- 22 The Proteobacteria 509
- 23 Firmicutes: The Low G + C Gram-Positive Bacteria 542

- 24 Actinobacteria: The High G + C Gram-Positive Bacteria 555
- 25 The Protists 568
- 26 The Fungi (Eumycota) 588
- 27 Viruses 604

Part Six Ecology and Symbiosis

- 28 Biogeochemical Cycling and Global Climate Change 632
- 29 Methods in Microbial Ecology 646
- 30 Microorganisms in Marine and Freshwater Ecosystems 660
- 31 Microorganisms in Terrestrial Ecosystems 679
- 32 Microbial Interactions 699

Part Seven Pathogenicity and Host Response

- 33 Innate Host Resistance 723
- 34 Adaptive Immunity 753
- 35 Pathogenicity and Infection 789

Part Eight Microbial Diseases, Detection, and Their Control

- 36 Clinical Microbiology and Immunology 808
- 37 Epidemiology and Public Health Microbiology 830
- 38 Human Diseases Caused by Viruses and Prions 854
- 39 Human Diseases Caused by Bacteria 888
- 40 Human Diseases Caused by Fungi and Protists 932

Part Nine Applied Microbiology

- 41 Microbiology of Food 958
- 42 Biotechnology and Industrial Microbiology 979
- 43 Applied Environmental Microbiology 996

Appendix 1 A Review of the Chemistry of Biological Molecules A-1

Appendix 2 Common Metabolic Pathways A-9

Index I-1

Secondary Lymphoid Organs and Tissues

The spleen is the most highly organized secondary lymphoid organ. It is a large organ located in the abdominal cavity that functions to filter the blood and trap blood-borne particles to be assessed for foreignness by phagocytes (figure 33.14). Macrophages and dendritic cells are present in abundance, and once trapped by splenic macrophages or dendritic cells, a pathogen is phagocytosed, killed, and digested. The resulting antigens are presented to lymphocytes, activating a specific immune response.

Lymph nodes lie at the junctions of lymphatic vessels, where macrophages and dendritic cells trap particles that enter the lymphatic system (figure 33.14c). If a particle is found to be foreign, it is then phagocytosed and degraded, and the resulting antigens are presented to lymphocytes.

Lymphoid tissues are found throughout the body as highly organized or loosely associated cellular complexes (figure 33.14). Some lymphoid cells are closely associated with specific tissues such as skin (skin-associated lymphoid tissue, or SALT) and mucous membranes (mucosal-associated lymphoid tissue, or MALT). SALT and MALT are good examples of highly organized lymphoid tissues that feature macrophages surrounded by specific areas of B and T lymphocytes and sometimes dendritic cells. Loosely associated lymphoid tissue is best represented by the bronchial-associated lymphoid tissue (BALT), because it lacks cellular partitioning. The primary role of these lymphoid tissues is to efficiently organize leukocytes to increase interaction between the innate and the adaptive arms of the immune response. Thus, the lymphoid tissues serve as the interface between the innate resistance mechanisms and adaptive immunity of a host. We now discuss these tissues in more detail.

Despite the skin's defenses, at times pathogenic microorganisms gain access to the tissue under the skin surface. Here they encounter a specialized set of cells called the **skin-associated lymphoid tissue (SALT)** (figure 33.15). The major function of SALT is to confine microbial invaders to the area immediately underlying the epidermis and to prevent them from gaining access to the bloodstream. One type of SALT cell is the **Langerhans cell**, a dendritic cell that phagocytoses microorganisms that penetrate the skin. Once the Langerhans cell has internalized a foreign particle or microorganism, it migrates from the epidermis to nearby lymph nodes, where it presents antigen to activate nearby lymphocytes, inducing a specific immune response to that antigen. This dendritic cell–lymphocyte interaction illustrates another bridge between innate resistance and adaptive immunity.

The epidermis also contains another type of SALT cell called the **intraepidermal lymphocyte** (figure 33.15), a specialized T cell having potent cytolytic and immunoregulatory responses to antigen. These cells are strategically located in the skin so that they can intercept any antigens that breach the first line of defense. Most of these specialized SALT cells have limited receptor diversity and have likely evolved to recognize common skin pathogen patterns.

Figure 33.15 Skin-Associated Lymphoid Tissue (SALT). Keratinocytes make up 90% of the epidermis. They are capable of secreting cytokines that cause an inflammatory response to invading pathogens. Langerhans cells internalize antigen and move to a lymph node, where they differentiate into dendritic cells that present antigen to helper T cells. The intraepidermal lymphocytes may function as T cells that can activate B cells to induce an antibody response.

The specialized lymphoid tissue in mucous membranes is called **mucosal-associated lymphoid tissue (MALT)**. There are several types of MALT. The system most studied is the **gut-associated lymphoid tissue (GALT)**. GALT includes the tonsils, adenoids, diffuse lymphoid areas along the gut, and specialized regions in the intestine called Peyer's patches. Less well-organized MALT also occurs in the respiratory system and

Molecular Microbiology and Immunology

The ninth edition includes updates on genetics, biotechnology, genomics, and immunology. The discussion of eukaryotic and archaeal genetics has been expanded and makes up a separate chapter to reflect the relatedness of genetic information flow. A streamlined discussion of immunity with enhanced detail between innate and adaptive linkages helps students grasp the complexity and specificity of immune responses.

A Modern Approach to Microbiology

(Figure 28.12). Ammonium runoff leaches into lakes and streams, frequently causing eutrophication—an increase in nutrient levels that stimulates the growth of a limited number of organisms, thereby disturbing the ecology of these aquatic ecosystems. By contrast, microbial nitrification can result in the oxidation of ammonium to nitrate, which can be immobilized by plants and microbes, as organisms need specific ratios of C:N:P. The process of denitrification converts this nitrate to N_2 and the reactive greenhouse nitrogen oxide. This cycle of nitrification/denitrification fueled by NH_4^+ introduced used as fertilizer is responsible for the highest N_2O levels in 650,000 years.

What are the consequences of disrupting the carbon and nitrogen cycles? Global climate change is the most obvious example. It is important to keep in mind that weather is not the same as climate. While North America has suffered some of the hottest summers on record in the past decade, a single day or week in July that is particularly hot is not, by itself, evidence of global climate change. Global climate change is measured over decades and includes many parameters such as surface temperature on land and sea, and in the atmosphere and troposphere; rates of precipitation; and frequency of extreme weather. Based on these analyses, the average global temperature has increased 0.74°C , and this rise is directly correlated with fossil fuel combustion to CO_2 (Figure 28.13). Depending on the rate of continued increase in greenhouse gases, the average global surface temperature is predicted to rise between 1.1 and 6.4°C by 2100.

An important question is how will microbes respond to a changing world. Because for the vast majority of Earth's history, microorganisms have been the drivers of elemental cycling, changes in microbial activities will have a major impact on the rate and magnitude of greenhouse gas accumulation and global climate change. The role microbes play in balancing carbon and nitrogen fluxes has opened new avenues of research in microbial ecology.

Retrieve, Infer, Apply

1. List three greenhouse gases. Discuss their origins.
2. Discuss the possible role of forests in the control of CO_2 .
3. How do changes in the nitrogen cycle caused by fertilization influence the carbon cycle?
4. Given that each microbial group has an optimum temperature range for growth, how might you predict changes to a soil microbial community living in your geographic area?

Figure 28.12 Natural and Human-Made Influences on the Nitrogen Cycle.
MICRO INQUIRY What organisms benefit from nitrification?

Figure 28.13 Global Annual-Mean Surface Air Temperature Change. Data is derived from the meteorological station network. Goddard Institute for Space Sciences, <http://data.giss.nasa.gov/temp/global/>.

21st-Century Microbiology

Prescott's Microbiology leads the way with updated text devoted to global climate change, biofuels, and microbial fuel cells. For more, see chapters 28, 30, 42, and 43.

Metagenomics and the Human Microbiome

The updated genomics chapter covers the technical aspects of metagenomics, and the human microbiome is discussed in the context of microbial interactions in chapters 18 and 32.

Laboratory Safety

Reflecting forthcoming recommendations from the American Society for Microbiology, chapter 37 provides specific guidance for laboratory best practices to help instructors provide safe conditions during the teaching of laboratory exercises.

Special Interest Essays

Organized into four themes—Microbial Diversity & Ecology, Techniques & Applications, Historical Highlights, and Disease—these focused and interesting essays provide additional insight to relevant topics.

Microbial Diversity & Ecology

3.1 Gram Positive and Gram Negative or Monoderms and Diderms?

The importance of the Gram stain in the history of microbiology cannot be overstated. The Gram stain reaction was for many years one of the critical pieces of information used by bacterial taxonomists to construct taxa, and it is still useful in identifying bacteria in clinical settings. The initial studies done to differentiate bacteria that stained Gram positive from those that stain Gram negative were done using model organisms such as *Bacillus subtilis* (Gram positive) and *Escherichia coli* (Gram negative). At the time, it was thought that all other bacteria would have similar cell wall structures. However, as the cell walls of more bacteria have been characterized, it has become apparent that it may be misleading to refer to bacteria as Gram positive or Gram negative. In other words, the long-held models of Gram-positive and Gram-negative cell walls do not hold true for all bacteria. Recently Iain Sutcliffe has proposed that microbiologists stop referring to bacteria as either Gram positive or Gram negative. He suggests that instead we should more precisely describe bacterial cell envelope architectures by focusing on the observation that some bacteria have envelopes with a single membrane—the plasma membrane as seen in typical Gram-positive bacteria—while others have envelopes with two membranes—the plasma membrane and an outer membrane as seen in typical Gram-negative bacteria. He proposed calling the former monoderms and the latter diderms.

But why make this change? Sutcliffe begins by pointing out that some bacteria staining Gram positive are actually diderms and some staining Gram negative are actually monoderms. By referring to Gram-positive-staining diderms as Gram-positive bacteria, it is too easy to mislead scientists

and many a budding microbiologist into thinking a bacterium has a typical Gram-positive envelope. By relating cell envelope architecture to the names of various bacterial taxa, we may gain insight into the evolution of these architectures. He notes that the *micutes* and *Actinobacteria* are composed almost of monoderm bacteria, whereas almost all other phyla consist of diderms.

There are interesting exceptions to the relationship between phylogeny and cell envelope structure. For instance, the genus *Mycobacterium* (e.g., *M. tuberculosis*) to the predominantly monoderm phylum *Actinobacteria* have cell walls that consist of peptidoglycan and an outer membrane. The outer membrane is of mycolic acids rather than the phospholipid polysaccharides (LPSs) found in the typical Gram-negative cell's outer membrane. **Suborder** Corynebacteriales (section 24.1).

Members of the genus *Deinococcus* are another interesting exception. These bacteria stain Gram positive. Their cell envelopes consist of the plasma membrane, what appears to be a typical Gram-negative cell's outer S-layer. Their outer membrane is distinctive in lacking LPS. *Deinococcus* are not unique in this respect. It is now known that there are several taxa with cell membranes that substitute other molecules for LPS.

Disease

26.1 White-Nose Syndrome Is Decimating North American Bat Populations

Bats evoke all kinds of images. Some people immediately think of vampire bats and are repulsed. Others think of the large fruit bats often called flying foxes. If you have spent a summer evening outdoors on the east coast of North America, mosquitoes and the small bats that eat them may come to mind. A new scene can now be added to these: bats with white fungal hyphae growing around their muzzles (box figure). This is the hallmark of white-nose syndrome (WNS), and if its rate of infection continues unchecked, it is projected to eliminate the most common bat species in eastern North America (*Myotis lucifugus*) by 2026.

WNS was first spotted in 2006 among bats hibernating in a cave near Albany, NY. Scientists quickly became alarmed for two reasons. First, it spreads rapidly—it's known to occur in at least six bat species and is now found from the mid-Atlantic United States, northward into Canada (Ontario, Quebec, and New Brunswick), and as far west as Oklahoma. Second, it is deadly. A population of bats declines from 30 to 99% in any given infected hibernacula (the place where bats hibernate, which unfortunately rhymes with Dracula).

WNS is caused by the ascomycete *Geomyces destructans*. It colonizes a bat's wings, muzzle, and ears where it first

erodes the epidermis and then invades the underlying skin and connective tissue. Despite the name WNS, the primary site of infection (and the anatomical site harmed most) is the wing. Wings provide a large surface area for colonization, and once infected, the thin layer of skin is easily damaged, leading to adverse physiological changes during hibernation. These in turn result in premature awakening, loss of essential fat reserves, and strange behavior.

Where did this pathogen come from and why does it infect bats? The best hypothesis regarding its origin is that humans inadvertently brought it from Europe, where it causes mild infection in at least one hibernating bat species. This makes *G. destructans* an apparent case of pathogen pollution—the human introduction of invasive pathogens of wildlife and domestic animal populations that threaten biodiversity and ecosystem function.

The capacity of *G. destructans* to sweep through bat populations results from a "perfect storm" of host- and pathogen-associated factors. *G. destructans* is psychrophilic, with a growth optimum around 12°C ; it does not grow above 20°C . All infected bat species hibernate in cold and humid environments such as caves and mines. Because their metabolic rate is drastically reduced during hibernation, their body temperature reaches that of their surroundings, between 2 and 7°C . Thus WNS is only seen in hibernating bats or those that have just emerged from hibernation. When metabolically active, the bat's body temperature is too warm to support pathogen growth.

While it is too late to save the estimated 6 million bats that have already succumbed to WNS, microbiologists, conservationists, and government agencies are trying to limit the continued decline in bat populations. Caves have been closed to human traffic, and protocols for decontamination after visiting hibernacula have been developed to limit the spread from cave to cave. Although we cannot cure sick bats, it is our responsibility to stop the continued spread of this pathogen.

Geomyces destructans causes WNS. A little brown bat (*Myotis lucifugus*) with the white fungal hyphae (arrow) for which WNS is named.

Viruses and Other Acellular Infectious Agents

Mustard, Catsup, and Viruses?

During the summer of 2010, over 21 million hot dogs were sold to fans attending games at major league baseball parks in the United States. Hot dogs and lunchmeats are popular at outings such as baseball games and in lunches carried to work or school. Yet each year in the United States, approximately 1,500 people are sickened by a bacterium that can contaminate the meat and, even worse, survive and grow when the meats are properly refrigerated.

The disease is called *Listeria monocytogenes*, a Gram-positive rod found in soil and many other environmental sites. It is not only cold-tolerant but also acid-tolerant as well. Although it is in the minor leagues when compared to some of the big hitters of foodborne disease (e.g., *Salmonella enterica*), it is of concern for two reasons: who it kills and how many it kills. *L. monocytogenes* targets the young and old, pregnant women, and immunocompromised individuals; about 15% of those infected die.

Infection in pregnant women is particularly heart-breaking. The woman usually suffers mild, flu-like symptoms; however, these innocuous symptoms belie the fact that the child she carries is in serious danger. Her pregnancy often ends in miscarriage or stillbirth. Newborns infected with the bacterium are likely to develop meningitis. Many will die as a result. Those who survive often have neurological disorders.

Currently, pregnant women are counseled against eating ready-to-eat food unless they have been cooked prior to consumption. However, *L. monocytogenes* is known to contaminate many foods other than hot dogs and these can always be heated. In 2006 the U.S. Food and Drug Administration (FDA) approved a new approach to prevent listeriosis: spraying viruses that attack and destroy the bacterium on ready-to-eat cold cuts and lunchmeats. In other words, the viruses are a food additive! The method is safe because the viruses only attack *L. monocytogenes*, not human cells.

Since approval, the use of viruses to control the transmission of listeriosis by other foods has been studied. Unfortunately, these studies did not include foods such as fresh fruit. In 2011 *L. monocytogenes*-contaminated

This young man is clearly enjoying his hot dog. Hot dogs and other ready-to-eat meats are a favorite at picnics, baseball games, and other sporting events. However, they can also transmit foodborne pathogens.

cantaloupes caused an outbreak of listeriosis in 20 states in the United States, which infected over 80 and killed over 20.

Viruses as agents of good will come as a surprise to many. Typically we think of them as major causes of disease. However, viruses are significant for other reasons. They are vital members of aquatic ecosystems. They interact with cellular microbes and contribute to the movement of organic matter from particulate forms to dissolved forms. Bacterial viruses are being used in some European countries to treat infections caused by bacteria. Finally, they are important model organisms. In the chapters, we introduce viruses and other acellular infectious agents. Aquatic viruses (section 38.2); Biological control of microorganisms (section 8.7)

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Define the term acellular
- ✓ Compare and contrast the terms viruses, viroids, satellites, and prions (section 1.1)

6.1 Viruses

After reading this section, you should be able to:

- Define the terms virology, bacteriophages, and phages
- List organisms that are hosts to viruses

The discipline of virology studies **viruses**, a unique group of infectious agents whose distinctiveness resides in their simple, acellular organization and pattern of multiplication. Despite this simplicity, viruses are major causes of disease. For instance, many human diseases are caused by viruses, and more are discovered every year, as demonstrated by the appearance of SARS in 2003, new avian influenza viruses over the past 5 to 6 years, and the H1N1 (swine) influenza virus in 2009. However, their simplicity also has made them attractive model organisms. They served as models for understanding DNA replication, RNA synthesis, and protein synthesis. Therefore, the study of viruses has contributed

New! Newsworthy Stories—Each chapter begins with a real-life story illustrating the relevance of the content covered in the upcoming text.

New! Readiness Check—The introduction to each chapter includes a skills checklist that defines the prior knowledge a student needs to understand the material that follows.

New! Learning Outcomes—Every section in each chapter begins with a list of content-based activities students should be able to perform after reading.

Micro Inquiry—Select figures throughout every chapter contain probing questions, adding another assessment opportunity for the student.

Figure 6.13 Release of 14 Virions by Lysis of the Host Cell. The host cell has been lysed (upper right portion of the cell) and virions have been released into the surroundings. Progeny virions also can be seen in the cytoplasm. In addition, empty capsids of the infecting virus particles coat the outside of the cell (XC36,500).

MICRO INQUIRY Why do the empty capsids remain attached to the cell after the viral genome enters the host cell?

by a multistep process. First, virus-encoded proteins are incorporated into the membrane. Then the nucleocapsid is simultaneously released and the envelope formed by membrane budding (figure 6.14). In several virus families, a matrix (M) protein attaches to the plasma membrane and aids in budding.

Figure 6.14 Release of Influenza Virus Virions by Budding. For simplicity, only one of the seven to eight possible nucleocapsids are shown.

6.3 Viral Multiplication 123

Most envelopes arise from the plasma membrane. The endoplasmic reticulum, Golgi apparatus, and other internal membranes also can be used to form envelopes. Mechanism for Releasing Enveloped Viruses
Interestingly, some viruses are not released from their host cell into the surrounding environment. Rather, their virions move from one host cell directly to another host cell. For example, vaccinia viruses elicit the formation of long actin tails that propel nucleocapsids through the plasma membrane, directly into an adjacent cell. In this way, the virus avoids detection by the host immune system. The genomes of plant viruses also move directly from cell to cell through small connections called plasmodesmata that link adjacent cells. This spread of the viral genome typically involves virus-encoded movement proteins. Cytoplasm of eukaryotes (section 5.3)

Retrieve, Infer, Apply

1. Explain why the receptors that viruses have evolved to use are host surface proteins that serve very important, and sometimes essential, functions for the host cell?
2. What probably plays the most important role in determining the tissue and host specificity of viruses? Give some specific examples.
3. How do you think the complexity of the viral assembly process correlates with viral genome size?
4. In general, DNA viruses can be much more dependent on their host cells than can RNA viruses. Why is this so?
5. Consider the origin of viral envelopes and suggest why enveloped viruses that infect plants and bacteria are rare.

Animation Icon—This symbol indicates material presented in the text is also accompanied by an animation on the text website at www.mhhe.com/wiley9.

Cross-Referenced Notes—In-text references refer students to other parts of the book to review.

Retrieve, Infer, Apply—Questions within the narrative of each chapter assist students in mastering section concepts before moving on to other topics.

Student-Friendly Organization

Vivid Instructional Art Program—Three-dimensional renditions and bright, attractive colors enhance learning.

More Annotated Figures—All key metabolic pathways and molecular processes are now annotated, so that each step is clearly illustrated and explained.

Key Concepts—At the end of each chapter and organized by numbered headings, this feature distills the content to its essential components with completely cross-referenced figures and tables.

Compare, Hypothesize, Invent—Includes questions taken from current literature; designed to stimulate analytical problem-solving skills.

422 CHAPTER 17 | Recombinant DNA Technology

Key Concepts

17.1 Key Developments in Recombinant DNA Technology

- Genetic engineering became possible after the discovery of restriction enzymes and reverse transcriptase, and the development of essential methods in nucleic acid chemistry such as the Southern blotting technique.
- Restriction enzymes are important because they cut DNA at specific sequences, thereby releasing fragments of DNA that can be joined or otherwise manipulated (figure 17.3 and table 17.2).
- Gel electrophoresis is used to separate molecules according to charge and size.
- DNA fragments are separated on agarose and ethidium bromide gels. Because DNA is acidic, it migrates from the negative to the positive end of a gel (figure 17.6).

17.2 Polymerase Chain Reaction

- The polymerase chain reaction (PCR) allows small amounts of specific DNA sequences to be increased in million-fold thousands of times (figure 17.8).
- PCR has numerous applications. It often is used to obtain genes for cloning and in diagnostic and forensic science.

17.3 Cloning Vectors and Creating Recombinant DNA

- There are four types of cloning vectors: plasmids, viruses, cosmids, and artificial chromosomes. Cloning vectors generally have at least three components: an origin of replication, a selectable marker, and a multicloning site or polylinker (table 17.3; figures 17.10 and 17.12).
- The most common approach to cloning is to digest both vector and DNA to be inserted with the same restriction enzyme or enzymes so that complementary sticky ends are generated. The vector and DNA are then joined in the presence of DNA ligase, which catalyzes the formation of phosphodiester bonds once the DNA fragment inserts into the vector.
- Once the recombinant plasmid has been introduced into host cells, cells carrying vector must be selected. This is often accomplished by allowing the growth of only

Compare, Hypothesize, Invent

1. You are performing a PCR to amplify a gene encoding a protein from a bacterium that has only recently been grown in pure culture. You are expecting a product of 954 bp. However, you generate three different products: only one is the expected size. List at least two possible explanations (excluding experimental error).
2. You have cloned a structural gene required for riboflavin synthesis in *E. coli*. You find that an *E. coli* riboflavin auxotroph carrying the cloned gene in a vector makes less riboflavin than does the wild-type strain. Why might this be the case?

744 CHAPTER 33 | Innate Host Defenses

recognition. They then encase the microorganism within a “killing chamber,” which uses whitlins to facilitate proteolysis dependent on the microbe. Recall that we discussed opsonic recognition in section 33.3, focusing on complement proteins and antibodies. We now discuss additional recognition of foreignness and provide more detail regarding the result of pattern recognition by phagocytes.

Recognition of Foreignness

The opsonin-independent mechanisms are germ-line encoded, receptor-based systems whereby molecular patterns common to many different pathogens are recognized to activate phagocytes (figure 33.17). A number of membrane-bound pattern-recognition receptors (PRRs) pepper the phagocyte surface, so as to

Figure 33.17 Recognition of Pathogen-Associated Molecular Patterns (PAMPs) by Pattern Recognition Receptors. PAMPs are often, especially in Gram-negative bacteria, lipopolysaccharides (LPS) or flagellin. PAMPs are recognized by PRRs on the phagocyte surface, which activate a signaling pathway that leads to the secretion of cytokines and chemokines, which recruit other immune cells to the site of infection.

List of Content Changes

Each chapter has been thoroughly reviewed and many have undergone significant revision. All now feature pedagogical elements, including a Readiness Check for the chapter and Learning Outcomes for each section therein.

Part I

Chapter 1—Evolution is the driving force of all biological systems; this is made clear by introducing essential concepts of microbial evolution first.

Chapter 3—Coverage of bacterial cellular structure and function. The chapter now includes a discussion of nutrient uptake in the section on bacterial plasma membranes.

Chapter 4—Growing understanding of the distinctive characteristics of archaea has warranted the creation of a new chapter that focuses on their cell structure and function. Comparisons to bacteria are made throughout the chapter.

Chapter 5—An introduction to eukaryotic cell structure and function, with emphasis on eukaryotic microbes. More detailed information on protist and fungal cells is presented in chapters 25 (*The Protists*) and 26 (*The Fungi*), which also focus on the diversity of these microbes. Comparisons between bacteria, archaea, and eukaryotes are included throughout the chapter.

Chapter 6—This chapter, entitled *Viruses and Other Acellular Infectious Agents*, surveys the essential morphological, physiological, and genetic elements of viruses as well as viroids, satellites, and prions. This chapter completes our four-chapter introduction of microbial life.

Part II

Chapter 7—Reorganized to initially focus on the growth of microbes outside the laboratory (including growth in oligotrophic environments) and the environmental factors that influence microbial reproduction. Topics related to laboratory culture of microbes follow.

Chapter 8—Reorganized to reflect emphasis on interruption of normal growth and reproduction functions to control microorganisms.

Chapter 9—Content focuses on the mechanism of action of each antimicrobial agent and stresses usage to limit drug resistance.

Part III

Chapter 10—This introduction to metabolism includes a new section that outlines the nature of biochemical pathways and

introduces the concept of metabolic flux through the interconnected biochemical pathways used by cells.

Chapter 11—The chapter now begins with an introduction to metabolic diversity and nutritional types.

Chapter 12—Updated coverage of CO₂-fixation pathways.

Part IV

Chapter 13—Now focuses on bacterial genetic information flow with improved coverage of bacterial promoters, sigma factors, termination of DNA replication, transcription cycle, and protein folding and secretion.

Chapter 14—Now focuses on the regulation of bacterial cellular processes. The coverage of regulation of complex cellular behaviors has been significantly updated and expanded, including new material on cyclic dimeric GMP.

Chapter 15—A new chapter that considers eukaryal and archaeal genome replication and expression together. In both cases, the discussion has been updated and expanded, and reflects the similarity of information flow as carried out by members of *Archaea* and *Eukarya*.

Chapter 16—Covers mutation, repair, and recombination in the context of processes that introduce genetic variation into populations. This is now related to the evolution of antibiotic-resistant bacteria.

Chapter 17—The use of recombinant DNA approaches to construct a synthetic genome is highlighted.

Chapter 18—New principles and applications of genomic techniques, including massively parallel genome sequencing and single cell genome sequencing, are now reviewed. The growing importance of metagenomics to environmental microbiology and its use in exploring the human microbiome are introduced here.

Part V

Chapter 19—Microbial evolution, introduced in chapter 1, is expanded with a complete discussion of the endosymbiotic theory, and the concept and definition of a microbial species.

Chapter 20—Expanded coverage of archaeal physiology includes new figures presenting archaeal-specific anabolic and catabolic pathways. The evolutionary advantage of each pathway is discussed in the context of archaeal ecology.

Chapter 21—Now includes mycoplasmas, in keeping with *Bergey's Manual*; new figures illustrating the life cycle of *Chlamydia* are included.

List of Content Changes

Chapter 22—Expanded coverage of proteobacterial physiology with content on C1 metabolism, including several figures.

Chapter 24—Increased coverage of streptomycetes, with new graphics illustrating their life cycle and their importance in antibiotic production.

Chapter 27—Updated discussion of virus taxonomy and phylogeny, including increased coverage of archaeal viruses and the CRISPR/CAS system.

Part VI

Chapter 28—The description of each nutrient cycle is accompanied by a new “student-friendly” figure that distinguishes between reductive and oxidative reactions. Expanded coverage of the interaction between nutrient cycles is also newly illustrated.

Chapter 29—This chapter continues to emphasize culture-based techniques as the “gold standard” and reviews some new, innovative approaches. The chapter also discusses a variety of culture-independent techniques used to assess populations and communities.

Chapter 30—Updated and expanded discussion of freshwater microbiology is complemented by discussion of carbon cycling in the open ocean and its implications for global climate change.

Chapter 31—New and updated coverage of mycorrhizae, with an emphasis on host-microbe communication and evolutionary similarities to rhizobia.

Chapter 32—Microbial relationships are presented along with human-microbe interactions, helping to convey the concept that the human body is an ecosystem. New and increased coverage of the human microbiome.

Part VII

Chapter 33—Reorganized and updated, this chapter on innate host resistance provides in-depth coverage of physical and chemical components of the nonspecific host response followed by an overview of cells, tissues, and organs of the immune system. This includes a step-by-step discussion of how microorganisms and damaged tissues are identified by the host using pattern recognition to remove them. Discussions of phagocytosis and inflammation are updated and reflect molecular mechanisms. The groundwork is laid for a full appreciation of the connections between the adaptive and innate arms of the immune system.

Chapter 34—Reorganized and updated to enhance linkages between innate and adaptive immune activities. Discussions integrate cell biology, physiology, and genetics concepts to present the immune system as a unified response having various components. Implications of dysfunctional immune actions are also discussed.

Chapter 35—This chapter has been re-titled *Pathogenicity and Infection*, reflecting its emphasis on microbial strategies for survival that can lead to human disease. The essential elements required for a pathogen to establish infection are introduced and virulence mechanisms highlighted. It follows the immunology chapters to stress that the host-parasite relationship is dynamic, with adaptations and responses offered by both host and parasite.

Part VIII

Chapter 36—This chapter has been updated to reflect the workflow and practice of a modern clinical laboratory. Emphasis is on modern diagnostic testing to identify infectious disease.

Chapter 37—Expanded focus on the important role of laboratory safety, especially in the teaching laboratory. Discussion emphasizes modern epidemiology as an investigative science and its role in preventative medicine. Disease prevention strategies are highlighted.

Chapter 38—Updated and expanded coverage includes viral pathogenesis and common viral infections.

Chapter 39—Expanded coverage of bacterial organisms and their common methods leading to human disease.

Chapter 40—Refocused to reflect disease transmission routes as well as expanded coverage of fungal and protozoal diseases.

Part IX

Chapter 41—Expanded discussion of probiotics in the context of the human microbiome.

Chapter 42—This chapter has been reorganized to illustrate the importance of industrial microbiology by presenting common microbial products—including biofuels—first. This is followed by an updated discussion of strain development, including in vivo and in vitro directed evolution.

Chapter 43—Updated discussion of water purification, wastewater treatment, and bioremediation. This includes the development and use of microbial fuel cells.

Acknowledgments

We would like to thank the Reviewers, who provided constructive reviews of every chapter. Their specialized knowledge helped us assimilate more reliable sources of information and find more effective ways of expressing an idea for the student reader.

The authors wish to extend their gratitude to our editors, Kathy Lowenberg, Kathleen Timp, Angela FitzPatrick, Sandy Wille, and Lynn Breithaupt. We would also like to thank our photo editor, Mary Reeg, and the tremendous talent and patience displayed by the artists. We are also very grateful to the many reviewers who provided helpful criticism and analysis. Finally, we thank our spouses and children who provided support and tolerated our absences (mental, if not physical) while we completed this demanding project.

About the Authors iii

Preface iv

Part One Introduction to Microbiology

| | |
|---|-----------|
| 1 The Evolution of Microorganisms and Microbiology | 1 |
| 1.1 Members of the Microbial World | 1 |
| 1.2 Microbial Evolution | 4 |
| 1.3 Microbiology and Its Origins | 11 |
| 1.4 Microbiology Today | 17 |
| 2 Microscopy | 22 |
| 2.1 Lenses and the Bending of Light | 22 |
| 2.2 Light Microscopes | 23 |
| 2.3 Preparation and Staining of Specimens | 31 |
| 2.4 Electron Microscopy | 34 |
| 2.5 Scanning Probe Microscopy | 39 |
| 3 Bacterial Cell Structure | 42 |
| 3.1 The "Prokaryote" Controversy | 42 |
| 3.2 A Typical Bacterial Cell | 43 |
| 3.3 Bacterial Plasma Membranes | 47 |
| 3.4 Bacterial Cell Walls | 53 |
| Microbial Diversity & Ecology 3.1 | |
| Gram Positive and Gram Negative or Monoderms and Diderms? | 54 |
| 3.5 Cell Envelope Layers Outside the Cell Wall | 61 |
| 3.6 Bacterial Cytoplasm | 62 |
| 3.7 External Structures | 69 |
| 3.8 Bacterial Motility and Chemotaxis | 72 |
| 3.9 Bacterial Endospores | 76 |
| 4 Archaeal Cell Structure | 82 |
| 4.1 A Typical Archaeal Cell | 82 |
| 4.2 Archaeal Cell Envelopes | 84 |
| 4.3 Archaeal Cytoplasm | 87 |
| 4.4 External Structures | 88 |
| 4.5 Comparison of <i>Bacteria</i> and <i>Archaea</i> | 90 |

The Evolution of Microorganisms and Microbiology

Over 2,000 Potential Planets Discovered

In February 2012, the National Aeronautics and Space Administration (NASA) reported that over 2,000 potential planets had been discovered by the 2009 *Kepler* mission. Using a telescope in space, the light emanating from stars as far as 3,000 light-years away had been monitored every half-hour. The *Kepler* telescope identified planets as they circulated their star and caused a brief decrease in emitted light; just as an object is detected as a blip by radar, a blip of “darkness” indicates a planet.

Unless you are a science fiction fan, you might wonder why NASA is interested in finding planets. By finding other planets, scientists can gather evidence to support or refute current models of planet formation. These models predict a process that is chaotic and violent. Planets are thought to begin as dust particles circling around newly formed stars. As these particles collide, they grow in size, forming larger chunks. Eventually a series of such collisions results in planet-sized bodies. Astrobiologists are interested in identifying characteristics of a planet that may allow it to support life. Using Earth as a model, they hypothesize that life-supporting planets will share many features with Earth. But how will life be recognized? Again, scientists look to life on Earth to answer this question, and increasingly they are turning to microbiologists for help.

Earth formed 4.5 billion years ago. Within the next billion years, the first cellular life forms—microbes—appeared. Since that time, microorganisms have evolved and diversified to occupy virtually every habitat on Earth: from oceanic geothermal vents to the coldest Arctic ice. The diversity of cellular microorganisms is best exemplified by their metabolic capabilities. Some carry out respiration, just as animals do. Others perform photosynthesis, rivaling plants in the amount of carbon dioxide they capture, forming organic matter and releasing oxygen into the atmosphere. Indeed, *Prochlorococcus*, a cyanobacterium (formerly called a blue-green alga), is thought to be the most abundant photosynthetic organism on Earth and

Artist's rendition of the six planets orbiting a star called Kepler-11. The drawing is based on observations made of the system by the Kepler spacecraft on August 26, 2010. Some are Earth-sized and may be habitable by life.

thus a major contributor to the functioning of the biosphere. In addition to these familiar types of metabolism, other microbes are able to use inorganic molecules as sources of energy in both oxic (oxygen available) and anoxic (no oxygen) conditions. It is these microbes that are of particular interest to NASA scientists, as it is thought that the organisms on other planets may have similar unusual metabolisms.

Our goal in this chapter is to introduce you to this amazing group of organisms and to outline the history of their evolution and discovery. Microbiology is a biological science, and as such, much of what you will learn in this text is similar to what you have learned in high school and college biology classes that focus on large organisms. But microbes have unique properties, so microbiology has unique approaches to understanding them. These too will be introduced. But before you delve into this chapter, check to see if you have the background needed to get the most from it.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ List the features of eukaryotic cells that distinguish them from other cell types
- ✓ List the attributes that scientists use to determine if an object is alive

1.1 Members of the Microbial World

After reading this section, you should be able to:

- Differentiate the biological entities studied by microbiologists from those studied by other biologists
- Explain Carl Woese's contributions in establishing the three domain system for classifying cellular life
- Provide an example of the importance to humans of each of the major types of microbes
- Determine the type of microbe (e.g., bacterium, fungus, etc.) when given a description of a newly discovered microbe

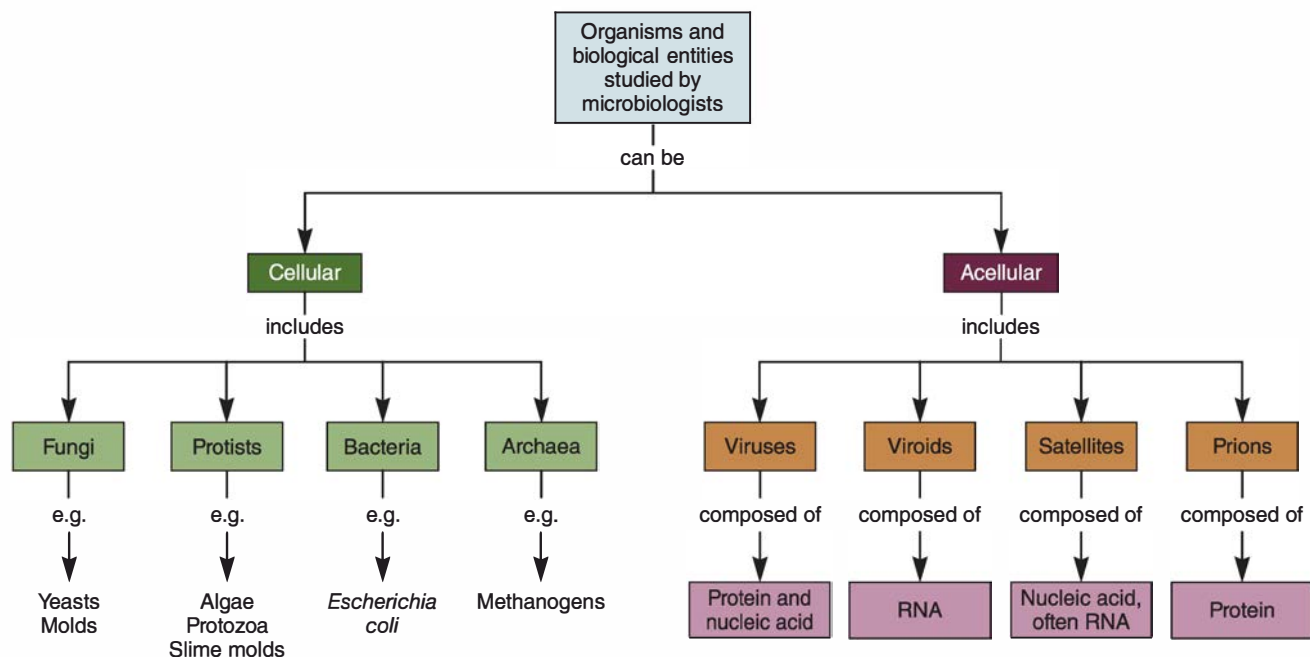

Figure 1.1 Concept Map Showing the Types of Biological Entities Studied by Microbiologists.

MICRO INQUIRY How would you alter this concept map so that it also distinguishes the cellular organisms from each other?

Microorganisms are defined as those organisms and acellular biological entities too small to be seen clearly by the unaided eye (figure 1.1). They are generally 1 millimeter or less in diameter. Although small size is an important characteristic of microbes, it alone is not sufficient to define them. Some cellular microbes, such as bread molds and filamentous photosynthetic microbes, are actually visible without microscopes. These macroscopic microbes are often colonial, consisting of small aggregations of cells. Some macroscopic microorganisms are multicellular. They are distinguished from other multicellular life forms such as plants and animals by their lack of highly differentiated tissues. Most unicellular microbes are microscopic. However, there are interesting exceptions, as we describe in chapter 3. In summary, cellular microbes are usually smaller than 1 millimeter in diameter, often unicellular and, if multicellular, lack differentiated tissues.

The diversity of microorganisms has always presented a challenge to microbial taxonomists. The early descriptions of cellular microbes as either plants or animals were too simple. For instance, some microbes are motile like animals but also have cell walls and are photosynthetic like plants. Such microbes cannot be placed easily into either kingdom. An important breakthrough in microbial taxonomy arose from studies of their cellular architecture, when it was discovered that cells exhibited one of two possible “floor plans.” Cells that came to be called **prokaryotic cells** (Greek *pro*, before, and *karyon*, nut or kernel; organisms with a primordial nucleus) have an open floor plan. That is, their contents are not divided

into compartments (“rooms”) by membranes (“walls”). The most obvious characteristic of these cells is that they lack the membrane-delimited nucleus observed in **eukaryotic cells** (Greek *eu*, true, and *karyon*, nut or kernel). Eukaryotic cells not only have a nucleus but also many other membrane-bound organelles that separate some cellular materials and processes from others.

These observations eventually led to the development of a classification scheme that divided organisms into five kingdoms: *Monera*, *Protista*, *Fungi*, *Animalia*, and *Plantae*. Microorganisms (except for viruses and other acellular infectious agents, which have their own classification system) were placed in the first three kingdoms. In this scheme, all organisms with prokaryotic cell structure were placed in *Monera*. The five-kingdom system was an important development in microbial taxonomy, but it is no longer accepted by microbiologists. This is because not all “prokaryotes” are the same and therefore should not be grouped together in a single kingdom. Furthermore, it is currently argued that the term *prokaryote* is not meaningful and should be abandoned. As we describe next, this discovery required several advances in the tools used to study microbes. ►► The “prokaryote” controversy (section 3.1)

Great progress has been made in three areas that profoundly affect microbial classification. First, much has been learned about the detailed structure of microbial cells from the use of electron microscopy. Second, microbiologists have determined the biochemical and physiological characteristics of many different microorganisms. Third, the sequences of nucleic acids and

proteins from a wide variety of organisms have been compared. The comparison of ribosomal RNA (rRNA), begun by Carl Woese in the 1970s, was instrumental in demonstrating that there are two very different groups of organisms with prokaryotic cell architecture: *Bacteria* and *Archaea*. Later studies based on rRNA comparisons showed that *Protista* is not a cohesive taxonomic unit (i.e., taxon) and that it should be divided into three or more kingdoms. These studies and others have led many taxonomists to reject the five-kingdom system in favor of one that divides cellular organisms into three domains: *Bacteria* (sometimes referred to as true bacteria or eubacteria), *Archaea* (sometimes called archaeobacteria or archaebacteria), and *Eukarya* (all eukaryotic organisms) (figure 1.2). We use this system throughout the text. A brief description of the three domains and of the microorganisms placed in them follows.

►► **Nucleic acids** (appendix I); **Proteins** (appendix I)

Members of domain ***Bacteria*** are usually single-celled organisms.¹ Most have cell walls that contain the structural molecule peptidoglycan. Although most bacteria exhibit typical prokaryotic cell structure (i.e., they lack a membrane-bound nucleus), a few members of the unusual phylum *Planctomycetes* have their genetic material surrounded by a membrane. This inconsistency is another argument made for abandoning the term “prokaryote.” Bacteria are abundant in soil, water, and air, including sites that have extreme temperatures, pH, or salinity. Bacteria are also major inhabitants of our skin, mouth, and intestines. Indeed, more microbial cells are found in and on the human body than there are human cells. These microbes begin to colonize humans shortly after birth. As the microbes establish themselves, they contribute to the development of the body’s immune system. Those microbes that inhabit the large intestine help the body digest food and produce vitamins. In these and other ways, microbes help maintain the health and well-being of their human hosts. ►► **Phylum *Planctomycetes*** (section 21.5)

Unfortunately, some bacteria cause disease, and some of these diseases have had a huge impact on human history. In 1347 the plague (Black Death), an arthropod-borne disease, struck Europe with brutal force, killing one-third of the population (about 25 million people) within four years. Over the next 80 years, the disease struck repeatedly, eventually wiping out 75% of the European population. The plague’s effect was so great that some historians believe it changed European culture and prepared the way for the Renaissance. Because of such plagues, it is easy for people to think that all bacteria are pathogens, but in fact, relatively few are. Most play beneficial roles, from global impact to maintaining human health. They break down dead plant and animal material and, in doing so, cycle elements in the biosphere. Furthermore, they are used extensively in industry to make bread, cheese, antibiotics, vitamins, enzymes, and other products.

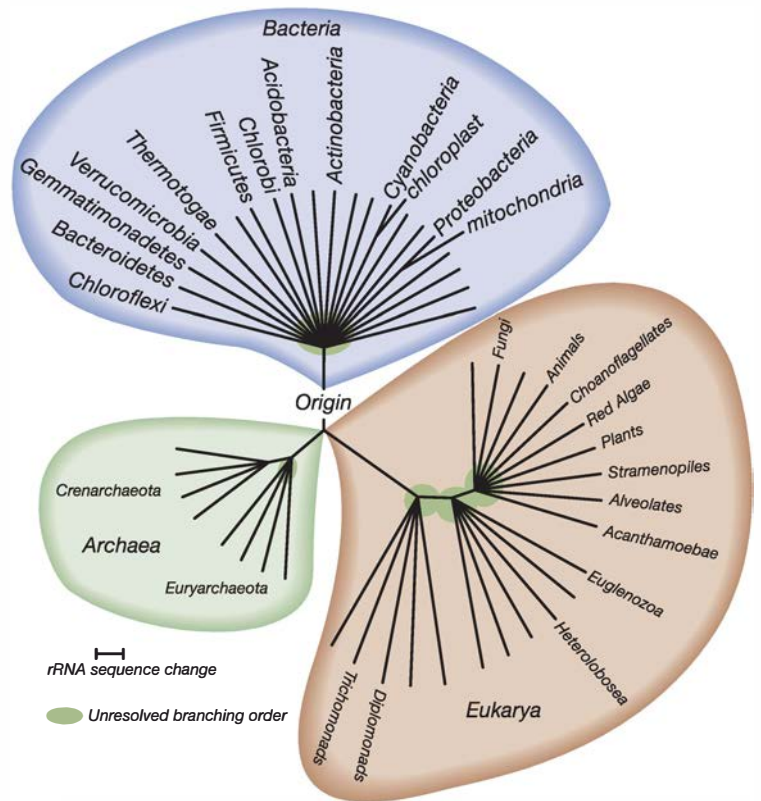

Figure 1.2 Universal Phylogenetic Tree. These evolutionary relationships are based on rRNA sequence comparisons. To save space, many lineages have not been identified.

MICRO INQUIRY How many of the taxa listed in the figure include microbes?

Members of domain ***Archaea*** are distinguished from bacteria by many features, most notably their distinctive rRNA sequences, lack of peptidoglycan in their cell walls, and unique membrane lipids. Some have unusual metabolic characteristics, such as the methanogens, which generate methane (natural) gas. Many archaea are found in extreme environments, including those with high temperatures (thermophiles) and high concentrations of salt (extreme halophiles). Although some archaea are members of a community of microbes involved in gum disease in humans, their role in causing disease has not been clearly established.

Domain ***Eukarya*** includes microorganisms classified as protists or fungi. Animals and plants are also placed in this domain. **Protists** are generally unicellular but larger than most bacteria and archaea. They have traditionally been divided into protozoa and algae. Despite their use, none of these terms has taxonomic value as protists, algae, and protozoa do

¹ In this text, the term *bacteria* (s., *bacterium*) is used to refer to those microbes belonging to domain *Bacteria*, and the term *archaea* (s., *archaeon*) is used to refer to those that belong to domain *Archaea*. In some publications, the term *bacteria* is used to refer to all cells having prokaryotic cell structure. That is not the case in this text.

not form cohesive taxa. However, for convenience, we use them here.

The major types of protists are algae, protozoa, slime molds, and water molds. **Algae** are photosynthetic. They, together with cyanobacteria, produce about 75% of the planet's oxygen and are the foundation of aquatic food chains. **Protozoa** are unicellular, animal-like protists that are usually motile. Many free-living protozoa function as the principal hunters and grazers of the microbial world. They obtain nutrients by ingesting organic matter and other microbes. They can be found in many different environments, and some are normal inhabitants of the intestinal tracts of animals, where they aid in digestion of complex materials such as cellulose. A few cause disease in humans and other animals. **Slime molds** are protists that behave like protozoa in one stage of their life cycle but like fungi in another. In the protozoan phase, they hunt for and engulf food particles, consuming decaying vegetation and other microbes. **Water molds** are protists that grow on the surface of freshwater and moist soil. They feed on decaying vegetation such as logs and mulch. Some water molds have produced devastating plant infections, including the Great Potato Famine of 1846–1847 in Ireland. ►► *The protists (chapter 25)*

Fungi are a diverse group of microorganisms that range from unicellular forms (yeasts) to molds and mushrooms. Molds and mushrooms are multicellular fungi that form thin, thread-like structures called hyphae. They absorb nutrients from their environment, including the organic molecules they use as sources of carbon and energy. Because of their metabolic capabilities, many fungi play beneficial roles, including making bread rise, producing antibiotics, and decomposing dead organisms. Some fungi associate with plant roots to form mycorrhizae. Mycorrhizal fungi transfer nutrients to the roots, improving growth of the plants, especially in poor soils. Other fungi cause plant diseases (e.g., rusts, powdery mildews, and smuts) and diseases in humans and other animals. ►► *The Fungi (chapter 26)*

The microbial world also includes numerous acellular infectious agents. **Viruses** are acellular entities that must invade a host cell to multiply. The simplest viruses are composed only of proteins and a nucleic acid, and can be extremely small (the smallest is 10,000 times smaller than a typical bacterium). However, their small size belies their power: they cause many animal and plant diseases and have caused epidemics that have shaped human history. Viral diseases include smallpox, rabies, influenza, AIDS, the common cold, and some cancers. Viruses also play important roles in aquatic environments, and their role in shaping aquatic microbial communities is currently being explored. **Viroids** and **satellites** are infectious agents composed only of ribonucleic acid (RNA). Viroids cause numerous plant diseases, whereas satellites cause plant diseases and some important animal diseases such as hepatitis. Finally, **prions**, infectious agents composed only of protein, are responsible for causing a variety of spongiform encephalopathies such as scrapie and “mad cow disease.” ►► *Viruses and other acellular infectious agents (chapter 6)*

Retrieve, Infer, Apply

1. How did the methods used to classify microbes change, particularly in the last half of the twentieth century? What was the result of these technological advances?
2. Identify one characteristic for each of these types of microbes that distinguishes it from the other types: bacteria, archaea, protists, fungi, viruses, viroids, satellites, and prions.

1.2 Microbial Evolution

After reading this section, you should be able to:

- Propose a time line of the origin and history of microbial life and integrate supporting evidence into it
- Design a set of experiments that could be used to place a newly discovered cellular microbe on a phylogenetic tree based on small subunit (SSU) rRNA sequences
- Compare and contrast the definitions of plant and animal species, microbial species, and microbial strains

A review of figure 1.2 reminds us that in terms of the number of taxa, microbes are the dominant organisms on Earth. How has microbial life been able to radiate to such an astonishing level of diversity? To answer this question, we must consider microbial evolution. The field of microbial evolution, like any other scientific endeavor, is based on the formulation of hypotheses, the gathering and analysis of data, and the reformation of hypotheses based on newly acquired evidence. That is to say, the study of microbial evolution is based on the scientific method (see www.mhhe.com/wiley9). To be sure, it is sometimes more difficult to amass evidence when considering events that occurred millions, and often billions, of years ago, but the advent of molecular methods has offered scientists a living record of life's ancient history. This section describes the outcome of this scientific research.

Evidence for the Origin of Life

Dating meteorites through the use of radioisotopes places our planet at an estimated 4.5 to 4.6 billion years old. However, conditions on Earth for the first 100 million years or so were far too harsh to sustain any type of life. Eventually bombardment by meteorites decreased, water appeared on the planet in liquid form, and gases were released by geological activity to form Earth's atmosphere. These conditions were amenable to the origin of the first life forms. But how did this occur, and what did these life forms look like?

Clearly, in order to find evidence of life and to develop hypotheses about its origin and subsequent evolution, scientists must be able to define life. Although even very young children can examine an object and correctly determine whether it is living or not, defining life succinctly has proven elusive for scientists. Thus most definitions of life consist of a set of attributes. The attributes of particular importance to paleobiologists are an orderly structure, the ability to obtain

and use energy (i.e., metabolism), and the ability to reproduce. Just as NASA scientists are using the characteristics of microbes on Earth today to search for life elsewhere (p. 1), so too are scientists examining **extant organisms**, those organisms present today, to explore the origin of life. Some extant organisms have structures and molecules that represent “relics” of ancient life forms. Furthermore, they can provide scientists with ideas about the type of evidence to seek when testing hypotheses.

The first direct evidence of primitive cellular life was the 1977 discovery of microbial fossils in the Swartkoppie chert. Chert is a type of granular sedimentary rock rich in silica. The Swartkoppie chert fossils as well as those from the Archaean Apex chert of Australia have been dated at about 3.5 billion years old (**figures 1.3 and 1.4**). Despite these findings, the microbial fossil record is understandably sparse. Thus to piece together the very early events that led to the origin of life, biologists must rely primarily on indirect evidence. Each piece of evidence must fit together as in a jigsaw puzzle for a coherent picture to emerge.

RNA World

The origin of life rests on a single question: How did early cells arise? At a minimum, modern cells consist of a plasma membrane

enclosing water in which numerous chemicals are dissolved and subcellular structures float. It seems likely that the first self-replicating entity was much simpler than even the most primitive modern living cells. Before there was life, most evidence suggests that Earth was a very different place: hot and anoxic, with an atmosphere rich in water vapor, carbon dioxide, and nitrogen. In the oceans, hydrogen, methane, and carboxylic acids were formed by geological and chemical processes. Areas near hydrothermal vents or in shallow pools may have provided the conditions that allowed chemicals to react with one another, randomly “testing” the usefulness of the reaction and the stability of its products. Some reactions released energy and would eventually become the basis of modern cellular

metabolism. Other reactions generated molecules that could function as catalysts, some aggregated with other molecules to form the predecessors of modern cell structures, and others were able to replicate and act as units of hereditary information.

In modern cells, three different molecules fulfill the roles of catalysts, structural molecules, and hereditary molecules (**figure 1.5**). Proteins have two major roles in modern cells: structural and catalytic. Catalytic proteins are called **enzymes**, and they speed up the myriad of chemical reactions that occur in cells. DNA stores hereditary information and can be replicated to pass the information on to the next generation. RNA is involved in converting the information stored in DNA into protein. Any hypothesis about the origin of life must account for the evolution of these molecules, but the very nature of their relationships to each other in modern cells complicates attempts to imagine how they evolved. As demonstrated in **figure 1.5**, proteins can do cellular work, but their synthesis involves other proteins and RNA, and uses information stored in DNA. DNA can't do cellular work. It stores genetic information and serves as the template for its own replication, a process that requires proteins. RNA is synthesized using DNA as the template and proteins as the catalysts for the reaction.

Based on these considerations, it is hypothesized that at some time in the evolution of life, there must have been a single molecule that could do both cellular work and replicate itself. A possible molecule was suggested in 1981 when Thomas Cech discovered a catalytic RNA molecule in a protist (*Tetrahymena* sp.) that could cut out an internal section of itself and splice the remaining sections back together. Since then, other catalytic RNA molecules have been discovered, including an RNA found in ribosomes that is responsible for forming peptide bonds—the bonds that hold together amino acids, the building blocks of proteins. Catalytic RNA molecules are now called **ribozymes**.

The discovery of ribozymes suggested that RNA at some time had the ability to catalyze its own replication, using itself as the template. In 1986 Walter Gilbert coined the term **RNA world** to describe a precellular stage in the evolution of life in which RNA was capable of storing, copying, and expressing genetic information, as well as catalyzing other chemical reactions. However, for this precellular stage to proceed to the evolution of cellular life forms, a lipid membrane must have formed around the RNA (**figure 1.6**). This important evolutionary step is easier to imagine than other events in the origin of cellular life forms because lipids, major structural components of the membranes of modern organisms, spontaneously form liposomes—vesicles bounded by a lipid bilayer. A fascinating experiment performed by Marin Hanczyc, Shelly Fujikawa, and Jack Szostak in 2003 showed that clay triggers the formation of liposomes that actually grow and divide. Together with the data on ribozymes, these data suggest that early cells may have been liposomes containing RNA molecules (**figure 1.6**).

▶▶ Lipids (appendix I)

Apart from its ability to perform catalytic activities, the function of RNA suggests its ancient origin. Consider that much of the cellular pool of RNA in modern cells exists in the

Figure 1.3 Microfossils of the Archaean Apex Chert of Australia.

These microfossils are similar to modern filamentous cyanobacteria.

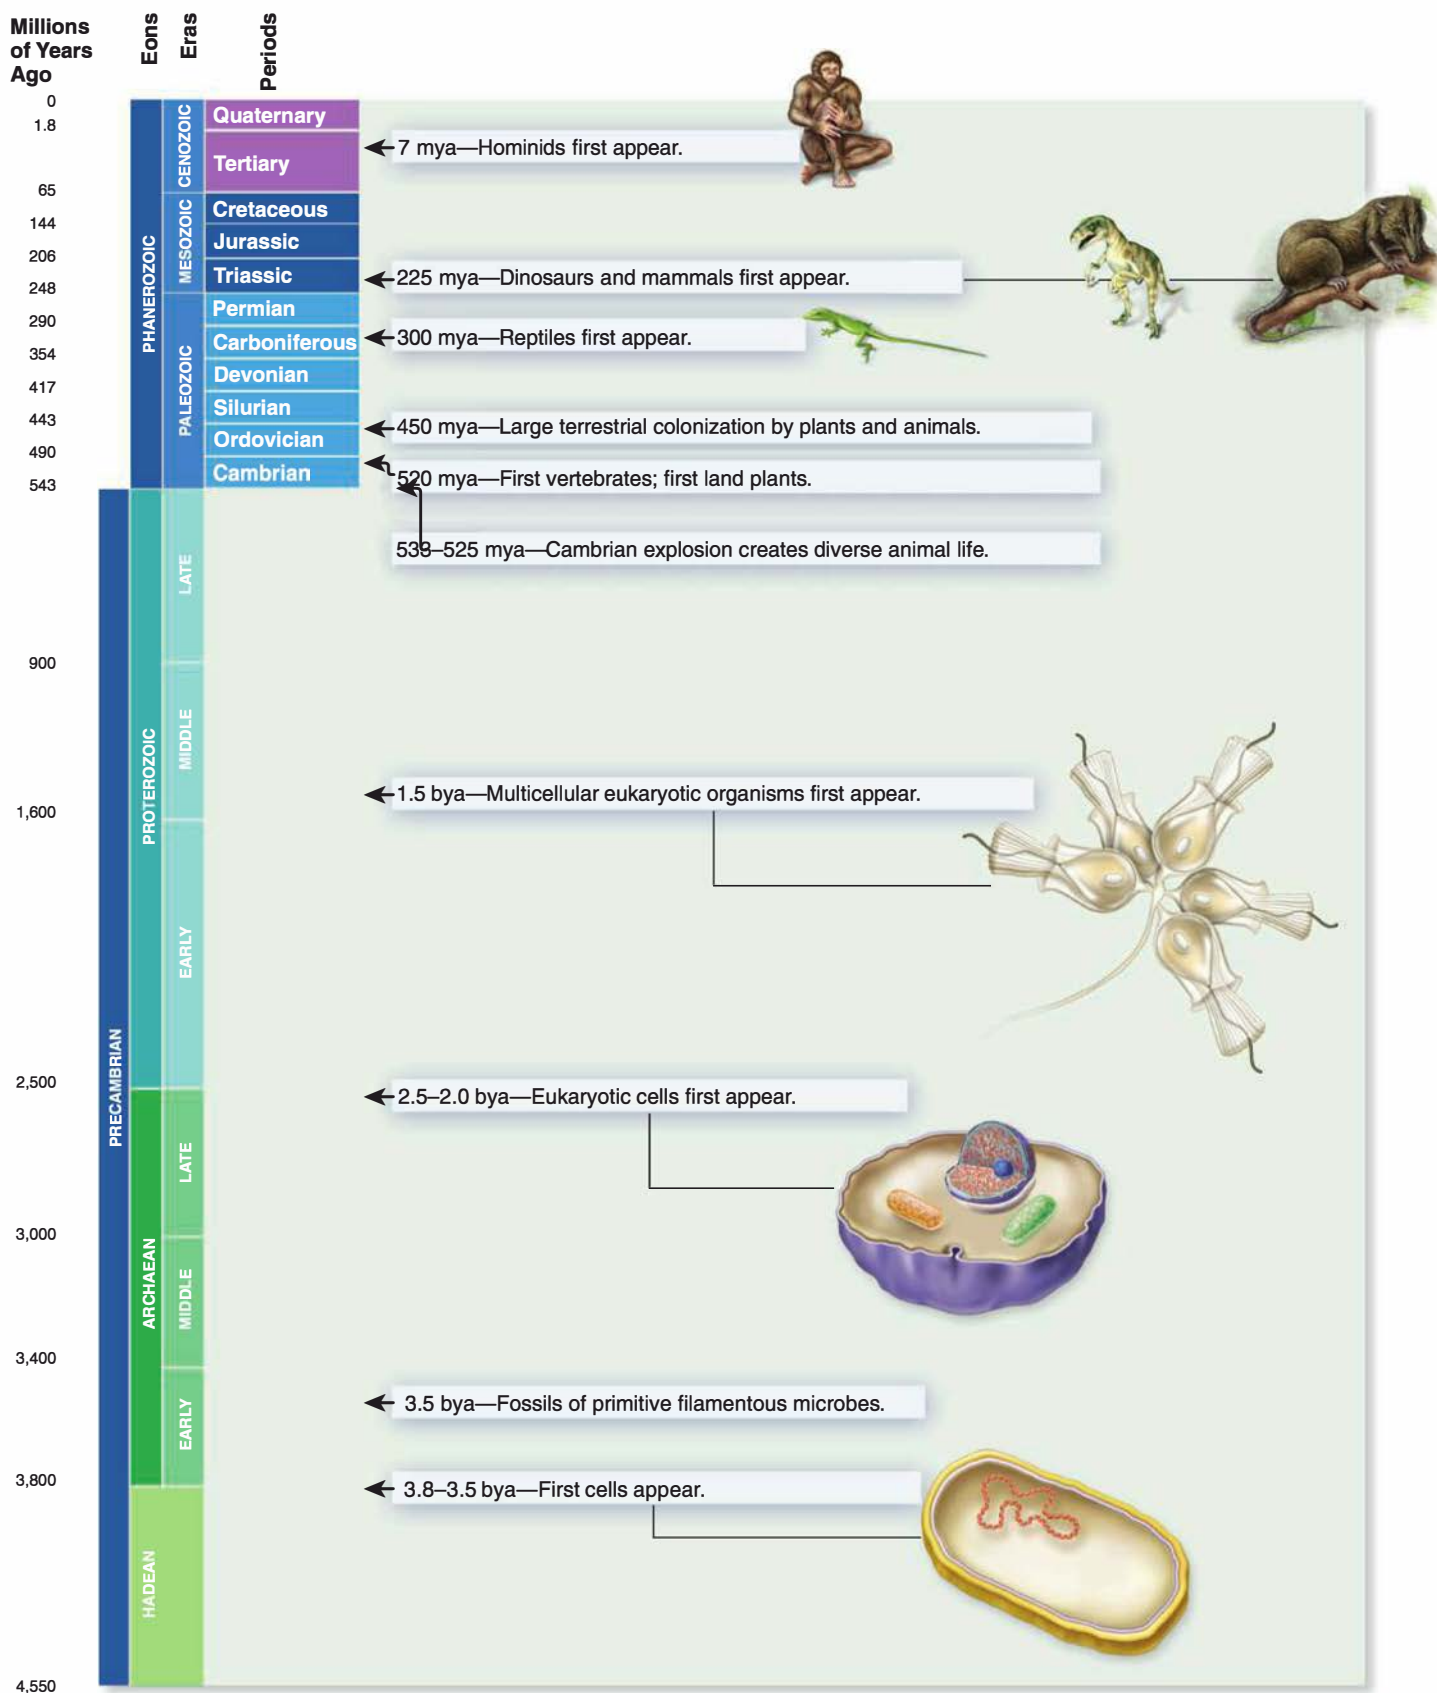

Figure 1.4 An Overview of the History of Life on Earth. mya = million years ago; bya = billion years ago.

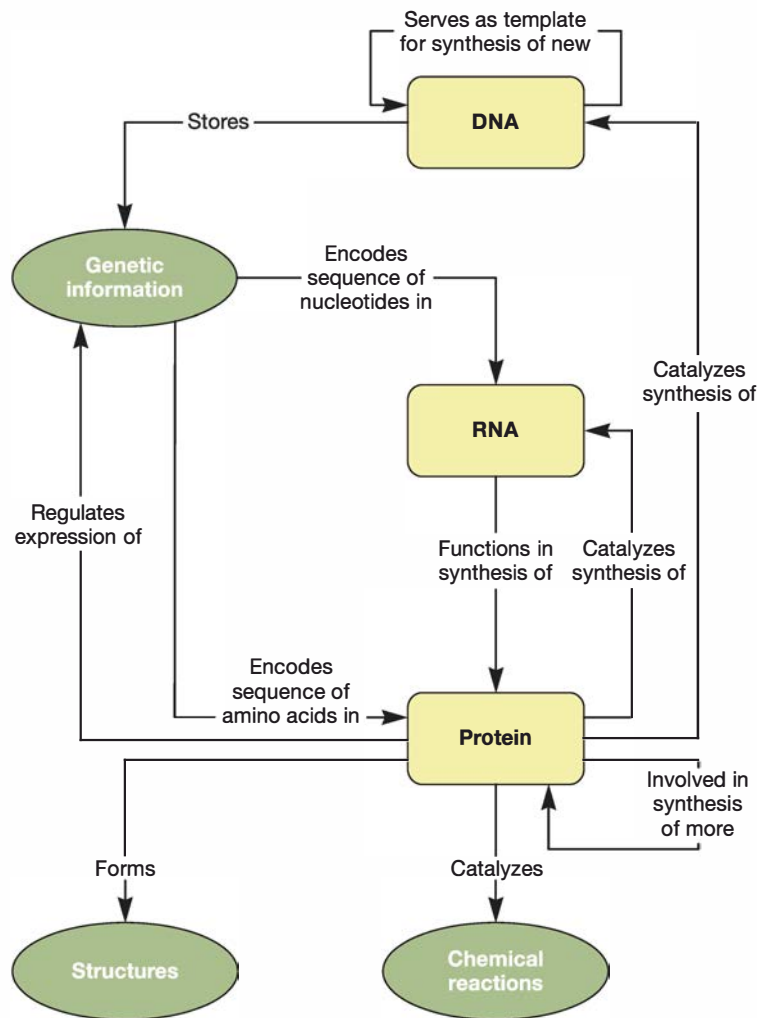

Figure 1.5 Functions of DNA, RNA, and Protein, and Their Relationships to Each Other in Modern Cells.

ribosome, a structure that consists largely of rRNA and uses messenger RNA (mRNA) and transfer RNA (tRNA) to construct proteins. Also recall that rRNA itself catalyzes peptide bond formation during protein synthesis. Thus RNA seems to be well poised for its importance in the development of proteins. Because RNA and DNA are structurally similar, RNA could have given rise to double-stranded DNA. It is suggested that once DNA evolved, it became the storage facility for genetic information because it provided a more chemically stable structure. Two other pieces of evidence support the RNA world hypothesis: the fact that the energy currency of the cell, ATP, is a ribonucleotide and the more recent discovery that RNA can regulate gene expression. So it would seem that proteins, DNA, and cellular energy can be traced back to RNA. ▶▶ ATP (section 10.2); *Riboswitches* (sections 14.3 and 14.4)

Despite the evidence supporting the hypothesis of an RNA world, it is not without problems, and many argue against it. Another area of research is also fraught with considerable de-

Figure 1.6 The RNA World Hypothesis for the Origin of Life.

MICRO INQUIRY Why are the probionts pictured above not considered cellular life?

bate: the evolution of metabolism, in particular, the evolution of energy-conserving metabolic processes. Recall that early Earth was a hot environment that lacked oxygen. Thus the cells that arose there must have been able to use the available energy sources under these harsh conditions. Today there are heat-loving archaea capable of using inorganic molecules such as FeS as a source of energy. Some suggest that this interesting metabolic capability is a remnant of the first form of energy metabolism. Another metabolic strategy, oxygen-releasing photosynthesis, appears to have evolved perhaps as early as 2.5 billion years ago. Fossils of cyanobacteria-like cells found in rocks dating to that time support this hypothesis,

(a)

(b)

Figure 1.7 Stromatolites. (a) Section of a fossilized stromatolite. Evolutionary biologists think the layers of material were formed when mats of cyanobacteria, layered one on top of each other, became mineralized. (b) Modern stromatolites from Western Australia. Each stromatolite is a rocklike structure, typically 1 m in diameter, containing layers of cyanobacteria.

as does the discovery of ancient stromatolites (**figure 1.7a**). Stromatolites are layered rocks, often domed, that are formed by the incorporation of mineral sediments into layers of microorganisms growing as thick mats on surfaces (**figure 1.7b**). The appearance of cyanobacteria-like cells was an important step in the evolution of life on Earth. The oxygen they released is thought to have altered Earth's atmosphere to its current oxygen-rich state, allowing the evolution of additional energy-capturing strategies such as aerobic respiration, the oxygen-consuming metabolic process that is used by many microbes and animals.

Evolution of the Three Domains of Life

As noted in section 1.1, rRNA comparisons were an important breakthrough in the classification of microbes; this analysis also provides insights into the evolutionary history of all life. What began with the examination of rRNA from relatively few organisms has been expanded by the work of many others, including Norman Pace. Dr. Pace has developed a **universal phylogenetic tree** (**figure 1.2**) based on comparisons of small subunit rRNA molecules (SSU rRNA), the rRNA found in the small subunit of the ribosome. Here we examine how these comparisons are made and what the universal phylogenetic tree tells us.

►► **Bacterial ribosomes** (section 3.6); *Exploring microbial taxonomy and phylogeny* (section 19.3)

Comparing SSU rRNA Molecules

The details of phylogenetic tree construction are discussed in chapter 19. However, the general concept is not difficult to understand. In one approach, the sequences of nucleotides in the genes that encode SSU rRNAs from diverse organisms are aligned, and pair-wise comparisons of the sequences are made. For each pair of SSU rRNA gene sequences, the number of differences in the nucleotide sequences is counted (**figure 1.8**). This value serves as a measure of the evolutionary distance between the organisms; the more differences counted, the greater the evolutionary dis-

tance. The evolutionary distances from many comparisons are used by sophisticated computer programs to construct the tree. Each branch in the tree represents one of the organisms used in the comparison. The distance from the tip of one branch to the tip of another is the evolutionary distance between the two organisms represented by the branches.

Two things should be kept in mind when examining phylogenetic trees developed in this way. The first is that they are molecular trees, not organismal trees. In other words, they represent, as accurately as possible, the evolutionary history of a molecule and the gene that encodes it. Second, the distance between branch tips is a measure of relatedness, not of time. If the distance along the lines is very long, then the two organisms are more evolutionarily diverged (i.e., less related). However, we do not know when they diverged from each other. This concept is analogous to a map that accurately shows the distance between two cities but because of many factors (traffic, road conditions, etc.) cannot show the time needed to travel that distance.

LUCA

What does the universal phylogenetic tree tell us about the evolution of life? At the center of the tree is a line labeled “Origin” (**figure 1.2**). This is where the data indicate the *last universal common ancestor* (LUCA) to all three domains should be placed. LUCA is on the bacterial branch, which means that *Archaea* and *Eukarya* evolved independently, separate from *Bacteria*. Thus the universal phylogenetic tree presents a picture in which all life, regardless of eventual domain, arose from a single common ancestor. One can envision the universal tree of life as a real tree that grows from a single seed.

The evolutionary relationship of *Archaea* and *Eukarya* is still the matter of considerable debate. According to the universal phylogenetic tree we show here, *Archaea* and *Eukarya* shared common ancestry but diverged and became separate domains. Other versions suggest that *Eukarya* evolved out of *Archaea*. The

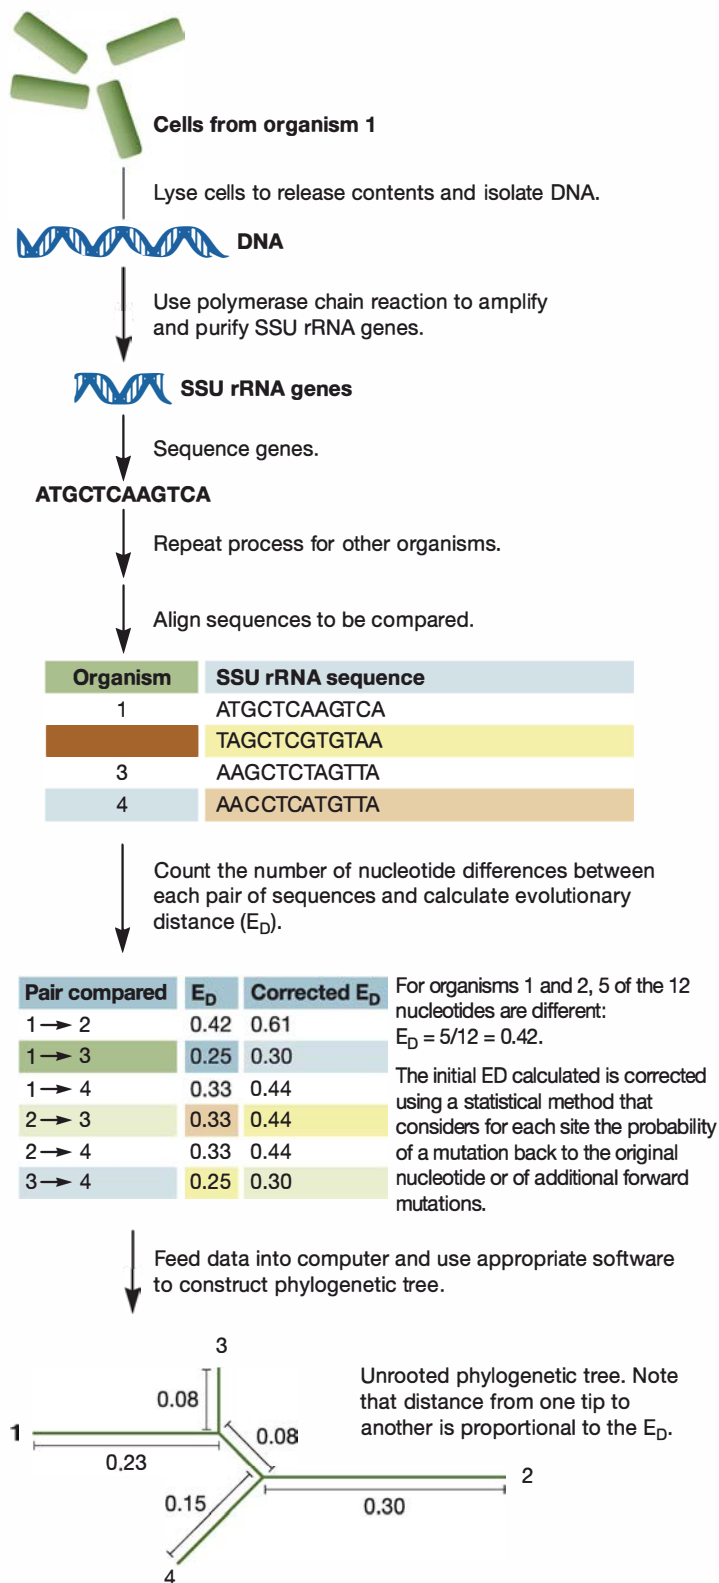

Figure 1.8 The Construction of Phylogenetic Trees Using a Distance Method.

MICRO INQUIRY Why does the branch length indicate amount of evolutionary change but not the time it took for that change to occur?

close evolutionary relationship of these two forms of life is still evident in the manner in which they process genetic information. For instance, certain protein subunits of archaeal and eukaryotic RNA polymerases, the enzymes that catalyze RNA synthesis, resemble each other to the exclusion of those of bacteria. However, archaea have other features that are most similar to their counterparts in bacteria (e.g., mechanisms for conserving energy). This has further complicated and fueled the debate. The evolution of the nucleus and endoplasmic reticulum is also at the center of many controversies. However, hypotheses regarding the evolution of other membrane-bound organelles are more widely accepted and are considered next.

Endosymbiotic Origin of Mitochondria, Chloroplasts, and Hydrogenosomes

The **endosymbiotic hypothesis** is generally accepted as the origin of three eukaryotic organelles: mitochondria, chloroplasts, and hydrogenosomes. Endosymbiosis is an interaction between two organisms in which one organism lives inside the other. The initial statement of the endosymbiotic hypothesis proposed that over time a bacterial endosymbiont of an ancestral cell in the eukaryotic lineage lost its ability to live independently, becoming either a mitochondrion, if the intracellular bacterium used aerobic respiration, or a chloroplast, if the endosymbiont was a photosynthetic bacterium (see figure 19.11).

Although the mechanism by which the endosymbiotic relationship was established is unknown, there is considerable evidence to support the hypothesis. Mitochondria and chloroplasts contain DNA and ribosomes; both are similar to bacterial DNA and ribosomes. Indeed, inspection of figure 1.2 shows that both organelles belong to the bacterial lineage based on SSU rRNA analysis. Further evidence for the origin of mitochondria comes from the genome sequence of the bacterium *Rickettsia prowazekii*, an obligate intracellular parasite and the cause of epidemic (lice-borne) typhus. Its genome is more similar to that of modern mitochondrial genomes than to any other bacterium. The chloroplasts of plants and green algae are thought to have descended from an ancestor of the cyanobacterial genus *Prochloron*, which contains species that live within marine invertebrates.

Recently the endosymbiotic hypothesis for mitochondria has been modified by the **hydrogen hypothesis**. This asserts that the endosymbiont was an anaerobic bacterium that produced H_2 and CO_2 as end products of its metabolism. Over time, the host became dependent on the H_2 produced by the endosymbiont. Ultimately the endosymbiont evolved into one of two organelles. If the endosymbiont developed the capacity to perform aerobic respiration, it evolved into a mitochondrion. However, if the endosymbiont did not develop this capacity, it evolved into a hydrogenosome—an organelle found in some extant protists that produce ATP by a process called fermentation (see figure 5.16).

Evolution of Cellular Microbes

Although the history of early cellular life forms may never be known, we know that once they arose, they were subjected to the same evolutionary processes as modern organisms. The ancestral bacteria, archaea, and eukaryotes possessed genetic information that could be duplicated, lost, or mutated. These mutations could have many outcomes. Some led to the death of the mutant microbe, but others allowed new functions and characteristics to evolve. Those mutations that allowed the organism to increase its reproductive ability were selected for and passed on to subsequent generations. In addition to selective forces, isolation of populations allowed some groups to evolve separately from others. Thus selection and isolation led to the eventual development of new collections of genes (i.e., genotypes) and many new species.

In addition to mutation, other mechanisms exist for reconfiguring the genotypes of a species and therefore creating genetic diversity. Most eukaryotic species increase their genetic diversity by reproducing sexually. Thus each offspring of the two parents has a mixture of parental genes and a unique genotype. Bacterial and archaeal species do not reproduce sexually. They increase their genetic diversity by horizontal (lateral) gene transfer (HGT). During HGT, genetic information from a donor organism is transferred to a recipient, creating a new genotype. Thus genetic information can be passed from one generation to the next as well as between individuals of the same generation and even between different microbial species. Genome sequencing has revealed that HGT has played an important role in the evolution of bacterial and archaeal species. Importantly, HGT still occurs and continues to shape their genomes, leading to the evolution of species with antibiotic resistance, new virulence properties, and novel metabolic capabilities. The outcome of HGT is that many bacterial and archaeal species have mosaic genomes composed of bits and pieces of the genomes of other organisms (**figure 1.9**). ►► *Microbial evolutionary processes (section 19.5)*

Microbial Species

All students of biology are introduced early in their careers to the concept of a species. But the term has different meanings, depending on whether the organism is sexual or not. Taxonomists working with plants and animals define a **species** as a group of interbreeding or potentially interbreeding natural populations that is reproductively isolated from other groups. This definition also is appropriate for the many eukaryotic microbes that reproduce sexually. However, bacterial and archaeal species cannot be defined by this criterion, since they do not reproduce sexually. An appropriate definition is currently the topic of considerable discussion. A common definition is that bacterial and archaeal species are a collection of strains that share many stable properties and differ

Figure 1.9 The Mosaic Nature of Bacterial and Archaeal

Genomes. Horizontal gene transfer (HGT) events move pieces of the genome of one organism to another. Over time, HGT creates organisms having mosaic genomes composed of portions of the genomes of other microbes. The length of segments drawn is arbitrary and is not meant to represent the actual size of the portion of genome transferred.

significantly from other groups of strains. A **strain** consists of the descendants of a single, pure microbial culture. Strains within a species may be described in a number of different ways. Biovars are variant strains characterized by biochemical or physiological differences, morphovars differ morphologically, serovars have distinctive properties that can be detected by antibodies (p. 17), and pathovars are pathogenic strains distinguished by the plants in which they cause disease. ►► *Evolutionary processes and the concept of a microbial species (section 19.5)*

Microbiologists name microbes using the binomial system of the eighteenth-century biologist and physician Carl Linnaeus. The Latinized, italicized name consists of two parts. The first part, which is capitalized, is the generic name (i.e., the name of the genus to which the microbe belongs), and the second is the uncapitalized species epithet. For example, the bacterium that causes plague is called *Yersinia pestis*. Often the name of an organism will be shortened by abbreviating the genus name with a single capital letter (e.g., *Y. pestis*).

1.3 Microbiology and Its Origins

After reading this section, you should be able to:

- Evaluate the importance of the contributions to microbiology made by Hooke, Leeuwenhoek, Pasteur, Koch, Cohn, Beijerinck, von Behring, Kitasato, Metchnikoff, and Winogradsky
- Outline a set of experiments that might be used to decide if a particular microbe is the causative agent of a disease
- Predict the difficulties that might arise when using Koch's postulates to determine if a microbe causes a disease unique to humans

Even before microorganisms were seen, some investigators suspected their existence and role in disease. Among others, the Roman philosopher Lucretius (about 98–55 BCE) and the physician Girolamo Fracastoro (1478–1553) suggested that disease was caused by invisible living creatures. However, until microbes could actually be seen or studied in some other way, their existence remained a matter of conjecture. Therefore **microbiology** is defined not only by the organisms it studies but also by the tools used to study them. The development of microscopes was the critical first step in the evolution of the discipline. However, microscopy alone is unable to answer the many questions microbiologists ask about microbes. A distinct feature of microbiology is that microbiologists often remove microorganisms from their normal habitats and culture them isolated from other microbes. This is called a pure or axenic culture. The development of techniques for isolating microbes in pure culture was another critical step in microbiology's history. However, it is now recognized as having limitations. Microbes in pure culture are in some ways like animals in a zoo; just as a zoologist cannot fully understand the ecology of animals by studying them in zoos, microbiologists cannot fully understand the ecology of microbes by studying them in pure culture. Today molecular genetic techniques and genomic analyses are providing new insights into the lives of microbes. ►► *Methods in microbial ecology (chapter 29); Microbial genomics (chapter 18)*

Here we describe how the tools used by microbiologists have influenced the development of the field. As microbiology evolved as a science, it contributed greatly to the well-being of humans. This is exemplified by the number of microbiologists who have won the Nobel Prize (see www.mhhe.com/willey9). The historical context of some of the important discoveries in microbiology is shown in [figure 1.10](#).

Microscopy and the Discovery of Microorganisms

The earliest microscopic observations of organisms appear to have been made between 1625 and 1630 on bees and weevils by the Italian Francesco Stelluti (1577–1652), using a microscope probably supplied by Galileo (1564–1642). Robert Hooke (1635–1703) is credited with publishing the first drawings of

microorganisms in the scientific literature. In 1665 he published a highly detailed drawing of the fungus *Mucor* in his book *Micrographia*. *Micrographia* is important not only for its exquisite drawings but also for the information it provided on building microscopes. One design discussed in *Micrographia* was probably a prototype for the microscopes built and used by the amateur microscopist Antony van Leeuwenhoek (1632–1723) of Delft, the Netherlands ([figure 1.11a](#)). Leeuwenhoek earned his living as a draper and haberdasher (a dealer in men's clothing and accessories) but spent much of his spare time constructing simple microscopes composed of double convex glass lenses held between two silver plates ([figure 1.11b](#)). His microscopes could magnify about 50 to 300 times, and he may have illuminated his liquid specimens by placing them between two pieces of glass and shining light on them at a 45° angle to the specimen plane. This would have provided a form of dark-field illumination whereby organisms appeared as bright objects against a dark background ([figure 1.11c](#)). Beginning in 1673, Leeuwenhoek sent detailed letters describing his discoveries to the Royal Society of London. It is clear from his descriptions that he saw both bacteria and protists.

Culture-Based Methods for Studying Microorganisms

As important as Leeuwenhoek's observations were, the development of microbiology essentially languished for the next 200 years until techniques for isolating and culturing microbes in the laboratory were formulated. Many of these techniques began to be developed as scientists grappled with the conflict over the theory of spontaneous generation. This conflict and the subsequent studies on the role played by microorganisms in causing disease ultimately led to what is now called the golden age of microbiology.

Spontaneous Generation

From earliest times, people had believed in **spontaneous generation**—that living organisms could develop from nonliving matter. This view finally was challenged by the Italian physician Francesco Redi (1626–1697), who carried out a series of experiments on decaying meat and its ability to produce maggots spontaneously. Redi placed meat in three containers. One was uncovered, a second was covered with paper, and the third was covered with fine gauze that would exclude flies. Flies laid their eggs on the uncovered meat and maggots developed. The other two pieces of meat did not produce maggots spontaneously. However, flies were attracted to the gauze-covered container and laid their eggs on the gauze; these eggs produced maggots. Thus the generation of maggots by decaying meat resulted from the presence of fly eggs, and meat did not spontaneously generate maggots, as previously believed. Similar experiments by others helped discredit the theory for larger organisms.

Leeuwenhoek's communications on microorganisms renewed the controversy. Some proposed that microbes arose by spontaneous generation even though larger organisms did not.

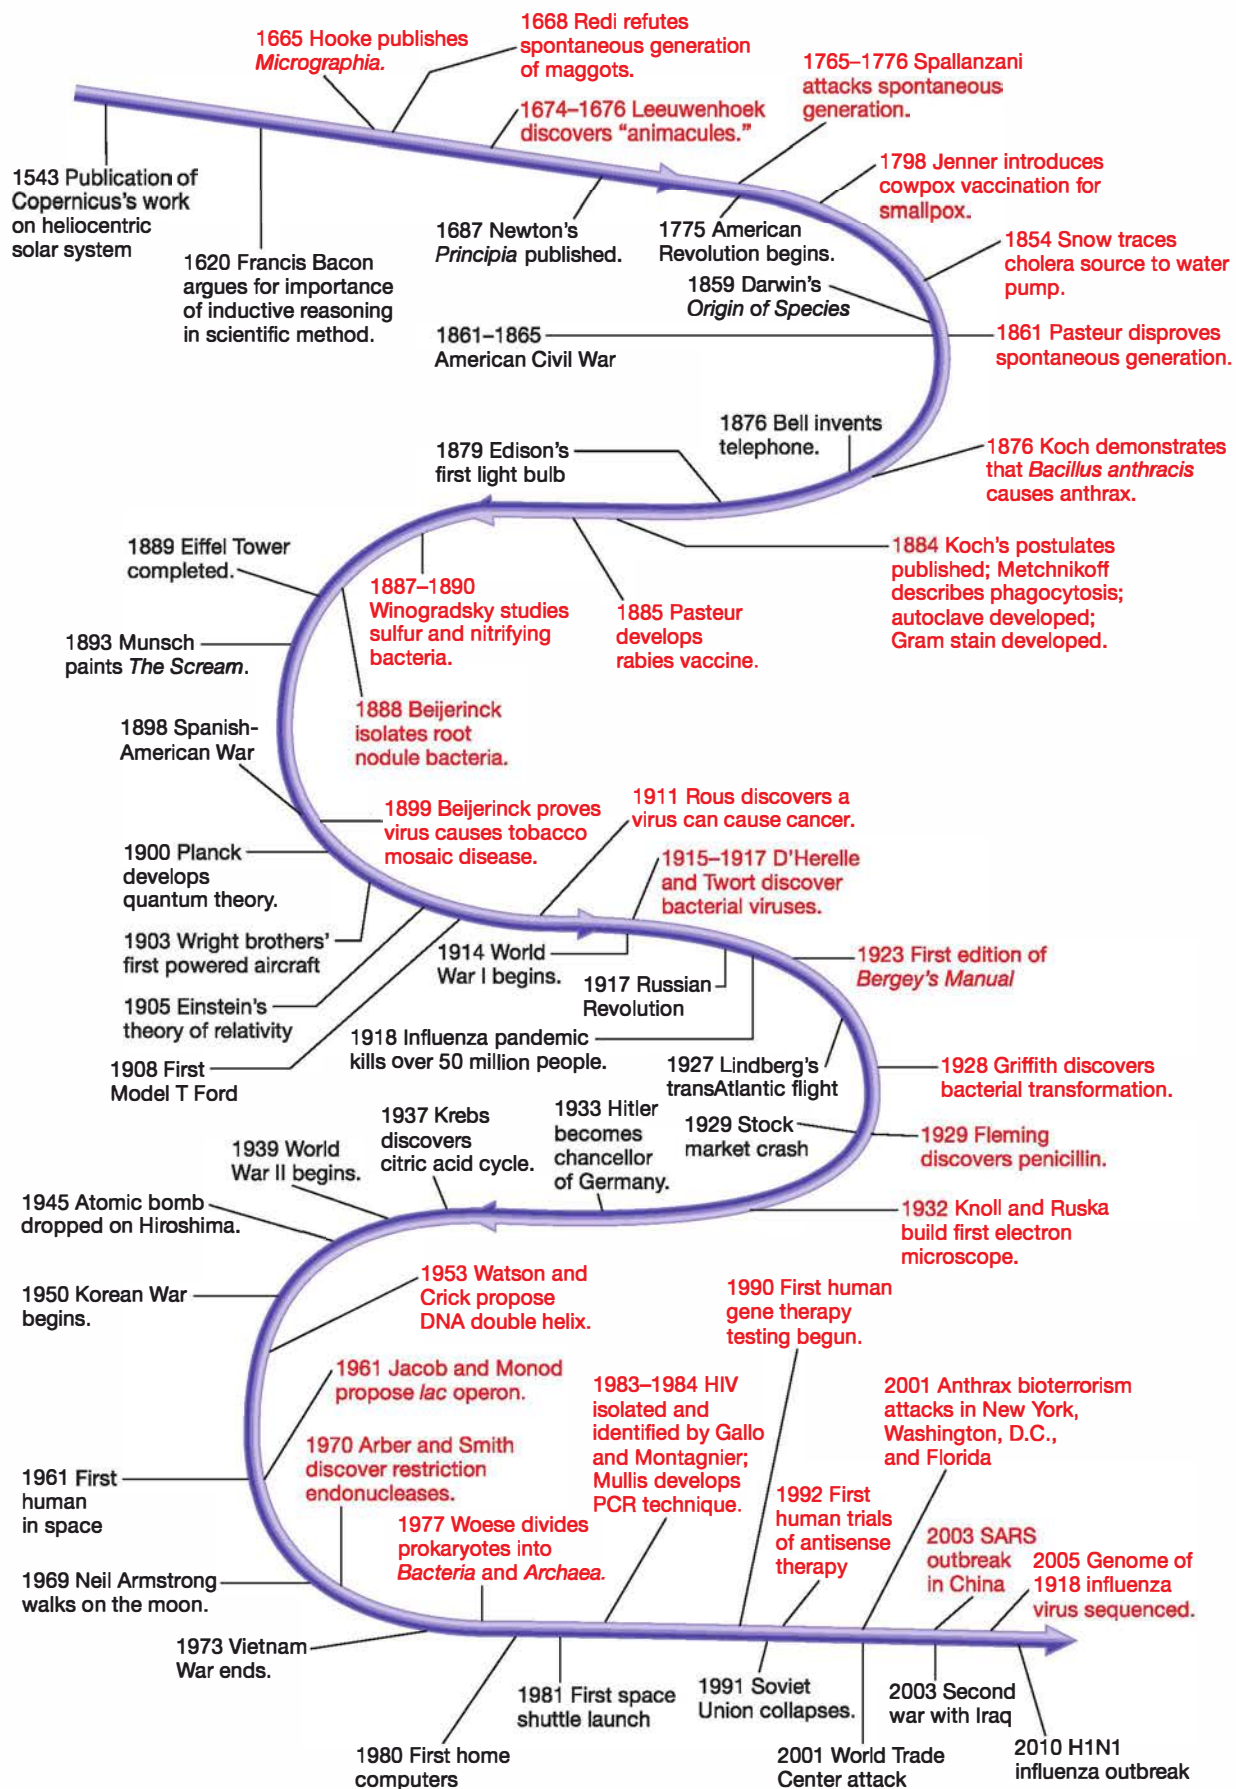

Figure 1.10 Some Important Events in the Development of Microbiology. Milestones in microbiology are marked in red; other historical events are in black.

(a)

(b)

(c)

Figure 1.11 Antony van Leeuwenhoek. (a) An oil painting of Leeuwenhoek. (b) A brass replica of the Leeuwenhoek microscope. Inset photo shows how it is held. (c) Leeuwenhoek's drawings of bacteria from the human mouth.

They pointed out that boiled extracts of hay or meat gave rise to microorganisms after sitting for a while. Indeed, such extracts were the forerunners of the culture media still used today in many microbiology laboratories.

In 1748 the English priest John Needham (1713–1781) reported the results of his experiments on spontaneous generation. Needham boiled mutton broth in flasks that he then tightly stoppered. Eventually many of the flasks became cloudy and contained microorganisms. He thought organic matter contained a vital force that could confer the properties of life on nonliving matter.

A few years later, the Italian priest and naturalist Lazzaro Spallanzani (1729–1799) improved on Needham's experimental design by first sealing glass flasks that contained water and seeds. If the sealed flasks were placed in boiling water for about 45 minutes, no growth took place as long as the flasks remained sealed. He proposed that air carried germs to the culture medium but also commented that the external air might be required for growth of animals already in the medium. The supporters of spontaneous generation maintained that heating the air in sealed flasks destroyed its ability to support life.

Several investigators attempted to counter such arguments. Theodore Schwann (1810–1882) allowed air to enter a flask containing a sterile nutrient solution after the air had passed through a red-hot tube. The flask remained sterile. Subsequently Georg Friedrich Schroder (1810–1885) and Theodor von Dusch (1824–1890) allowed air to enter a flask of heat-sterilized medium after it had passed through sterile cotton wool. No growth occurred in the medium even though the air had not been heated. Despite these experiments, the French naturalist Felix Pouchet (1800–1872) claimed in 1859 to have carried out experiments conclusively proving that microbial growth could occur without air contamination.

Pouchet's claim provoked Louis Pasteur (1822–1895) to settle the matter of spontaneous generation. Pasteur (**figure 1.12**) first filtered air through cotton and found that objects resembling plant spores had been trapped. If a piece of the cotton was placed in sterile medium after air had been filtered through it, microbial growth occurred. Next he placed nutrient solutions in flasks, heated their necks in a flame, and drew them out into a variety of curves. The swan-neck flasks that he produced in this way had necks open to the atmosphere. Pasteur then boiled the solutions for a few minutes and allowed them to cool. No growth took place even though the contents of the flasks were exposed to the air (**figure 1.13**). Pasteur pointed out that growth did not occur because dust and germs had been

Figure 1.12 Louis Pasteur.

Figure 1.13 Pasteur's Experiments with Swan-Neck Flasks.

trapped on the walls of the curved necks. If the necks were broken, growth commenced immediately. Pasteur had not only resolved the controversy by 1861 but also had shown how to keep solutions sterile.

The English physicist John Tyndall (1820–1893) and the German botanist Ferdinand Cohn (1828–1898) dealt a final blow to spontaneous generation. In 1877 Tyndall demonstrated that dust did indeed carry germs and that if dust was absent, broth remained sterile even if directly exposed to air. During the course of his studies, Tyndall provided evidence for the existence of exceptionally heat-resistant forms of bacteria. Working independently, Cohn discovered that the heat-resistant bacteria recognized by Tyndall were species capable of producing bacterial endospores. Cohn later played an instrumental role in establishing a classification system for bacteria based on their morphology and physiology.

►► Bacterial endospores (section 3.9)

Clearly, these early microbiologists not only disproved spontaneous generation but also contributed to the rebirth of microbiology. They developed liquid media for culturing microbes. They also developed methods for sterilizing media and maintaining their sterility. These techniques were next applied to understanding the role of microorganisms in disease.

Retrieve, Infer, Apply

1. What does the theory of spontaneous generation propose? How did Pasteur, Tyndall, and Cohn finally settle the spontaneous generation controversy?
2. What did Pasteur prove when he showed that a cotton plug that had filtered air would trigger microbial growth when transferred to the medium? What argument made previously was he addressing?

Microorganisms and Disease

Although Fracastoro and a few others had suggested that invisible organisms produced disease, most people believed that disease was caused by supernatural forces, poisonous vapors called miasmas, and imbalances among the four humors thought to be present in the body. The role of the four humors (blood, phlegm, yellow bile [choler], and black bile [melancholy]) in disease had been widely accepted since the time of the Greek physician Galen (129–199). Support for the idea that microorganisms cause disease—that is, the germ theory of disease—began to accumulate in the early nineteenth century from diverse fields. Agostino Bassi (1773–1856) demonstrated in 1835 that a silkworm disease was due to a fungal infection. He also suggested that many diseases were due to microbial infections. In 1845 M. J. Berkeley (1803–1889) proved that the great potato blight of Ireland was caused by a water mold (then thought to be a fungus), and in 1853 Heinrich de Bary (1831–1888) showed that smut and rust fungi caused cereal crop diseases.

Pasteur also contributed to this area of research in several ways. His contributions began in what may seem an unlikely way. Pasteur was trained as a chemist and spent many years studying the alcoholic fermentations that yield ethanol and are used in the production of wine and other alcoholic beverages. When he began his work, the leading chemists were convinced that fermentation was due to a chemical instability that degraded the sugars in grape juice and other substances to alcohol. Pasteur did not agree; he believed that fermentations were carried out by living organisms.

In 1856 M. Bigo, an industrialist in Lille, France, where Pasteur worked, requested Pasteur's assistance. His business produced ethanol from the fermentation of beet sugars, and the alcohol yields had recently declined and the product had become sour. Pasteur discovered that the fermentation was failing because the yeast normally responsible for alcohol formation had been replaced by bacteria that produced acid rather than ethanol. In solving this practical problem, Pasteur demonstrated that all fermentations were due to the activities of specific yeasts and bacteria, and he published several papers on fermentation between 1857 and 1860.

Pasteur was also called upon by the wine industry in France for help. For several years, poor-quality wines had been produced. Pasteur referred to the wines as diseased and demonstrated that particular wine diseases were linked to particular microbes contaminating the wine. He eventually suggested a method for heating the wines to destroy the undesirable microbes. The process is now called pasteurization.

Indirect evidence for the germ theory of disease came from the work of the English surgeon Joseph Lister (1827–1912) on the prevention of wound infections. Lister, impressed with Pasteur's studies on fermentation and putrefaction, developed a system of antiseptic surgery designed to prevent microorganisms from entering wounds. Instruments were heat sterilized, and phenol was used on surgical dressings and at times sprayed over the surgical area. The approach was remarkably successful and transformed surgery. It also provided strong indirect evidence for the role of

Figure 1.14 Robert Koch. Koch examining a specimen in his laboratory.

microorganisms in disease because phenol, which kills bacteria, also prevented wound infections.

Koch's Postulates

The first direct demonstration that bacteria cause disease came from the study of anthrax by the German physician Robert Koch (1843–1910). Koch (**figure 1.14**) used the criteria proposed by his former teacher Jacob Henle (1809–1885) and others to establish the relationship between *Bacillus anthracis* and anthrax; he published his findings in 1876. Koch injected healthy mice with material from diseased animals, and the mice became ill. After transferring anthrax by inoculation through a series of 20 mice, he incubated a piece of spleen containing the anthrax bacillus in beef serum. The bacteria grew, reproduced, and produced endospores. When isolated bacteria or their spores were injected into healthy mice, anthrax developed. His criteria for proving the causal relationship between a microorganism and a specific disease are known as **Koch's postulates**. Koch's proof that *B. anthracis* caused anthrax was independently confirmed by Pasteur and his coworkers. They discovered that after burial of dead animals, anthrax spores survived and were brought to the surface by earthworms. Healthy animals then ingested the spores and became ill.

After completing his anthrax studies, Koch fully outlined his postulates in his work on the cause of tuberculosis (**figure 1.15**). In 1884 he reported that this disease was caused by the rod-shaped bacterium *Mycobacterium tuberculosis*, and in 1905 he was awarded the Nobel Prize in Physiology or Medicine. Koch's postulates were quickly adopted by others and used to connect many diseases to their causative agent.

While Koch's postulates are still widely used, their application is at times not feasible. For instance, organisms such as

Mycobacterium leprae, the causative agent of leprosy, cannot be isolated in pure culture. Some human diseases are so deadly (e.g., Ebola hemorrhagic fever) that it would be unethical to use humans as the experimental organism; if an appropriate animal model does not exist, the postulates cannot be fully met. To avoid some of these difficulties, microbiologists sometimes use molecular and genetic evidence. For instance, molecular methods might be used to detect the nucleic acid of a virus in body tissues, rather than isolating the virus, or the genes thought to be associated with the virulence of a pathogen might be mutated. In this case, the mutant organism should have decreased ability to cause disease. Introduction of the normal gene back into the mutant should restore the pathogen's virulence.

Pure Culture Methods

During Koch's studies on bacterial diseases, it became necessary to isolate suspected bacterial pathogens in pure culture (p. 11). At first Koch cultured bacteria on the sterile surfaces of cut, boiled potatoes, but the bacteria did not always grow well. Eventually he developed culture media using meat extracts and protein digests, reasoning these were similar to body fluids. Initially he tried to solidify the media by adding gelatin. Separate bacterial colonies developed after the surface of the solidified medium had been streaked with a bacterial sample. The sample could also be mixed with liquefied gelatin medium. When the medium hardened, individual bacteria produced separate colonies.

Despite its advantages, gelatin was not an ideal solidifying agent because it can be digested by many microbes and melts at temperatures above 28°C. A better alternative was provided by Fanny Eilshemius Hesse (1850–1934), the wife of Walther Hesse (1846–1911), one of Koch's assistants. She suggested the use of agar, which she used to make jellies, as a solidifying agent. Agar was not attacked by most bacteria. Furthermore, it did not melt until reaching a temperature of 100°C and, once melted, did not solidify until reaching a temperature of 50°C; this eliminated the need to handle boiling liquid. Some of the media developed by Koch and his associates, such as nutrient broth and nutrient agar, are still widely used. Another important tool developed in Koch's laboratory was a container for holding solidified media—the Petri dish (plate), named after Richard Petri (1852–1921), who devised it. These developments directly stimulated progress in all areas of microbiology. ▶▶ *Culture media (section 7.5); Enrichment and isolation of pure cultures (section 7.5)*

Our focus thus far has been on the development of methods for culturing bacteria. But viral pathogens were also being studied during this time, and methods for culturing them were also being developed. The discovery of viruses and their role in disease was made possible when Charles Chamberland (1851–1908), one of Pasteur's associates, constructed a porcelain bacterial filter in 1884. Dimitri Ivanowski (1864–1920) and Martinus Beijerinck (pronounced “by-a-rink”; 1851–1931) used the filter to study tobacco mosaic disease. They found that plant extracts and sap from diseased plants were infectious, even after being filtered with Chamberland's filter. Because the infectious agent passed through

Postulate

1. The microorganism must be present in every case of the disease but absent from healthy organisms.
2. The suspected microorganisms must be isolated and grown in a pure culture.
3. The same disease must result when the isolated microorganism is inoculated into a healthy host.
4. The same microorganisms must be isolated again from the diseased host.

Experimentation

- Koch developed a staining technique to examine human tissue. *Mycobacterium tuberculosis* could be identified in diseased tissue.
- Koch grew *M. tuberculosis* in pure culture on coagulated blood serum.
- Koch injected cells from the pure culture of *M. tuberculosis* into guinea pigs. The guinea pigs subsequently died of tuberculosis.
- Koch isolated *M. tuberculosis* in pure culture on coagulated blood serum from the dead guinea pigs.

**Figure 1.15** Koch's Postulates Applied to Tuberculosis.

a filter that was designed to trap bacterial cells, they reasoned that the agent must be something smaller than a bacterium. Beijerinck proposed that the agent was a “filterable virus.” Eventually viruses were shown to be tiny, acellular infectious agents.

Retrieve, Infer, Apply

1. Discuss the contributions of Lister, Pasteur, and Koch to the germ theory of disease and the treatment or prevention of diseases. What other contributions did Koch make to microbiology?
2. Describe Koch's postulates. What is a pure culture? Why are pure cultures important to Koch's postulates?

Immunology

The ability to culture microbes also played an important role in early immunological studies. During studies on the bacterium that causes chicken cholera, Pasteur and Pierre Roux (1853–1933) discovered that incubating the cultures for long intervals between transfers resulted in cultures that had lost their ability to cause the

disease. These cultures were said to be attenuated. When the chickens were injected with attenuated cultures, they not only remained healthy but also were able to resist the disease when exposed to virulent cultures. Pasteur called the attenuated culture a vaccine (Latin *vacca*, cow) in honor of Edward Jenner (1749–1823) because, many years earlier, Jenner had used material from cowpox lesions to protect people against smallpox (see *Historical Highlights 37.5*). Shortly after this, Pasteur and Chamberland developed an attenuated anthrax vaccine. ▶▶ Vaccines and immunizations (section 37.7)

Pasteur also prepared a rabies vaccine using an attenuated strain of rabies virus. During the course of these studies, Joseph Meister, a nine-year-old boy who had been bitten by a rabid dog, was brought to Pasteur. Since the boy's death was certain in the absence of treatment, Pasteur agreed to try vaccination. Joseph was injected 13 times over the next 10 days with increasingly virulent preparations of the attenuated virus. He survived. In gratitude for Pasteur's development of vaccines, people from around the world contributed to the construction of the Pasteur

Institute in Paris, France. One of the initial tasks of the institute was vaccine production.

These early advances in immunology were made without any concrete knowledge about how the immune system works. Immunologists now know that the immune system uses chemicals produced by several types of blood cells to provide protection. Among the chemicals are soluble proteins called antibodies, which can be found in blood, lymph, and other body fluids. The role of soluble substances in preventing disease was recognized by Emil von Behring (1854–1917) and Shibasaburo Kitasato (1852–1931). After the discovery that diphtheria was caused by a bacterial toxin, they injected inactivated diphtheria toxin into rabbits. The inactivated toxin induced rabbits to produce an antitoxin, which protected against the disease. Antitoxins are now known to be antibodies that specifically bind toxins, neutralizing them. The first immune system cells were discovered when Elie Metchnikoff (1845–1916) found that some white blood cells could engulf disease-causing bacteria. He called these cells phagocytes and the process phagocytosis (Greek *phagein*, eating).

Microbial Ecology

Culture-based techniques were also applied to the study of microbes in soil and aquatic habitats. Early microbial ecologists studied microbial involvement in the carbon, nitrogen, and sulfur cycles. The Russian microbiologist Sergei Winogradsky (1856–1953) made many contributions to soil microbiology. He discovered that soil bacteria could oxidize iron, sulfur, and ammonia to obtain energy and that many of these bacteria could incorporate CO₂ into organic matter much as photosynthetic organisms do. Winogradsky also isolated anaerobic nitrogen-fixing soil bacteria and studied the decomposition of cellulose. Martinus Beijerinck was one of the great general microbiologists who made fundamental contributions not only to virology but to microbial ecology as well. He isolated aerobic nitrogen-fixing bacteria (*Azotobacter* spp.), a root nodule bacterium also capable of fixing nitrogen (genus *Rhizobium*), and sulfate-reducing bacteria. Beijerinck and Winogradsky also developed the enrichment culture techniques and the use of selective media, which have been of great importance in microbiology. ►► *Biogeochemical cycling* (section 28.1); *Culture media* (section 7.5)

Retrieve, Infer, Apply

1. How did Jenner, Pasteur, von Behring, Kitasato, and Metchnikoff contribute to the development of immunology? How was the ability to culture microbes important to their studies?
2. How did Winogradsky and Beijerinck contribute to the study of microbial ecology? What new culturing techniques did they develop in their studies?
3. How might the work of Winogradsky and Beijerinck have contributed to research on bacterial pathogens? Conversely, how might Koch and Pasteur have influenced Winogradsky's and Beijerinck's study of microbial ecology?

1.4 Microbiology Today

After reading this section, you should be able to:

- Construct a concept map, table, or drawing that illustrates the diverse nature of microbiology and how it has improved human conditions
- Support the belief held by many microbiologists that microbiology is experiencing its second golden age

Microbiology today is as diverse as the organisms it studies. It has both basic and applied aspects. The basic aspects are concerned with the biology of microorganisms themselves. The applied aspects are concerned with practical problems such as disease, water and wastewater treatment, food spoilage and food production, and industrial uses of microbes. The basic and applied aspects of microbiology are intertwined. Basic research is often conducted in applied fields, and applications often arise out of basic research.

An important recent development in microbiology is the increasing use of molecular and genomic methods to study microbes and their interactions with other organisms. These methods have led to a time of rapid advancement that rivals the golden age of microbiology. Indeed, many feel that microbiology is in its second golden age. Here we describe some of the important advances that have enabled microbiologists to use molecular and genomic techniques. We then discuss some of the important research being done in the numerous subdisciplines of microbiology.

Molecular and Genomic Methods for Studying Microbes

Molecular and genomic methods for studying microbes rely on the ability of scientists to manipulate the genes and genomes of the organisms being studied. An organism's **genome** is all the genetic information that organism contains. To study single genes or the entire genome, microbiologists must be able to isolate DNA and RNA, cut DNA into smaller pieces, insert one piece of DNA into another, and determine the sequence of nucleotides in DNA.

Cutting double-stranded DNA into smaller pieces was accomplished using bacterial enzymes now known as restriction endonucleases, or simply, restriction enzymes. These enzymes were discovered by Werner Arber and Hamilton Smith in the 1960s. Their discovery was followed by the report in 1972 that David Jackson, Robert Symons, and Paul Berg had successfully generated recombinant DNA molecules—molecules made by combining two or more different DNA molecules together. They did this by cutting DNA from two different organisms with the same restriction enzyme, mixing the two DNA molecules together, and linking them together with an enzyme called DNA ligase. ►► *Key developments in recombinant DNA technology* (section 17.1)

The next major breakthrough was the development of methods to determine the sequence of nucleotides in DNA. In the late

1970s, Frederick Sanger introduced a method that has since been modified and adapted for use in automated systems. Today entire genomes of organisms can be sequenced in a matter of days. In addition, newer, even more rapid sequencing methods have been devised. ►► *Genome sequencing (section 18.2)*

Genome sequencing is the first step in **genomic analysis**. Once the genome sequence is in hand, microbiologists must decipher the information found in the genome. This involves identifying potential protein-coding genes, determining what they code for, and identifying other regions of the genome that may have other important functions (e.g., genes encoding tRNA and rRNA or sequences playing a role in regulating the function of genes). This work requires the use of computers, which has given rise to the scientific discipline **bioinformatics**. Bioinformaticists manage the ever-increasing amount of genetic information available for analysis. They also determine the function of genes and generate hypotheses that can be tested either in silico (i.e., in the computer) or in the laboratory. ►► *Bioinformatics (section 18.3)*

Major Fields in Microbiology

As noted in section 1.1, pathogenic microbes, though relatively few in number, have had and continue to have considerable impact on humans. Thus one of the most active and important fields in microbiology is medical microbiology, which deals with diseases of humans and animals. Medical microbiologists identify the agents causing infectious diseases and help plan measures for their control and elimination. Frequently they are involved in tracking down new, unidentified pathogens such as those causing variant Creutzfeldt-Jakob disease (the human version of “mad cow disease”), hantavirus pulmonary syndrome, and West Nile encephalitis. These microbiologists also study the ways microorganisms cause disease. As described in section 1.3, our understanding of the role of microbes in disease began to crystallize when we were able to isolate them in pure culture. Today, clinical laboratory scientists, the microbiologists who work in hospital and other clinical laboratories, use a variety of techniques to provide information needed by physicians to diagnose infectious disease. Increasingly, molecular genetic techniques are also being used.

Major epidemics have regularly affected human history. The 1918 influenza pandemic is of particular note; it killed more than 50 million people in about a year. Public health microbiology is concerned with the control and spread of such communicable diseases. Public health microbiologists and epidemiologists monitor the amount of disease in populations. Based on their observations, they can detect outbreaks and developing epidemics, and implement appropriate control measures. They also conduct surveillance for new diseases as well as bioterrorism events. Public health microbiologists working for local governments monitor community food establishments and water supplies to ensure they are safe and free from pathogens.

To understand, treat, and control infectious disease, it is important to understand how the immune system protects the

body from pathogens; this question is the concern of immunology. Immunology is one of the fastest growing areas in science. Much of the growth began with the discovery of the human immunodeficiency virus (HIV), which specifically targets cells of the immune system. Immunology also deals with the nature and treatment of allergies and autoimmune diseases such as rheumatoid arthritis. ►► *Innate host resistance (chapter 33); Adaptive immunity (chapter 34)*

Microbial ecology is another important field in microbiology. Microbial ecology developed when early microbiologists such as Winogradsky and Beijerinck chose to investigate the ecological role of microorganisms rather than their role in disease. Today, a variety of approaches, including non-culture-based techniques, are used to describe the vast diversity of microbes in terms of their morphology, physiology, and relationships with organisms and the components of their habitats. The importance of microbes in global and local cycling of carbon, nitrogen, and sulfur is well documented; however, many questions are still unanswered. Of particular interest is the role of microbes in both the production and removal of greenhouse gases such as carbon dioxide and methane. Microbial ecologists also are employing microorganisms in bioremediation to reduce pollution. A new frontier in microbial ecology is the study of the microbes normally associated with the human body—so-called human microbiota. Scientists are currently trying to identify all members of the human microbiota using molecular techniques that grew out of Woese’s pioneering work to establish the phylogeny of microbes. ►► *Global climate change (section 28.2); Biodegradation and bioremediation (section 43.4)*

Agricultural microbiology is a field related to both medical microbiology and microbial ecology. Agricultural microbiology is concerned with the impact of microorganisms on agriculture. Microbes such as nitrogen-fixing bacteria play critical roles in the nitrogen cycle and affect soil fertility. Other microbes live in the digestive tracts of ruminants such as cattle and break down the plant materials these animals ingest. There are also plant and animal pathogens that have significant economic impact if not controlled. Furthermore, some pathogens of domestic animals also can cause human disease. Agricultural microbiologists work on methods to increase soil fertility and crop yields, study rumen microorganisms in order to increase meat and milk production, and try to combat plant and animal diseases. Currently many agricultural microbiologists are studying the use of bacterial and viral insect pathogens as substitutes for chemical pesticides. ►► *Agricultural biotechnology (section 42.4)*

Agricultural microbiology has contributed to the ready supply of high-quality foods, as has the discipline of food and dairy microbiology. Numerous foods are made using microorganisms. On the other hand, some microbes cause food spoilage or are pathogens that are spread through food. Excellent examples of the latter are the rare *Escherichia coli* O104:H4, which in 2011 caused a widespread outbreak of disease in Europe thought to have been spread by bean sprouts, and also in 2011, contaminated ground turkey was implicated in a *Salmonella* outbreak in the United States. Food and dairy

microbiologists explore the use of microbes in food production. They also work to prevent microbial spoilage of food and the transmission of food-borne diseases. This involves monitoring the food industry for the presence of pathogens. Increasingly, molecular methods are being used to detect pathogens in meat and other foods. Food and dairy microbiologists also conduct research on the use of microorganisms as nutrient sources for livestock and humans. ►► *Microbiology of food (chapter 41)*

Humans unknowingly exploited microbes for thousands of years. However, the systematic and conscious use of microbes in industrial microbiology did not begin until the 1800s. Industrial microbiology developed in large part from Pasteur's work on alcoholic fermentations, as described in section 1.3. His success led to the development of pasteurization to preserve wine during storage. Pasteur's studies on fermentation continued for almost 20 years. One of his most important discoveries was that some fermentative microorganisms were anaerobic and could live only in the absence of oxygen, whereas others were able to live either aerobically or anaerobically. ►► *Controlling food spoilage (section 41.2)*

Another important advance in industrial microbiology occurred in 1929 when Alexander Fleming discovered that the fungus *Penicillium* sp. produced what he called penicillin, the first antibiotic that could successfully control bacterial infections. Although it took World War II for scientists to learn how to mass-produce penicillin, scientists soon found other microorganisms capable of producing additional antibiotics. Today industrial microbiologists also use microorganisms to make products such as vaccines, steroids, alcohols and other solvents, vitamins, amino acids, and enzymes. Microbes are also being used to produce biofuels such as ethanol. These alternative fuels are renewable and may help decrease pollution associated with burning fossil fuels. ►► *Major products of industrial microbiology (section 42.1); Biofuel production (section 42.2)*

Industrial microbiologists identify or genetically engineer microbes of use to industrial processes, medicine, agriculture, and other commercial enterprises. They also utilize techniques to improve production by microbes and devise systems for culturing them and isolating the products they make.

The advances in medical microbiology, agricultural microbiology, food and dairy microbiology, and industrial microbiology are in many ways outgrowths of the labor of many microbiologists doing basic research in areas such as microbial physiology, microbial genetics, molecular biology, and bioinformatics. Microbes are metabolically diverse and can employ a wide variety of energy sources, including organic matter, inorganic molecules (e.g., H_2 and NH_3), and sunlight. Microbial physiologists study many aspects of the biology of microorganisms, including their metabolic capabilities. They also study the synthesis of antibiotics and toxins, the ways in which microorganisms survive harsh environmental conditions, and the effects of chemical and physical agents on microbial growth and survival. Microbial geneticists, molecular biologists, and bioinformaticists study the nature of genetic information and how it regulates the development and function of cells and organisms. The bacteria *E. coli* and *Bacillus subtilis*, the yeast *Saccharomyces cerevisiae* (baker's yeast), and bacterial viruses such as T4 and lambda continue to be important model organisms used to understand biological phenomena.

Clearly, the future of microbiology is bright. Genomics in particular is revolutionizing microbiology, as scientists are now beginning to understand organisms in toto, rather than in a reductionist, piecemeal manner. How the genomes of microbes evolve, the nature of host-pathogen interactions, the minimum set of genes required for an organism to survive, and many more topics are aggressively being examined by molecular and genomic analyses. This is an exciting time to be a microbiologist. Enjoy the journey.

Retrieve, Infer, Apply

1. Since the 1970s, microbiologists have been able to study individual genes and whole genomes at the molecular level. What advances made this possible?
2. Briefly describe the major subdisciplines in microbiology. Which do you consider to be applied fields? Which are basic?
3. Log all the microbial products you use in a week. Be sure to consider all foods and medications (including vitamins).
4. List all the activities or businesses you can think of in your community that directly depend on microbiology.

Key Concepts

1.1 Members of the Microbial World

- Microbiology studies microscopic cellular organisms that are often unicellular or, if multicellular, do not have highly differentiated tissues. Microbiology also focuses on biological entities that are acellular (**figure 1.1**).
- Microbiologists divide cellular organisms into three domains: *Bacteria*, *Archaea*, and *Eukarya* (**figure 1.2**).
- Domains *Bacteria* and *Archaea* consist of prokaryotic microorganisms. The eukaryotic microbes (protists and

fungi) are placed in *Eukarya*. Viruses, viroids, satellites, and prions are acellular entities that are not placed in any of the domains but are classified by a separate system.

1.2 Microbial Evolution

- Evolutionary biologists and others interested in the origin of life must rely on many types of evidence.
- Earth is approximately 4.5 billion years old. Within the first 1 billion years of its existence, life arose (**figure 1.4**).

- The RNA world hypothesis posits that the earliest self-replicating entity on the planet used RNA both to store genetic information and to conduct cellular processes (figure 1.6).
- Comparisons of small subunit (SSU) rRNA genes have been useful in creating universal phylogenetic trees. These trees provide information about the evolution of life after it arose (figure 1.8).
- The last universal common ancestor (LUCA) is placed on the bacterial branch of the universal phylogenetic tree. Thus, *Bacteria* diverged first, and *Archaea* and *Eukarya* arose later.
- Mitochondria, chloroplasts, and hydrogenosomes are thought to have evolved from bacterial endosymbionts of ancestral cells in the eukaryotic lineage.
- The concept of a bacterial or archaeal species is difficult to define and is the source of considerable debate because these microbes do not reproduce sexually. Species are named using the binomial system of Linnaeus.

1.3 Microbiology and Its Origins

- Microbiology is defined not only by the organisms it studies but also by the tools it uses. Microscopy and culture-based techniques have played and continue to play important roles in the evolution of the discipline.
- Antony van Leeuwenhoek used simple microscopes and was the first person to extensively describe microorganisms (figure 1.11).
- Culture-based techniques for studying microbes began to develop as scientists debated the theory of spontaneous generation. Experiments by Redi and others disproved the theory of spontaneous generation of larger organisms. The spontaneous generation of microorganisms was disproved by Spallanzani, Pasteur, Tyndall, Cohn, and others (figure 1.13).

- The availability of culture-based techniques played an important role in the study of the microbes as the causative agents of disease. Support for the germ theory of disease came from the work of Bassi, Pasteur, Koch, Lister, and others.
- Koch's postulates are used to prove a direct relationship between a suspected pathogen and a disease. Koch and his coworkers developed the techniques required to grow bacteria on solid media and to isolate pure cultures of pathogens (figure 1.15).
- Viruses were discovered following the invention of a bacterial filter by Chamberland. Dimitri Ivanowski and Martinus Beijerinck were important contributors to the field of virology.
- The field of immunology developed as early microbiologists created vaccines and discovered antibodies and phagocytic cells. Pasteur, von Behring, Kitasato, and Mechnikov made important contributions to this field.
- Microbial ecology grew out of the work of Winogradsky and Beijerinck. They studied the role of microorganisms in carbon, nitrogen, and sulfur cycles and developed enrichment culture techniques and selective media.

1.4 Microbiology Today

- Today molecular and genomic analyses have paved the way for understanding microbes as biological systems. These methods include recombinant DNA techniques, nucleic acid sequencing methods, and genome sequencing.
- There are many fields in microbiology. These include medical, public health, industrial, and food and dairy microbiology. Microbial ecology, physiology, and genetics are important subdisciplines of microbiology.

Compare, Hypothesize, Invent

1. Microscopic organisms such as rotifers are not studied by microbiologists. Why is this so?
2. Why aren't viruses, viroids, satellites, and prions included in the three domain system?
3. Why was the belief in spontaneous generation an obstacle to the development of microbiology as a scientific discipline?
4. Would microbiology have developed more slowly if Fanny Hesse had not suggested the use of agar? Give your reasoning.
5. Some individuals can be infected by a pathogen yet not develop disease. In fact, some become chronic carriers of the pathogen. How does this observation affect Koch's postulates? How might the postulates be modified to account for the existence of chronic carriers?
6. Develop a list of justifications for the usefulness of microorganisms as experimental models.
7. History is full of examples in which one group of people lost a struggle against another.
 - a. Choose an example of a battle or other human activity such as exploration of new territory and determine the impact of microorganisms, either indigenous or transported to the region, on that activity.
 - b. Discuss the effect that the microbe(s) had on the outcome in your example.
 - c. Suggest whether the advent of antibiotics, food storage and preparation technology, or sterilization technology would have made a difference in the outcome.

8. Antony van Leeuwenhoek is often referred to as the father of microbiology. However, many historians feel that Louis Pasteur, Robert Koch, or perhaps both, deserve that honor. Decide who should be considered the father of microbiology and justify your decision.
9. Consider the discoveries described in sections 1.3 and 1.4. Which do you think were the most important to the development of microbiology? Why?
10. Support this statement: “Vaccinations against various childhood diseases have contributed to the entry of women, particularly mothers, into the full-time workplace.”
11. Scientists are very interested in understanding when cyanobacteria first emerged because, as the first organisms capable of oxygenic photosynthesis, it is thought that they triggered a sharp rise in atmospheric oxygen. For many years, certain lipid biomarkers have served as “molecular fossils” to date the first appearance of cyanobacteria. However, a 2010 study questioned whether these lipids, called 2-methylhopanoids, provide accurate information in

light of a 2007 discovery that they also are produced by an anoxygenic phototrophic bacterium—a bacterium that does not produce oxygen as it uses light energy. The authors of the 2010 study identified genes in extant bacteria involved in synthesis of the lipid biomarkers and then constructed phylogenetic trees based on comparisons of these genes. They also identified the phyla to which the bacteria belonged (based on SSU rRNA analysis) and noted the habitats and metabolic capabilities of the bacteria used in the study. Discuss the specific challenges encountered in the study of microbial evolution. What results from the phylogenetic analysis would support their claim that 2-methylhopanoids are not reliable biomarkers? Why were habitat and metabolic characteristics also part of their analysis?

Read the original paper: Welander, P. V., et al. 2010. Identification of a methylase required for 2-methylhopanoid production and implications for the interpretation of sedimentary hopanes. *Proc. Natl. Acad. Sci.* 107(19):8537.

Microscopy

Anthrax Bioterrorism Attack 2001

While on a trip to North Carolina in late September 2001, a sixty-three-year-old photojournalist and outdoor enthusiast from Florida began feeling ill. His muscles ached, he felt nauseous, and he had a fever. His symptoms were annoying and varied in severity during his trip. After returning home, his symptoms worsened considerably. On October 2, he awoke with vomiting. Even more alarming was his mental confusion. When his wife took him to a local emergency room, doctors found that he was unable to answer simple questions not only about his illness but also about where he was and what time it was. His doctors performed a spinal tap and collected cerebral spinal fluid (CSF). The fluid was sent to the hospital laboratory where it was stained using the Gram-staining technique. Much to the surprise of the clinical lab scientists, the CSF contained long, Gram-positive rods that formed chains, a morphology unlike that of typical meningitis-causing bacteria. Based on the Gram-stain results, doctors made an initial diagnosis of inhalation anthrax. What made this diagnosis so surprising was that inhalation anthrax is extremely rare in the United States. Indeed, the last diagnosed case was in 1976. Doctors immediately began treatment with antibiotics, but the photojournalist's condition worsened, and he died October 5.

Thus began the first anthrax bioterrorism attack in the United States. Over the next several weeks, 16 other people developed inhalation anthrax; four of these individuals died. Much was learned about the disease from this attack. Much was also learned about the nation's readiness to deal with bioterrorism. This event is also a reminder of the continuing importance of microscopy in microbiology and in diagnosing disease.

As we describe in chapter 1, the invention of microscopes in the 1600s was a critical step in the evolution of microbiology. By the 1800s, microscopes had become relatively sophisticated, and methods for staining specimens were developed so that they could be seen more easily. Indeed, the Gram-staining technique is over 150 years old.

Hazardous materials (hazmat) personnel outside the U.S. Capitol building during the 2001 anthrax bioterrorism attack.

In this chapter, we introduce some of the most commonly used types of microscopy. We begin with light microscopes and then describe other common types of microscopes, as well as how specimens are prepared for examination by microscopes.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Explain why microscopy is a major tool used by microbiologists (sections 1.1 and 1.3)
- ✓ Define magnification
- ✓ Express the size of organisms using the metric system (**table 2.1**)

Table 2.1 Common Units of Measurement

| Unit | Abbreviation | Value |
|--------------|---------------|---------------------------------|
| 1 centimeter | cm | 10^{-2} meter or 0.394 inches |
| 1 millimeter | mm | 10^{-3} meter |
| 1 micrometer | μm | 10^{-6} meter |
| 1 nanometer | nm | 10^{-9} meter |
| 1 Angstrom | Å | 10^{-10} meter |

2.1 Lenses and the Bending of Light

After reading this section, you should be able to:

- Relate the refractive indices of glass and air to the path light takes when it passes through a prism or convex lens
- Correlate lens strength and focal length

Light microscopes were the first microscopes invented and they continue to be the most commonly used type. Therefore to understand light microscopy, we must consider the way lenses bend

and focus light to form images. When a ray of light passes from one medium to another, refraction occurs; that is, the ray is bent at the interface. The **refractive index** is a measure of how greatly a substance slows the velocity of light; the direction and magnitude of bending are determined by the refractive indices of the two media forming the interface. For example, when light passes from air into glass, a medium with a greater refractive index, it is slowed and bent toward the normal, a line perpendicular to the surface (figure 2.1). As light leaves glass and returns to air, a medium with a lower refractive index, it accelerates and is bent away from the normal. Thus a prism bends light because glass has a different refractive index from air and the light strikes its surface at an angle.

Lenses act like a collection of prisms operating as a unit. When the light source is distant so that parallel rays of light strike the lens, a convex lens focuses the rays at a specific point, the focal point (F in figure 2.2). The distance between the center of the lens and the focal point is called the focal length (f in figure 2.2).

Our eyes cannot focus on objects nearer than about 25 cm (i.e., about 10 inches). This limitation may be overcome by using

Figure 2.1 The Bending of Light by a Prism. Normals (lines perpendicular to the surface of the prism) are indicated by dashed lines. As light enters the glass, it is bent toward the first normal. When light leaves the glass and returns to air, it is bent away from the second normal. As a result, the prism bends light passing through it.

Figure 2.2 Lens Function. A lens functions somewhat like a collection of prisms. Light rays from a distant source are focused at the focal point F . The focal point lies a distance f , the focal length, from the lens center.

MICRO INQUIRY How would the focal length change if the lens shown here were thicker?

a convex lens as a simple magnifier (or microscope) and holding it close to an object. A magnifying glass provides a clear image at much closer range, and the object appears larger. Lens strength is related to focal length; a lens with a short focal length magnifies an object more than a lens having a longer focal length.

Retrieve, Infer, Apply

1. Define refraction, refractive index, focal point, and focal length.
2. Describe the path of a light ray through a prism or lens.
3. How is lens strength related to focal length? How is this principle applied to corrective eyeglasses?

2.2 Light Microscopes

After reading this section, you should be able to:

- Evaluate the parts of a light microscope in terms of their contributions to image production and use of the microscope
- Predict the relative degree of resolution based on light wavelength and numerical aperture of the lens used to examine a specimen
- Create a table that compares and contrasts the various types of light microscopes in terms of their uses, how images are created, and the quality of images produced

Microbiologists currently employ a variety of light microscopes in their work; bright-field, dark-field, phase-contrast, fluorescence, and confocal microscopes are most commonly used. Each is useful for certain applications. Modern microscopes are all compound microscopes; that is, they have two sets of lenses. The **objective lens** is the lens closest to the specimen. It forms a magnified image that is further enlarged by one or more additional lenses.

Bright-Field Microscope: Dark Object, Bright Background

The **bright-field microscope** is routinely used in microbiology labs to examine both stained and unstained specimens. It is called a bright-field microscope because it forms a dark image against a brighter background. It consists of a sturdy metal stand composed of a base and an arm to which the remaining parts are attached (figure 2.3). A light source, either a mirror or an electric illuminator, is located in the base. Two focusing knobs, the fine and coarse adjustment knobs, are located on the arm and can move either the stage or the nosepiece vertically to focus the image.

The stage is positioned about halfway up the arm. It holds microscope slides either by simple slide clips or by a mechanical stage clip. A mechanical stage uses stage control knobs to smoothly move a slide during viewing. The **substage condenser** (or simply, condenser) is mounted within or beneath the stage and focuses a cone of light on the slide. Its position often is fixed in simpler microscopes but can be adjusted vertically in more advanced models.

Figure 2.3 A Bright-Field Microscope.

The curved upper part of the arm holds the body assembly, to which a nosepiece and one or more **ocular lenses** (also called **eyepieces**) are attached. More advanced microscopes have eyepieces for both eyes and are called binocular microscopes. The body assembly contains a series of mirrors and prisms so that the barrel holding the eyepiece may be tilted for ease in viewing. The nosepiece holds three to five objective lenses of differing magnifying power and can be rotated to position any objective lens beneath the body assembly. Ideally a microscope should be **parfocal**; that is, the image should remain in focus when objective lenses are changed.

The image seen when viewing a specimen with a compound microscope is created by the objective and ocular lenses working together. Light from the illuminated specimen is focused by the objective lens, creating an enlarged image within the microscope. The ocular lens further magnifies this primary image. The total magnification is calculated by multiplying the objective and eyepiece magnifications together. For example, if a 45 \times objective lens is used with a 10 \times eyepiece, the overall magnification of the specimen is 450 \times .

Microscope Resolution

The most important part of the microscope is the objective lens, which must produce a clear image, not just a magnified one. Thus resolution is extremely important. **Resolution** is the ability of a lens to separate or distinguish between small objects that are close together.

Resolution is described mathematically by an equation developed in the 1870s by Ernst Abbé, a German physicist responsible for much of the optical theory underlying microscope design. The Abbé equation states that the minimal distance (d) between two objects that reveals them as separate entities depends on the wavelength of light (λ) used to illuminate the specimen and on the **numerical aperture** of the lens ($n \sin \theta$), which is the ability of the lens to gather light.

$$d = \frac{0.5 \lambda}{n \sin \theta}$$

As d becomes smaller, the resolution increases, and finer detail can be discerned in a specimen; d becomes smaller as the wavelength of light used decreases and as the numerical aperture increases. Thus the greatest resolution is obtained using a lens with the largest possible numerical aperture and light of the shortest wavelength, light at the blue end of the visible spectrum (in the range of 450 to 500 nm).

The numerical aperture ($n \sin \theta$) of a lens is defined by two components: n is the refractive index of the medium in which the lens works (e.g., air) and θ is 1/2 the angle of the cone of light entering an objective (**figure 2.4**). A cone with a narrow angle does not adequately separate the rays of light emanating from closely packed objects, and the images are not resolved. A cone of light with a very wide angle does separate the rays, and the closely packed objects appear widely separated and resolved. Recall that the refractive indices of all materials through which light waves

Figure 2.4 Numerical Aperture in Microscopy. The angular aperture θ is 1/2 the angle of the cone of light that enters a lens from a specimen, and the numerical aperture is $n \sin \theta$. In the right-hand illustration, the lens has larger angular and numerical apertures; its resolution is greater and its working distance smaller.

pass determine the direction of the light rays emanating from the specimen. Some objective lenses work in air, which has a refractive index of 1.00. Since $\sin \theta$ cannot be greater than 1 (the maximum θ is 90° and $\sin 90^\circ$ is 1.00), no lens working in air can have a numerical aperture greater than 1.00. The only practical way to raise the numerical aperture above 1.00, and therefore achieve higher resolution, is to increase the refractive index with immersion oil, a colorless liquid with the same refractive index as glass (table 2.2). If air is replaced with immersion oil, many light rays that did not enter the objective due to reflection and refraction at the surfaces of the objective lens and slide will now do so (figure 2.5). This results in an increase in numerical aperture and resolution.

Numerical aperture is related to another characteristic of an objective lens, the working distance. The working distance of an objective is the distance between the surface of the lens and the surface of the cover glass (if one is used) or the specimen when it is in sharp focus (figure 2.4). Objectives with large numerical apertures and great resolving power have short working distances (table 2.2).

Numerical aperture is also an important feature of a microscope's condenser. The condenser is a large, light-gathering lens used to project a wide cone of light through the slide and into the objective lens. Most microscopes have a condenser with a numerical

Figure 2.5 The Oil Immersion Objective. An oil immersion objective operating in air and with immersion oil.

aperture between 1.2 and 1.4. However, the condenser's numerical aperture will not be much above about 0.9 unless the top of the condenser is oiled to the bottom of the slide. During routine microscope operation, the condenser usually is not oiled, and this limits the overall resolution, even with an oil immersion objective.

The most accurate calculation of a microscope's resolving power considers both the numerical aperture of the objective lens and that of the condenser, as is evident from the following equation, where NA is the numerical aperture.

$$d_{\text{microscope}} = \frac{\lambda}{(\text{NA}_{\text{objective}} + \text{NA}_{\text{condenser}})}$$

However, in most cases the limit of resolution of a light microscope is calculated using the Abbé equation, which considers the objective lens only. The maximum theoretical resolving power of a microscope when viewing a specimen using an oil immersion objective (numerical aperture of 1.25) and blue-green light is approximately $0.2 \mu\text{m}$.

$$d = \frac{(0.5)(530 \text{ nm})}{1.25} = 212 \text{ nm or } 0.2 \mu\text{m}$$

At best, a bright-field microscope can distinguish between two dots about $0.2 \mu\text{m}$ apart (the same size as a very small bacterium). Thus the vast majority of viruses cannot be examined with a light microscope.

Given the limit of resolution of a light microscope, the largest useful magnification—the level of magnification needed to

Table 2.2 Properties of Objective Lenses

| Property | OBJECTIVE | | | |
|--|-------------------|-------------------|--------------------|--------------------|
| | Scanning | Low Power | High Power | Oil Immersion |
| Magnification | 4× | 10× | 40–45× | 90–100× |
| Numerical aperture | 0.10 | 0.25 | 0.55–0.65 | 1.25–1.4 |
| Approximate focal length (f) | 40 mm | 16 mm | 4 mm | 1.8–2.0 mm |
| Working distance | 17–20 mm | 4–8 mm | 0.5–0.7 mm | 0.1 mm |
| Approximate resolving power with light of $450 \mu\text{m}$ (blue light) | $2.3 \mu\text{m}$ | $0.9 \mu\text{m}$ | $0.35 \mu\text{m}$ | $0.18 \mu\text{m}$ |

increase the size of the smallest resolvable object to be visible with the light microscope—can be determined. Our eye can just detect a speck 0.2 mm in diameter. When the acuity of the eye and the resolution of the microscope are considered together, it is calculated that the useful limit of magnification is about 1,000 times the numerical aperture of the objective lens. Most standard microscopes come with 10 \times eyepieces and have an upper limit of about 1,000 \times with oil immersion. A 15 \times eyepiece may be used with good objective lenses to achieve a useful magnification of 1,500 \times . Any further magnification does not enable a person to see more detail. Indeed, a light microscope can be built to yield a final magnification of 10,000 \times , but it would simply be magnifying a blur. Only the electron microscope provides sufficient resolution to make higher magnifications useful (p. 34).

Visualizing Living, Unstained Microbes

Bright-field microscopes are probably the most common microscope found in research and clinical laboratories and certainly in teaching laboratories. However, many microbes are unpigmented and are not clearly visible because there is little difference in contrast between the cells, subcellular structures, and water. As we discuss in section 2.3, one solution to this problem is to stain cells before observation to increase contrast and create variations in color between cell structures. Unfortunately, staining procedures usually kill cells. But what if an investigator must view living cells to observe a dynamic process such as movement or phagocytosis? Three types of light microscopes create detailed, clear images of living specimens: dark-field microscopes, phase-contrast microscopes, and differential interference contrast microscopes.

Dark-Field Microscope: Bright Object, Dark Background

The **dark-field microscope** produces detailed images of living, unstained cells and organisms by simply changing the way in

Figure 2.6 Dark-Field Microscopy. In dark-field microscopy, a dark-field stop (inset) is placed underneath the condenser lens system. The condenser then produces a hollow cone of light so that the only light entering the objective comes from the specimen.

which they are illuminated. A hollow cone of light is focused on the specimen in such a way that unreflected and unrefracted rays do not enter the objective. Only light that has been reflected or refracted by the specimen forms an image (**figure 2.6**). The field surrounding a specimen appears black, while the object itself is brightly illuminated (**figure 2.7**). The dark-field microscope can reveal considerable internal structure in larger eukaryotic microorganisms (**figure 2.7b**). It also is used to identify certain bacteria such as the thin and distinctively shaped *Treponema pallidum*, the causative agent of syphilis (**figure 2.7a**).

(a) *T. pallidum*

(b) *Volvox*

Figure 2.7 Examples of Dark-Field Microscopy. (a) *Treponema pallidum*, the spirochete that causes syphilis. (b) *Volvox*. Note daughter colonies within the mature *Volvox* colony.

Phase-Contrast Microscope

A **phase-contrast microscope** converts slight differences in refractive index and cell density into easily detected variations in light intensity (**figure 2.8**; see also *figure 2.21a*). The condenser of a phase-contrast microscope has an annular stop, an opaque disk with a thin transparent ring, that produces a hollow cone of light (**figure 2.9**). As this cone of light passes through a cell, some light rays are bent due to variations in density and refractive index

(a) An amoeba

(b) *Paramecium*

Figure 2.8 Examples of Phase-Contrast Microscopy.

(a) An amoeba, a eukaryotic microbe that moves by means of pseudopodia, which extend out from the main part of the cell body. (b) *Paramecium* sp. stained to show a large central macronucleus with a small spherical micronucleus at its side ($\times 100$).

within the specimen, and are retarded by about $1/4$ wavelength. The deviated light is focused to form an image of the object. Undeviated light rays strike a phase ring in the phase plate, an optical disk located in the objective, while the deviated rays miss the ring and pass through the rest of the plate. If the phase ring is constructed in such a way that the undeviated light passing through it is advanced by $1/4$ wavelength, the deviated and undeviated waves will be about $1/2$ wavelength out of phase and will cancel each

Figure 2.9 Phase-Contrast Microscopy. The optics of a dark-phase-contrast microscope.

MICRO INQUIRY What is the purpose of the annular stop in a phase-contrast microscope? Is it found in any other kinds of light microscopes?

other when they come together to form an image (figure 2.10). The background, formed by undeviated light, is bright, while the unstained object appears dark and well defined. This type of microscopy is called dark-phase-contrast microscopy. Color filters often are used to improve the image.

Phase-contrast microscopy is especially useful for studying microbial motility, determining the shape of living cells, and detecting bacterial structures such as endospores and inclusions. These are clearly visible because they have refractive indices markedly different from that of water. Phase-contrast microscopes also are widely used to study eukaryotic cells.

►► Bacterial endospores (section 3.9); Inclusions (section 3.6)

Differential Interference Contrast Microscope

The **differential interference contrast (DIC) microscope** is similar to the phase-contrast microscope in that it creates an image by detecting differences in refractive indices and thickness. Two beams of plane-polarized light at right angles to each other are generated by prisms. In one design, the object beam passes through the specimen, while the reference beam passes through a clear area of the slide. After passing through the specimen, the two beams are combined and interfere with each other to form an image. A live, unstained specimen appears brightly colored and seems to pop out from the background, giving the viewer the sense that a three-dimensional image is being viewed (figure 2.11). Structures such as cell walls, endospores, granules, vacuoles, and nuclei are clearly visible.

Figure 2.11 Differential Interference Contrast Microscopy. A micrograph of the protozoan *Amoeba proteus*. The image appears three-dimensional and contains considerable detail.

Figure 2.10 The Production of Contrast in Phase-Contrast Microscopy. The behavior of deviated and undeviated (i.e., undiffracted) light rays in the dark-phase-contrast microscope. Because the light rays tend to cancel each other out, the image of the specimen will be dark against a brighter background.

Retrieve, Infer, Apply

1. List the parts of a light microscope and describe their functions.
2. If a specimen is viewed using a $5\times$ objective in a microscope with a $15\times$ eyepiece, how many times has the image been magnified?
3. How does resolution depend on the wavelength of light, refractive index, and numerical aperture? How are resolution and magnification related?
4. What is the function of immersion oil?
5. Why don't most light microscopes use $30\times$ ocular lenses for greater magnification?

Fluorescence Microscopes: Using Emitted Light to Create Images

The light microscopes thus far considered produce an image from light that passes through a specimen. An object also can be seen because it emits light: this is the basis of fluorescence microscopy. When some molecules absorb radiant energy, they become excited and release much of their trapped energy as light. Any light emitted by an excited molecule has a longer wavelength (i.e., has lower energy) than the radiation originally absorbed. **Fluorescent light** is emitted very quickly by the excited molecule as it gives up its trapped energy and returns to a more stable state.

The **fluorescence microscope** excites a specimen with a specific wavelength of light and forms an image with the fluorescent light emitted by the object. The most commonly used fluorescence microscopy is epifluorescence microscopy, also called incident light or reflected light fluorescence microscopy. Epifluorescence microscopes employ an objective lens that also acts as a condenser so the specimen is illuminated from above rather than below (figure 2.12). A mercury vapor arc lamp or other source produces an intense beam of light that passes through an exciter filter. The exciter filter transmits only

Figure 2.12 Epifluorescence Microscopy. The principles of operation of an epifluorescence microscope.

the desired wavelength of light. The excitation light is directed down the microscope by the dichromatic mirror. This mirror reflects light of shorter wavelengths (i.e., the excitation light) but allows light of longer wavelengths to pass through. The excitation light continues down, passing through the objective lens to the specimen, which is usually stained with molecules called **fluorochromes** (table 2.3). The fluorochrome absorbs light energy from the excitation light and fluoresces brightly. The emitted fluorescent light travels up through the objective lens into the microscope. Because the emitted fluorescent light has a longer wavelength, it passes through the dichromatic mirror to a barrier filter, which blocks out any residual excitation light. Finally, the emitted light passes through the barrier filter to the eyepieces.

The fluorescence microscope has become an essential tool in microbiology. Bacterial pathogens can be identified after staining with fluorochromes or specifically tagging them with fluorescently labeled antibodies using immunofluorescence procedures. In ecological studies, fluorescence microscopy is used to observe microorganisms stained with fluorochrome-labeled probes or

fluorochromes that bind specific cell constituents (table 2.3). In addition, microbial ecologists use epifluorescence microscopy to visualize photosynthetic microbes, as their pigments naturally fluoresce when excited by light of specific wavelengths. It is even possible to distinguish live bacteria from dead bacteria by the color they fluoresce after treatment with a specific mixture of stains (figure 2.13a). Thus the microorganisms can be viewed and directly counted in a relatively undisturbed ecological niche.

▶▶ *Assessing microbial diversity* (section 29.2); *Identification of microorganisms from specimens* (section 36.2)

Another important use of fluorescence microscopy is the localization of specific proteins within cells. One approach is to use genetic engineering techniques that fuse the gene for the

Figure 2.13 Fluorescent Dyes and Tags. (a) Dyes that cause live cells to fluoresce green and dead ones red. (b) Fluorescent antibodies tag specific molecules. In this case, the antibody binds to a molecule that is unique to *Streptococcus pyogenes*, the bacterium that causes strep throat.

MICRO INQUIRY How might the fluorescently labeled antibody used in figure 2.13b be used to diagnose strep throat?

Table 2.3 Commonly Used Fluorochromes

| Fluorochrome | Uses |
|---|--|
| Acridine orange | Stains DNA |
| Diamidino-2-phenyl indole (DAPI) | Stains DNA |
| Fluorescein isothiocyanate (FITC) | Often attached to DNA probes or to antibodies that bind specific cellular components |
| Tetramethyl rhodamine isothiocyanate (TRITC or rhodamine) | Often attached to antibodies that bind specific cellular components |

protein of interest to a gene isolated from jellyfish belonging to the genus *Aequorea*. This jellyfish gene encodes a protein that naturally fluoresces green when exposed to light of a particular wavelength and is called green fluorescent protein (GFP). Thus when the protein is made by the cell, it is fluorescent. GFP has been used extensively in studies on bacterial cell division and related phenomena (figure 2.14). In fact, the 2008 Nobel Prize in Chemistry was awarded to Osamu Shimomura of Japan and Americans Martin Chalfie and Roger Tsien for their development of this important tool. ►► *Fluorescence labeling* (section 17.6)

Confocal Microscopy

Like the large and small beads illustrated in figure 2.15a, biological specimens are three-dimensional. When three-dimensional objects are viewed with traditional light microscopes, light from all areas of

the object, not just the plane of focus, enters the microscope and is used to create an image. The resulting image is murky and fuzzy (figure 2.15b). This problem has been solved by the confocal scanning laser microscope (CSLM), or simply, **confocal microscope**.

Figure 2.14 Green Fluorescent Protein. Visualization of Mbl, a cytoskeletal protein of *Bacillus subtilis*. The Mbl protein has been fused with green fluorescent protein and therefore fluoresces green.

(a) All three-dimensional objects are defined by three axes: x, y, and z. The confocal scanning laser microscope (CSLM) is able to create images of planes formed by the x and y axes (x-y planes) and planes formed by the x and z axes (x-z planes).

(b) The light microscope image of the two beads shown in (a). Note that neither bead is clear and that the smaller bead is difficult to recognize as a bead. This is because the image is generated from light emanating from multiple planes of focus.

(c) A CSLM uses light from a single plane of focus to generate an image. A computer connected to a CSLM can make a composite image of the two beads using digitized information collected from multiple planes within the beads. The result is a much clearer and more detailed image.

(d) The computer can also use digitized information collected from multiple planes within the beads to generate a three-dimensional reconstruction of the beads.

(e) The computer can also generate views of the specimen using different planes. The top left panel is the image of a single x-y plane (i.e., looking down from the top of the beads). The two lines represent the two x-z planes imaged in the other two panels. The vertical line indicates the x-z plane shown in the top right panel (i.e., a view from the right side of the beads) and the horizontal line indicates the x-z plane shown in the bottom panel (i.e., a view from the front face of the beads).

(f) A three-dimensional reconstruction of a *Pseudomonas aeruginosa* biofilm. The biofilm was exposed to an antibacterial agent and then stained with dyes that distinguish living (green) from dead (red) cells. The cells on the surface of the biofilm have been killed, but those in the lower layers are still alive. This image clearly demonstrates the difficulty of killing all the cells in a biofilm.

Figure 2.15 Light and Confocal Microscopy. (a–e) Two beads examined by light and confocal microscopy. (f) Three-dimensional reconstruction of a biofilm.

Figure 2.16 A Ray Diagram of a Confocal Microscope. The yellow lines represent laser light used for illumination. Red lines symbolize the light arising from the plane of focus, and the blue lines stand for light from parts of the specimen above and below the focal plane.

MICRO INQUIRY How does the light source differ between a confocal light microscope and other light microscopes?

The confocal microscope uses a laser beam to illuminate a specimen, usually one that has been fluorescently stained. A major component of the confocal microscope is an aperture placed above the objective lens. The aperture eliminates stray light from parts of the specimen that lie above and below the plane of focus (figure 2.16). Thus the only light used to create the image is from the plane of focus, and a much sharper image is formed.

Computers are integral to the process of creating confocal images. A computer interfaced with the confocal microscope receives digitized information from each plane in the specimen that is examined. This information can be used to create a composite image that is very clear and detailed (figure 2.15c) or to create a three-dimensional reconstruction of the specimen (figure 2.15d). Images of x-z plane cross sections of the specimen can also be generated, giving the observer views of the specimen from three perspectives (figure 2.15e). Confocal microscopy has numerous applications. One is the study of biofilms, which can form on many different types of surfaces, including indwelling medical devices such as hip joint replacements. As shown in figure 2.15f, it is difficult to kill all cells in a biofilm. This makes biofilms a particular concern to the medical field because their formation on medical devices can result in infections that are difficult to treat. ►► *Biofilms* (section 7.4)

Retrieve, Infer, Apply

1. Briefly describe how dark-field, phase-contrast, differential interference contrast, epifluorescence, and confocal microscopes work and the kind of image or images provided by each. Give a specific use for each type.
2. GFP is used much like a fluorochrome is used. However, the two are not the same. Explain why this is so.
3. Do all specimens examined by fluorescence microscopy need to be stained with a fluorochrome? Explain.

2.3 Preparation and Staining of Specimens

After reading this section, you should be able to:

- Recommend a fixation process to use when the microbe is a bacterium or archaeon and when the microbe is a protist
- Plan a series of appropriate staining procedures to describe an unknown bacterium as fully as possible
- Compare what happens to Gram-positive and Gram-negative bacterial cells at each step of the Gram-staining procedure

As noted in section 2.2, specimens examined by bright-field microscopy are often fixed and stained before being examined. Such preparation serves to increase the visibility of the microorganisms, accentuate specific morphological features, and preserve them for future study. Importantly, some staining procedures help microbiologists identify the organism being examined.

Fixation

Stained cells seen in a microscope should resemble living cells as closely as possible. **Fixation** is the process by which the internal and external structures of specimens are preserved and fixed in position. It inactivates enzymes that might disrupt cell morphology and toughens cell structures so that they do not change during staining and observation. A microorganism usually is killed and attached firmly to the microscope slide during fixation.

There are two fundamentally different types of fixation. **Heat fixation** is routinely used to observe bacteria and archaea. Typically, a film of cells (a smear) is gently heated. Heat fixation preserves overall morphology and inactivates enzymes. However, it also destroys proteins that may be part of subcellular structures, which may distort their appearance. **Chemical fixation** is used to protect fine cellular substructure as well as morphology. It is often used when examining larger, more delicate microorganisms such as protists. Chemical fixatives penetrate cells and react with cellular components, usually proteins and lipids, to render them inactive, insoluble, and immobile. Common fixative mixtures contain ethanol, acetic acid, mercuric chloride, formaldehyde, and glutaraldehyde.

Dyes and Simple Staining

The many types of dyes used to stain microorganisms have two features in common: they have **chromophore groups**—chemical moieties with conjugated double bonds that give the dye its color, and they can bind cells with ionic, covalent, or hydrophobic bonds.

Dyes that bind cells by ionic interactions are probably the most commonly used dyes. These ionizable dyes may be divided into two general classes based on the nature of their charged group: basic dyes and acidic dyes (**table 2.4**). The staining effectiveness of ionizable dyes may be altered by pH, since the nature and number of the charged moieties on cell components change with pH. Thus acidic dyes stain best under acidic conditions when proteins and many other molecules

(a) Crystal violet stain of *Escherichia coli*

(b) Methylene blue stain of *Corynebacterium*

Figure 2.17 Simple Stains.

carry a positive charge; basic dyes are most effective at higher pH values.

Dyes that bind through covalent bonds or that have certain solubility characteristics are also useful. For instance, DNA can be stained by the Feulgen procedure in which the staining compound (Schiff's reagent) is covalently attached to the deoxyribose sugars of DNA. Sudan III (Sudan Black) selectively stains lipids because it is lipid soluble but does not dissolve in aqueous portions of the cell.

Microorganisms can be stained by **simple staining**, in which a single dye is used (**figure 2.17**). Simple staining's value lies in its simplicity and ease of use. The fixed smear is covered with stain for a short period, excess stain is washed off with water, and the slide is blotted dry. Basic dyes such as crystal violet, methylene blue, and carbolfuchsin are frequently used in simple staining to determine the size, shape, and arrangement of bacterial and archaeal cells.

While most dyes directly stain the cell or object of interest, some dyes (e.g., India ink and nigrosin) are used in **negative staining**. Here the background but not the cell is stained; the unstained cells appear as bright objects against a dark background.

Differential Staining

The **Gram stain**, developed in 1884 by the Danish physician Christian Gram, is the most widely employed staining method in bacteriology. It is routinely used in clinical laboratories and is an important first step in laboratory diagnosis of infectious

Table 2.4 Ionizable Dyes

| Type of Dye | Examples | Characteristics |
|--------------------|---|---|
| Basic dyes | Methylene blue, basic fuchsin, crystal violet, safranin, malachite green | Have positively charged groups; bind to negatively charged molecules such as nucleic acids, many proteins, and the surfaces of bacterial and archaeal cells |
| Acidic dyes | Eosin, rose bengal, and acid fuchsin—possess groups such as carboxyls ($-\text{COOH}$) and phenolic hydroxyls ($-\text{OH}$). | In their ionized form, have a negative charge and bind to positively charged cell structures |

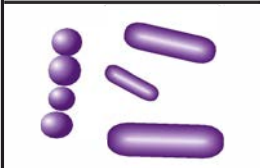

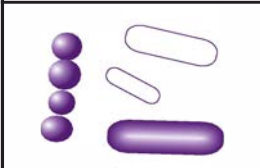

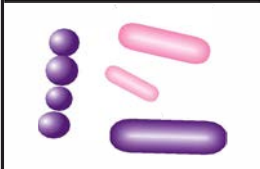

| Steps in Staining | State of Bacteria |
|---|---|
|  | Cells stain purple. |
|  | Cells remain purple. |
|  | Gram-positive cells remain purple. Gram-negative cells become colorless. |
|  | Gram-positive cells remain purple. Gram-negative cells appear red. |

Figure 2.18 Gram Stain. Steps in the Gram-staining procedure.

MICRO INQUIRY Why is the decolorization step considered the most critical in the Gram-staining procedure?

disease, as we described in the chapter case study. The Gram stain is an example of **differential staining**—procedures that distinguish organisms based on their staining properties. Use of the Gram stain divides most bacteria (but not archaea) into two groups—those that stain Gram negative and those that stain Gram positive.

The Gram-staining procedure is illustrated in **figure 2.18**. In the first step, the smear is stained with a primary stain (crystal violet). This is followed by treatment with an iodine solution. Iodine functions as a **mordant**, a substance that helps bind the dye to a target molecule. Iodine increases the interaction between the cell and the dye so that the cell is stained more strongly. The smear is then decolorized by washing with alcohol or acetone. This step generates the differential aspect of the Gram stain; Gram-positive bacteria retain the crystal violet, whereas Gram-negative bacteria lose the crystal violet and become colorless. Finally, the smear is counterstained, usually with safranin, which colors Gram-negative bacteria pink to red and leaves Gram-positive bacteria dark purple (**figure 2.19a**). ►► *Bacterial cell walls* (section 3.4)

Acid-fast staining is another important differential staining procedure. It can be used to identify *Mycobacterium tuberculosis* and *M. leprae* (**figure 2.19b**), the pathogens responsible

for tuberculosis and leprosy, respectively. These bacteria have cell walls containing lipids constructed from mycolic acids, a group of branched-chain hydroxy fatty acids, which prevent dyes from readily binding to the cells (*see figure 24.11*). However, *M. tuberculosis* and *M. leprae* can be stained by the Ziehl-Neelsen method, which uses heat and phenol to drive basic fuchsin into cells. Once basic fuchsin has penetrated, *M. tuberculosis* and *M. leprae* are not easily decolorized by acidified alcohol (acid-alcohol) and thus are said to be acid-fast. Non-acid-fast bacteria are decolorized by acid-alcohol and thus are stained blue by methylene blue counterstain.

Many differential staining procedures are based on detecting the presence of specific structures. **Endospore staining**, like acid-fast staining, requires heat to drive dye into a target, in this case an endospore. An endospore is an exceptionally resistant structure produced by members of some Gram-positive bacterial genera (e.g., *Bacillus* and *Clostridium*). It can survive for long periods in an unfavorable environment and is called an endospore because it develops within the parent (mother) bacterial cell. Endospore morphology and location vary with species and often are valuable in identification. Endospores are not stained well by most dyes, but once stained, they strongly resist decolorization. This property is the basis of most endospore staining methods (**figure 2.19c**). In the Schaeffer-Fulton procedure (not shown), endospores are first stained with malachite green in the presence of heat. After malachite green treatment, the mother cell is washed free of dye with water and is counterstained with safranin. This technique stains endospores bluish-green and the vegetative cells pink to red. ►► *Bacterial endospores* (section 3.9); *Class Clostridia* (section 23.1); and *Class Bacilli* (section 23.2)

One of the simplest staining procedures is **capsule staining** (**figure 2.19d**), a technique that reveals the presence of capsules, a network usually made of polysaccharides that surrounds many bacteria and some fungi. Cells are mixed with India ink or nigrosin dye and spread out in a thin film on a slide. After air-drying, the cells appear as lighter bodies in the midst of a blue-black background because ink and dye particles cannot penetrate either the cell or its capsule. Thus capsule staining is an example of negative staining. The extent of the light region is determined by the size of the capsule and of the cell itself. There is little distortion of cell shape, and the cell can be counterstained for even greater visibility. ►► *Capsules and slime layers* (section 3.5)

Flagella staining provides taxonomically valuable information about the presence and distribution pattern of flagella on bacterial and archaeal cells (**figure 2.19e**; *see also figure 3.43*). Their flagella are fine, threadlike organelles of locomotion that are so slender (about 10 to 30 nm in diameter), they can only be seen directly using an electron microscope (although bundles of flagella can be visualized by dark-field microscopy). To observe bacterial flagella with a light microscope, their thickness is increased by coating them with mordants such as tannic acid and potassium alum and then staining with pararosaniline (Leifson method) or basic fuchsin (Gray method). ►► *Bacterial flagella* (section 3.7)

Retrieve, Infer, Apply

1. Describe the two general types of fixation. Which would you use when Gram staining a bacterium? Which would you use before observing the organelles of a protist?
2. Why would basic dyes be more effective under alkaline conditions?
3. Explain what happens to Gram-positive and Gram-negative bacterial cells at each step of the Gram-staining procedure.
4. What other differential staining procedures can be useful in identifying a bacterium? What information do they provide?

2.4 Electron Microscopy

After reading this section, you should be able to:

- Create a concept map, illustration, or table that compares transmission electron microscopes (TEMs) to light microscopes
- Decide when it would be best to examine a microbe by TEM, scanning electron microscopy (SEM), and electron cryotomography

For centuries the light microscope has been the most important instrument for studying microorganisms. However, even the best light microscopes have a resolution limit of about $0.2\ \mu\text{m}$, which greatly compromises their usefulness for detailed studies of many microorganisms (figure 2.20). Viruses, for example, are too small to be seen with light microscopes. Bacteria and archaea can be observed, but because they are usually only 1 to $2\ \mu\text{m}$ in diameter, only their general shape and major morphological features are visible. The detailed internal structure of larger microorganisms also cannot be effectively studied by light microscopy. These limitations arise from the nature of visible light waves, not from any inadequacy of the light microscope itself. Electron microscopes have much greater resolution. Their use has transformed microbiology and added immeasurably to our knowledge. Here we briefly review the nature of the electron microscope and the ways in which specimens are prepared for observation.

Transmission Electron Microscope

Recall that the resolution of a light microscope increases with a decrease in the wavelength of the light it uses for illumination. In electron microscopes, electrons replace light as the illuminating beam. The electron beam can be focused, much as light is in a light microscope, but its wavelength is about 100,000 times shorter than that of visible light. Therefore electron microscopes have a practical resolution roughly 1,000 times better than the light microscope; with many electron microscopes, points closer than $0.5\ \text{nm}$ can be distinguished, and the useful magnification is well over $100,000\times$ (figure 2.20). The value of the electron microscope is evident on comparison of the photographs in figure 2.21: microbial morphology can now be studied in great detail.

A modern **transmission electron microscope (TEM)** is complex, but the basic principles behind its operation can be readily understood (figure 2.22). A heated tungsten filament in the electron gun generates a beam of electrons that is focused on the specimen by the condenser (figure 2.23). Since electrons cannot pass through a glass lens, doughnut-shaped electromagnets called magnetic lenses are used to focus the beam. The column containing the lenses and specimen must be under high vacuum to obtain a clear image because electrons are deflected by collisions with air molecules. The specimen scatters some electrons, but those that pass through are used to form an enlarged image of the specimen on a fluorescent screen. A denser region in the specimen scatters more electrons and therefore appears darker in the image since fewer electrons strike that area of the screen; these regions are said to be “electron dense.” In contrast,

Figure 2.20 The Limits of Microscopic Resolution.

Dimensions are indicated with a logarithmic scale (each major division represents a tenfold change in size). To the right side of the scale are the approximate sizes of cells, viruses, molecules, and atoms.

Figure 2.23 A Comparison of Light and Transmission Electron Microscopes.

electron-transparent regions are brighter. The image can be captured as a photograph for a permanent record.

Table 2.5 compares some of the important features of light and transmission electron microscopes. The TEM has distinctive features that place harsh restrictions on the nature of samples that can be viewed and the means by which those samples must be prepared. Specimens must be viewed in a vacuum because electrons are deflected by air molecules. Only extremely thin slices (20 to 100 nm) of a specimen can be viewed because electron beams are easily absorbed and scattered by solid matter. To cut such a thin slice, the specimen must be embedded in a supportive matrix; the necessary support is provided by plastic. After fixation with chemicals such as glutaraldehyde and osmium tetroxide to stabilize cell structure, the specimen is dehydrated with organic solvents (e.g., acetone or ethanol). Complete dehydration is

essential because most plastics used for embedding are not water soluble. Next the specimen is soaked in unpolymerized, liquid epoxy plastic until it is completely permeated, and then the plastic is hardened to form a solid block. Thin sections are cut from the block with a glass or diamond knife using a device called an ultramicrotome.

As with bright-field light microscopy, cells usually must be stained before they can be seen clearly with a TEM. The probability of electron scattering is determined by the density (atomic number) of atoms in the specimen. Biological molecules are composed primarily of atoms with low atomic numbers (H, C, N, and O), and electron scattering is fairly constant throughout an unstained cell or virus. Therefore specimens are prepared for observation by soaking thin sections with solutions of heavy metal salts such as lead citrate and uranyl acetate. The lead and uranium ions bind to structures in the specimen and make them more electron opaque, thus increasing contrast in the material. Heavy osmium atoms from the osmium tetroxide fixative also stain specimens and increase their contrast. The stained thin sections are then mounted on tiny copper grids and viewed.

Two other important techniques for preparing specimens are negative staining and shadowing. In negative staining, the specimen is spread out in a thin film with either phosphotungstic acid or uranyl acetate. Just as in negative staining for light microscopy, heavy metals do not penetrate the specimen but render the background dark, whereas the specimen appears bright in photographs. Negative staining is an excellent way to study the structure of virus particles, bacterial gas vacuoles, and other similar objects (**figure 2.24a**). In shadowing, a specimen is coated with a thin film of platinum or other heavy metal by evaporation at an angle of about 45° from horizontal so that the metal strikes the microorganism on only one side. In one commonly used imaging method, the area coated with metal appears dark in photographs, whereas the uncoated side and the shadow region created by the object are light (**figure 2.24b**). This technique is particularly useful in studying virus particle morphology, bacterial and archaeal flagella, and DNA.

The shapes of organelles within cells can be observed by TEM if specimens are prepared by the freeze-etching procedure. When cells are rapidly frozen in liquid nitrogen, they become very brittle and can be broken along lines of greatest weakness, usually down the middle of internal membranes (**figure 2.25**). The exposed surfaces are then shadowed and coated with layers of platinum and carbon to form a replica of the surface. After the specimen has been removed chemically,

Table 2.5 Characteristics of Light and Transmission Electron Microscopes

| Feature | Light Microscope | Transmission Electron Microscope |
|----------------------------------|---------------------------------------|-------------------------------------|
| Highest practical magnification | About 1,000–1,500 | Over 100,000 |
| Best resolution ¹ | 0.2 μm | 0.5 nm |
| Radiation source | Visible light | Electron beam |
| Medium of travel | Air | High vacuum |
| Type of lens | Glass | Electromagnet |
| Source of contrast | Differential light absorption | Scattering of electrons |
| Focusing mechanism | Adjust lens position mechanically | Adjust current to the magnetic lens |
| Method of changing magnification | Switch the objective lens or eyepiece | Adjust current to the magnetic lens |
| Specimen mount | Glass slide | Metal grid (usually copper) |

¹ The resolution limit of a human eye is about 0.2 mm.

MICRO INQUIRY Why are all electron micrographs black and white (although they are sometimes artificially colorized after printing)?

this replica is studied in the TEM, providing a detailed view of intracellular structure. An advantage of freeze-etching is that it minimizes the danger of artifacts because the cells are frozen quickly, rather than being subjected to chemical fixation, dehydration, and embedding in plastic.

Figure 2.25 Example of Freeze-Etching. A freeze-etched preparation of the bacterium *Thiobacillus kabobis*. Note the differences in structure between the outer surface, S; the outer membrane of the cell wall, OM; the plasma membrane, PM; and the cytoplasm, C.

Scanning Electron Microscope

Transmission electron microscopes form an image from radiation that has passed through a specimen. The **scanning electron microscope (SEM)** produces an image from electrons released from atoms on an object's surface. The SEM has been used to examine the surfaces of microorganisms in great detail; many SEMs have a resolution of 7 nm or less.

Specimen preparation for SEM is relatively easy, and in some cases, air-dried material can be examined directly. However, microorganisms usually must first be fixed, dehydrated, and dried to preserve surface structure and prevent collapse of the cells when they are exposed to the SEM's high vacuum. Before viewing, dried samples are mounted and coated with a thin layer of metal to prevent the buildup of an electrical charge on the surface and to give a better image.

To create an image, the SEM scans a narrow, tapered electron beam back and forth over the specimen (**figure 2.26**). When the beam strikes a particular area, surface atoms discharge a tiny shower of electrons called secondary electrons, and these are trapped by a detector. Secondary electrons entering the detector strike a scintillator, causing it to emit light flashes that a photomultiplier converts to an electrical current and amplifies. The signal is sent to a cathode-ray tube and produces an image that can be viewed or photographed.

Figure 2.26 The Scanning Electron Microscope.

The number of secondary electrons reaching the detector depends on the nature of the specimen's surface. When the electron beam strikes a raised area, a large number of secondary electrons enter the detector; in contrast, fewer electrons escape a depression in the surface and reach the detector. Thus raised areas appear lighter on the screen and depressions are darker. A realistic three-dimensional image of the microorganism's surface results (**figure 2.27**). The actual in situ location of microorganisms in ecological niches such as the human skin and the lining of the gut also can be examined.

Electron Cryotomography

Beginning approximately 40 years ago, a series of advances in electron microscopy paved the way for the development of **electron cryotomography**, a technique that since the 1990s has been providing exciting insights into the structure and function of cells and viruses. *Cryo-* refers to sample preparation and visualization. Samples are prepared by rapidly plunging the specimen into an extremely cold liquid (e.g., ethane); the sample is kept frozen while being examined. Rapid freezing of the sample results in the formation of vitreous ice rather than ice crystals. Vitreous ice is a glasslike solid that preserves the native state of structures and immobilizes the specimen so that it can be viewed in the high vacuum of the electron microscope. Tomography refers to the method used to create images. The object is viewed from many directions, referred to as a tilt series. The individual images are recorded and processed by computer programs, and finally merged to form a three-dimensional reconstruction of the object. Three-dimensional views, slices, and other types of representations of the object can be derived from the reconstruction (**figure 2.28**). The ultrastructure of bacterial and archaeal cells has been the focus of numerous studies using electron cryotomography. Some of these studies have revealed new cytoskeletal elements, such as those associated with magnetosomes, the inclusions used by some bacteria to orient themselves in magnetic fields (see **figure 3.39**).

Retrieve, Infer, Apply

1. Why does the transmission electron microscope have much greater resolution than the light microscope?
2. Describe in general terms how the TEM functions. Why must the TEM use high vacuum and very thin sections?
3. Under what circumstances would it be desirable to prepare specimens for the TEM by negative staining? Shadowing? Freeze-etching?
4. How does the scanning electron microscope operate, and in what way does its function differ from that of the TEM? The SEM is used to study which aspects of morphology?

2.5 Scanning Probe Microscopy

After reading this section, you should be able to:

- Distinguish scanning tunneling from atomic force microscopes in terms of how they create images and their uses
- Evaluate light microscopy, electron microscopy, and scanning probe microscopy in terms of their uses, resolution, and the quality of the images created

Among the most powerful microscopes are **scanning probe microscopes**. These microscopes measure surface features of an object by moving a sharp probe over the object's surface. The **scanning tunneling microscope** was invented in 1980. It can achieve magnifications of 100 million times, and it allows scientists to

view atoms on the surface of a solid. The scanning tunneling microscope has a needlelike probe with a point so sharp that often there is only one atom at its tip. The probe is lowered toward the specimen surface until its electron cloud just touches that of the surface atoms. If a small voltage is applied between the tip and specimen, electrons flow through a narrow channel in the electron clouds. This tunneling current, as it is called, is extraordinarily sensitive to distance and will decrease about a thousandfold if the probe is moved away from the surface by a distance equivalent to the diameter of an atom.

The arrangement of atoms on the specimen surface is determined by moving the probe tip back and forth over the surface while keeping the probe at a constant height above the specimen. As the tip moves up and down while following the surface contours, its motion is recorded and analyzed by a computer to create an accurate three-dimensional image of the surface atoms. The surface map can be displayed on a computer screen or plotted on paper. The resolution is so great that individual atoms are observed easily. Even more exciting is that the microscope can examine objects when they are immersed in water. Therefore it can be used to study biological molecules such as DNA (figure 2.29). The microscope's inventors, Gerd Binnig and Heinrich Rohrer, shared the 1986 Nobel Prize in Physics for their work, together with Ernst Ruska, the designer of the first transmission electron microscope.

More recently, a second type of scanning probe microscope has been developed. The **atomic force microscope** moves a sharp probe over the specimen surface while keeping the distance between the probe tip and the surface constant. It does this by exerting a very small amount of force on the tip, just enough to maintain a constant distance but not enough force to damage the surface. The vertical motion of the tip usually is followed by measuring the deflection of a laser beam that strikes the lever holding

Figure 2.29 Scanning Tunneling Microscopy of DNA. The DNA double helix with approximately three turns shown (false color; $\times 2,000,000$).

MICRO INQUIRY Compare the magnification of this image with that shown in figures 2.24 (TEM) and 2.27 (SEM). Which has the highest magnification and which has the lowest?

Figure 2.30 The Basic Elements of an Atomic Force Microscope.

The tip used to probe the specimen is attached to a cantilever. As the probe passes over the “hills and valleys” of the specimen’s surface, the cantilever is deflected vertically. A laser beam directed at the cantilever is used to monitor these vertical movements. Light reflected from the cantilever is detected by the photodiode and used to generate an image of the specimen.

the probe (**figure 2.30**). Unlike the scanning tunneling microscope, the atomic force microscope can be used to study surfaces that do not conduct electricity well. The atomic force microscope has been used to study the interactions of proteins, to follow the behavior of living bacteria and other cells, and to visualize membrane proteins such as aquaporins (**figure 2.31**).

Figure 2.31 The Membrane Protein Aquaporin Visualized by Atomic Force Microscopy.

Aquaporin is a membrane-spanning protein that allows water to move across the membrane. (a) Each circular structure represents the surface view of a single aquaporin protein. (b) A single aquaporin molecule observed in more detail and at higher magnification.

Retrieve, Infer, Apply

1. Briefly describe each of the most popular versions of the scanning probe microscope. What are these microscopes used for?
2. Scanning probe microscopy can be applied to samples that have not been dehydrated, while electron microscopy cannot. Why is this an important advantage?

Key Concepts

2.1 Lenses and the Bending of Light

- A light ray moving from air to glass or vice versa is bent in a process known as refraction.
- Lenses focus light rays at a focal point and magnify images (**figure 2.2**).

2.2 Light Microscopes

- In a compound microscope such as the bright-field microscope, the primary image is an enlarged image formed by the objective lens. The primary image is further enlarged by the ocular lens to yield the final image (**figure 2.3**).
- Microscope resolution increases as the wavelength of radiation used to illuminate the specimen decreases. The maximum resolution of a light microscope is about 0.2 μm .
- The dark-field microscope uses only refracted light to form an image, and objects glow against a black background (**figure 2.6**).
- The phase-contrast microscope converts variations in the refractive index and density of cells into changes in light intensity and thus makes colorless, unstained cells visible (**figure 2.9**).

- The differential interference contrast microscope uses two beams of light to create high-contrast images of live specimens.
- The fluorescence microscope illuminates a fluorochrome-labeled specimen and forms an image from its fluorescence (**figure 2.12**).
- The confocal microscope is used to study thick, complex specimens. It creates an image by using only the light emanating from the plane of focus, while blocking out light from above and below the plane of focus (**figures 2.15 and 2.16**).

2.3 Preparation and Staining of Specimens

- Specimens are often fixed and stained before viewing them in the bright-field microscope.
- Most dyes are either positively charged basic dyes or negatively charged acidic dyes that bind to ionized parts of cells.
- In simple staining, a single dye is used to stain microorganisms (**figure 2.17**).
- Differential staining procedures such as Gram and acid-fast staining distinguish between microbial groups by

staining them differently (figures 2.18 and 2.19a,b). Other differential staining techniques are specific for particular structures such as endospores, bacterial capsules, and flagella (figure 2.19c–e).

2.4 Electron Microscopy

- The transmission electron microscope (TEM) uses magnetic lenses to form an image from electrons that have passed through a very thin section of a specimen (figure 2.23). Resolution is high because the wavelength of a beam of electrons is very short.
- Specimens for TEM are usually prepared by methods that increase contrast. Specimens can be stained by treatment with solutions of heavy metals such as osmium tetroxide, uranium, and lead. They can also be prepared for TEM by negative staining, shadowing with metal, or freeze-etching (figures 2.24 and 2.25).

- The scanning electron microscope is used to study external surface features of microorganisms (figure 2.26).
- Electron cryotomography freezes specimens rapidly, keeps them frozen while being examined, and creates images from a series of directions that are combined and processed to form a three-dimensional reconstruction of the object (figure 2.28).

2.5 Scanning Probe Microscopy

- Scanning probe microscopes reach very high magnifications that allow scientists to observe biological molecules (figures 2.29 and 2.31).
- Scanning tunneling microscopy enables the visualization of molecular surfaces using electron interaction between the probe and the specimen, whereas atomic force microscopy can scan the surface of molecules that do not conduct electricity well (figure 2.30).

Compare, Hypothesize, Invent

1. If you prepared a sample of a specimen for light microscopy, stained it with the Gram stain, and failed to see anything when you looked through your light microscope, list the things that you may have done incorrectly.
2. In a journal article, find an example of a light micrograph, a scanning or transmission electron micrograph, or a confocal image. Discuss why the figure was included in the article and why that particular type of microscopy was the method of choice for the research. What other figures would you like to see used in this study? Outline the steps that the investigators would take to obtain such photographs or figures.
3. How are freeze etching and electron cryotomography similar? How do they differ? What is the advantage of electron cryotomography?
4. STED microscopes were first developed about 10 years ago. They are modifications of confocal microscopes that use two highly focused beams of light rather than one as in

typical confocal microscopy. The first beam uses a wavelength that excites the fluorophore with which a specimen is labeled. This creates a fluorescent spot where the fluorophore is located. The second beam is a hollow cone. It strikes the outermost edges of the fluorescent spot illuminated by the first beam. The wavelength used by the second beam returns the fluorophore to its ground state, thus only the center of the fluorescent spot is visible. The result is that the resolution of STED microscopes is greater and objects smaller than 200 nm can be resolved. In 2010 a STED microscope was used to observe the mechanism by which human immunodeficiency virus (HIV) particles are transferred from dendritic cells to T cells. These are important immune system cells and play critical roles in the development of HIV infection. Why was STED microscopy used rather than TEM or electron cryotomography?

Bacterial Cell Structure

Ulcer-Causing Bacterium “Smells” Its Way to Safety

H*elicobacter pylori*, the ulcer-causing bacterium, is thought to infect nearly 50% of the world’s population. Many infected individuals are asymptomatic, but some develop either duodenal or gastric ulcers. *H. pylori* is one of the few bacteria that can survive in the extreme acidity of the human stomach. But surprisingly, it is not acid-loving. An important question then is, how does it survive in its hostile environment? *H. pylori* uses two tactics. One is to produce the enzyme urease, which hydrolyzes urea, producing ammonia. The ammonia neutralizes the acid in the cell’s local environment. Another tactic is to seek out and find regions in the stomach lining called gastric crypts. The bacterium moves deep into the crypts and is bathed in mucus with a less acidic pH. However, once it finds this safe haven, it must maintain it in the face of constant turnover of gastric mucus. *H. pylori* finds and stays in a safe place by “testing the waters,” responding to a pH gradient by moving away from regions that are too acidic. As a result, it is nearly always on the move as it fights to stay away from stomach acid.

Clearly, even small, seemingly simple organisms such as bacteria can exhibit complex behaviors. To understand these amazing microbes, we must first examine their cell structure and begin to relate it to the functions they carry out. As we consider bacterial cell structure, it is important to remember that only about 1% of bacterial species have been cultured. Of the cultivated species, only a few have been studied in great detail. From this small sample, many generalizations are made, and it is presumed that most other bacteria are like the well-studied model organisms. However, part of the wonder and fun of science is that nature is full of surprises. As the biology of more and more bacteria is analyzed, our understanding of them may change in interesting and exciting ways.

An endoscopic image of the duodenum and a duodenal ulcer. Duodenal ulcers are lesions in the wall of the duodenum. In this image, the duodenal ulcer appears as a depression with a dark center and is indicated by an arrow. Helicobacter pylori is estimated to be responsible for 90% of all duodenal ulcers.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Describe the application of small subunit (SSU) rRNA analysis to the establishment of the three domain classification system proposed by Carl Woese (section 1.2)
- ✓ Identify the following structures or regions of a plant or animal cell and describe their functions: cell wall, plasma membrane, cytoplasm, mitochondria, chloroplasts, and ribosomes
- ✓ Define and give examples of essential nutrients; describe how they are used by cells

3.1 The “Prokaryote” Controversy

After reading this section, you should be able to:

- List the characteristics originally used to describe prokaryotic cells
- Form an opinion on the “prokaryote” controversy using current evidence about bacterial cells

Bacteria and archaea have long been lumped together and referred to as prokaryotes. Although the term was first introduced early in the twentieth century, the concept of a prokaryote was not fully outlined until 1962, when R. Stanier and C. B. van Niel described prokaryotes in terms of what they lacked in comparison to eukaryotic cells. For instance, Stanier and van Niel pointed out that prokaryotes lack a membrane-bound nucleus, a cytoskeleton, membrane-bound organelles, and internal membranous structures such as the endoplasmic reticulum and Golgi apparatus.

Since the 1960s, biochemical, genetic, and genomic analyses, coupled with improved methods for imaging bacterial and archaeal cells, have shown that *Bacteria* and *Archaea* are

distinct taxa. Because of this and other discoveries, some microbiologists question our traditional ways of thinking about prokaryotes. For instance, some members of the bacterial phylum *Planctomycetes* have their genetic material enclosed in a membrane; other members of this interesting taxon have a membrane-bound organelle called the anammoxosome. This organelle is the site of anoxic ammonia oxidation, an unusual metabolic process that is important in the nitrogen cycle. Other discoveries include the finding that cytoskeletal elements are widespread in members of both domains and that some bacteria have extensive intracytoplasmic membranes. Because of these discoveries, some microbiologists think the term prokaryote should be abandoned. ►► *Phylum Planctomycetes* (section 21.5); *Nitrogen cycle* (section 28.1)

The current controversy creates a dilemma for both the textbook author and the student of microbiology—to use or not to use the term prokaryote. However, it also illustrates that microbiology is an exciting, dynamic, and rapidly changing field of study. All of us are waiting to see the outcome of this debate. Until then, we will try to limit our use of the term prokaryote and to be as explicit as possible about which characteristics are associated with members of *Bacteria*, which with members of *Archaea*, and which with members of both taxa.

3.2 A Typical Bacterial Cell

After reading this section, you should be able to:

- Distinguish a typical bacterial cell from a typical plant or animal cell in terms of cell shapes and arrangements, size, and cell structures
- Discuss the factors that determine the size and shape of a bacterial cell

Much of this chapter is devoted to a discussion of individual cell components. Therefore a preliminary overview of the features common to many bacterial cells is in order. We begin by considering overall cell morphology and then move to cell structures.

Shape, Arrangement, and Size

It might be expected that bacterial cells, being small and relatively simple, would be uniform in shape and size. This is not the case, as the microbial world offers considerable variety in terms of morphology. However, the two most common shapes are cocci and rods (figure 3.1). **Cocci** (s., **coccus**) are roughly spherical cells. They can exist singly or can be associated in characteristic arrangements that can be useful in their identification. **Diplococci** (s., **diplococcus**) arise when cocci divide and remain together to form pairs. Long chains of cocci result when cells adhere after repeated divisions in one plane; this pattern is seen in the genera *Streptococcus*, *Enterococcus*, and *Lactococcus* (figure 3.1a). Members of the genus *Staphylococcus* divide in random planes to generate irregular, grapelike clumps (figure 3.1b). Divisions in two or three planes can produce symmetrical clusters of cocci. Bacteria in the genus *Micrococcus* often divide in two planes to form square groups of four cells called tetrads. In the genus *Sarcina*, cocci divide in three planes, producing cubical packets of eight cells.

Bacillus megaterium is an example of a bacterium with a rod shape (figure 3.1c). Rods, sometimes called **bacilli** (s., **bacillus**), differ considerably in their length-to-width ratio, the coccobacilli being so short and wide that they resemble cocci. The shape of the rod's end often varies between species and may be flat, rounded, cigar-shaped, or bifurcated. Although many rods occur singly, some remain together after division to form pairs or chains (e.g., *Bacillus megaterium* is found in long chains).

Figure 3.1 Cocci and Rods. (a) *Streptococcus agalactiae*, the cause of Group B streptococcal infections; color-enhanced scanning electron micrograph (×4,800). (b) *Staphylococcus aureus*; color-enhanced scanning electron micrograph. (c) *Bacillus megaterium*, Gram stain (×600).

(a) *V. cholerae*—comma-shaped vibrios(b) *C. jejuni*—Spiral-shaped spirillum(c) *Leptospira interrogans*—a spirochete(d) *Hyphomicrobium*(e) *Streptomyces*—a filamentous bacterium(f) *M. stipitatus* fruiting body

Figure 3.2 Other Cell Shapes. (a) *Vibrio cholerae*, note polar flagella; scanning electron micrograph (SEM). (b) *Campylobacter jejuni*, SEM. (c) *Leptospira interrogans*, the spirochete that causes the waterborne disease leptospirosis. (d) *Hyphomicrobium*, electron micrograph with negative staining. (e) *Streptomyces*, SEM. (f) *Myxococcus stipitatus* fruiting body composed of thousands of cells.

Other cell shapes and arrangements are also observed. **Vibrios** are comma-shaped (figure 3.2a). **Spirilla** are rigid, spiral-shaped cells (figure 3.2b). Many have tufts of flagella at one or both ends. **Spirochetes** are flexible, spiral-shaped bacteria that have a unique, internal flagellar arrangement (figure 3.2c). These bacteria are distinctive in other ways, and all belong to a single phylum, *Spirochaetes*. The oval- to pear-shaped members of the genus *Hyphomicrobium* (figure 3.2d) produce a bud at the end of a long hypha. Other bacteria are **pleomorphic**, being variable in shape and lacking a single, characteristic form. ▶▶ *Phylum Spirochaetes* (section 21.7); *The Caulobacteraceae and Hyphomicrobiaceae* (section 22.1)

Some bacteria can be thought of as multicellular. Actinomycetes typically form long filaments called hyphae. The hyphae may branch to produce a network called a **mycelium** (figure 3.2e), and in this sense, they are similar to eukaryotic filamentous fungi. Many cyanobacteria, a group of photosynthetic bacteria, are also filamentous. Being filamentous allows some degree of differentiation among cells in the filament. For instance, some filamentous cyanobacteria form heterocysts within the filament; these are specialized cells that carry out nitrogen fixation. The myxobacteria are of particular note. These bacteria sometimes aggregate to form complex structures

called fruiting bodies (figure 3.2f). ▶▶ *Suborder Streptomycineae* (section 24.1); *Phylum Cyanobacteria* (section 21.4); *Order Myxococcales* (section 22.4)

Escherichia coli is an excellent representative of the average size of bacteria. This rod-shaped bacterium is 1.1 to 1.5 μm wide by 2.0 to 6.0 μm long. However, the size range of bacterial cells extends far beyond this average (figure 3.3). Near the small end of the size continuum are members of the genus *Mycoplasma* (0.3 μm in diameter). At the other end of the continuum are bacteria such as some spirochetes, which can reach 500 μm in length, and the cyanobacterium *Oscillatoria*, which is about 7 μm in diameter (the same diameter as a red blood cell). The huge bacterium *Epulopiscium fishelsoni* lives in the intestine of the brown surgeonfish (*Acanthurus nigrofusus*). *E. fishelsoni* grows as large as 600 by 80 μm , a little smaller than a printed hyphen and clearly larger than the well-known eukaryote *Paramecium* (figure 3.4). An even larger bacterium, *Thiomargarita namibiensis*, has been discovered in ocean sediment (see figure 22.24). Thus a few bacteria are much larger than the average eukaryotic cell (typical plant and animal cells are around 10 to 50 μm in diameter).

The variety of sizes and shapes exhibited by bacteria raises a fundamental question. What causes a bacterial species to have a particular size and shape? Although far from being answered,

Figure 3.3 Sizes of Bacteria Relative to a Red Blood Cell and Viruses. Recall that 1,000 nm = 1 μ m. Thus *E. coli* is 1.3×4 μ m.

Figure 3.4 A Giant Bacterium. This photograph, taken with pseudo dark-field illumination, shows *Epulopiscium fishelsoni* at the top of the figure dwarfing the paramecia at the bottom ($\times 200$).

recent discoveries have fueled a renewed interest in this question, and it is clear that size and shape determination are related and have been selected for during the evolutionary history of each bacterial species. For many years it was thought that microbes had to be small because being small increases the surface area-to-volume ratio (S/V ratio; **figure 3.5**). As this ratio increases, the uptake of nutrients and the diffusion of these and other molecules within the cell become more efficient, which in turn facilitates a rapid

Figure 3.5 The Surface-to-Volume Ratio. Surface area is calculated by the formula $4\pi r^2$. Volume is calculated by the formula $\frac{4}{3}\pi r^3$. Shape also affects the S/V ratio; rods with the same diameter as a coccus have a greater S/V ratio.

growth rate. Shape affects the S/V ratio. A rod with the same volume as a coccus has a higher S/V ratio than does the coccus. This means that a rod can have greater nutrient flux across its plasma membrane. However, the discovery of *E. fishelsoni* demonstrates that bacteria can be very large. For bacteria to be large, they must have other characteristics that maximize their S/V ratio, or their size must be beneficial in some way. For instance, *E. fishelsoni* has a highly convoluted plasma membrane, which increases its S/V ratio. In addition, large cells are less likely to be eaten by predatory protists. Cells that are filamentous, have prostheca (e.g., the hypha and bud of a *Hyphomicrobium* sp.), or are oddly shaped are less susceptible to predation. Prokaryotic Cell Shapes

Cell Organization

Structures often observed in bacterial cells are summarized and illustrated in **table 3.1** and **figure 3.6**. Note that no single bacterium possesses all of these structures at all times. Some are found only in certain cells in certain conditions or in certain phases of the life cycle.

Bacterial cells are often surrounded by several layers, which are collectively called the cell envelope. The innermost layer of the cell envelope is the plasma membrane, which surrounds the cytoplasm. Most bacteria have a chemically complex cell wall, which covers the plasma membrane. Many bacteria are surrounded by a capsule or slime layer external to the cell wall. Because most bacteria do not contain internal, membrane-bound organelles, their interior appears morphologically simple. The genetic material is localized in a discrete region called the nucleoid and usually is not separated from the surrounding cytoplasm by membranes. Ribosomes and larger masses called inclusions are scattered about the cytoplasm. Many bacteria use flagella for locomotion.

In the remaining sections of this chapter, we describe the major structures observed in bacterial cells in more detail. We begin with the cell envelope. We then proceed inward to consider

Table 3.1 Common Bacterial Structures and Their Functions

| | |
|---------------------------|--|
| Plasma membrane | Selectively permeable barrier, mechanical boundary of cell, nutrient and waste transport, location of many metabolic processes (respiration, photosynthesis), detection of environmental cues for chemotaxis |
| Gas vacuole | An inclusion that provides buoyancy for floating in aquatic environments |
| Ribosomes | Protein synthesis |
| Inclusions | Storage of carbon, phosphate, and other substances |
| Nucleoid | Localization of genetic material (DNA) |
| Periplasmic space | In typical Gram-negative bacteria, contains hydrolytic enzymes and binding proteins for nutrient processing and uptake; in typical Gram-positive bacteria, may be smaller or absent |
| Cell wall | Protection from osmotic stress, helps maintain cell shape |
| Capsules and slime layers | Resistance to phagocytosis, adherence to surfaces |
| Fimbriae and pili | Attachment to surfaces, bacterial conjugation and transformation, twitching and gliding motility |
| Flagella | Swimming and swarming motility |
| Endospore | Survival under harsh environmental conditions |

**Figure 3.6** Structure of a Bacterial Cell.

structures located within the cytoplasm. Next the discussion moves outward, to a variety of appendages that are involved in attachment to surfaces, motility, or both. Finally, we consider the bacterial endospore.

Retrieve, Infer, Apply

1. Why is the term prokaryote considered an inadequate descriptor by some microbiologists?
2. What characteristic shapes can bacteria assume? Describe the ways in which bacterial cells cluster together.
3. What advantages might a bacterial species that forms multicellular arrangements (e.g., clusters or chains) have that are not afforded unicellular bacteria?
4. What is the relevance of the surface area-to-volume ratio?

3.3 Bacterial Plasma Membranes

After reading this section, you should be able to:

- Describe the fluid mosaic model of membrane structure and identify the types of lipids typically found in bacterial membranes
- Distinguish macroelements (macronutrients) from micronutrients (trace elements) and provide examples of each
- Provide examples of growth factors needed by some microorganisms
- Compare and contrast passive diffusion, facilitated diffusion, active transport, and group translocation, and provide examples of each
- Discuss the difficulty of iron uptake and describe how bacteria overcome this difficulty

The **cell envelope** is defined as the plasma membrane and all the surrounding layers external to it. The cell envelopes of many bacteria consist of the plasma membrane, cell wall, and at least one additional layer (e.g., capsule or slime layer). Of all these layers, the **plasma membrane** is the most important because it encompasses the cytoplasm and defines the cell. If it is removed, the cell's contents spill into the environment and the cell no longer exists. Furthermore, despite being the innermost layer of the cell envelope, the plasma membrane is responsible for much of the cell's relationship with the outside world. Thus we begin our consideration of bacterial cell structure by describing the plasma membrane.

Cells must interact in a selective fashion with their environment, acquire nutrients, and eliminate waste. They also have to maintain their interior in a

constant, highly organized state in the face of external changes. Plasma membranes are an absolute requirement for all living organisms because they are involved in carrying out these cellular tasks.

A primary role of all plasma membranes is that they are selectively permeable barriers: they allow particular ions and molecules to pass either into or out of the cell, while preventing the movement of others. Thus the plasma membrane prevents the loss of essential components through leakage while allowing the movement of other molecules. Bacterial plasma membranes play other critical roles. They are the location of several crucial metabolic processes: respiration, photosynthesis, and the synthesis of lipids and cell wall constituents.

In addition to the plasma membrane, some bacteria have extensive intracytoplasmic membrane systems (p. 64). These internal membranes and the plasma membrane share a basic design. However, they can differ significantly in terms of the lipids and proteins they contain. To understand these chemical differences and the many functions of the plasma membrane and other membranes, it is necessary to become familiar with membrane structure.

Fluid Mosaic Model of Membrane Structure

The most widely accepted model for membrane structure is the **fluid mosaic model** of Singer and Nicholson, which proposes that membranes are lipid bilayers within which proteins float (**figure 3.7**). The model is based on studies of eukaryotic and bacterial membranes, and was established using a variety of experimental approaches, including transmission electron microscopy (TEM) and atomic force microscopy. Cell membranes are

Figure 3.7 The Fluid Mosaic Model of Bacterial Membrane Structure. This diagram shows the integral membrane proteins (blue) floating in a lipid bilayer. Peripheral membrane proteins (purple) are associated loosely with the inner membrane surface. Small spheres represent the hydrophilic ends of membrane phospholipids, and wiggly tails are the hydrophobic fatty acid chains. Other membrane lipids such as hopanoids (red) may be present. Phospholipids are drawn much larger than their actual size.

very thin structures, about 5 to 10 nm thick, that look like two darklines on either side of a light interior when imaged by TEM. This characteristic appearance is evidence that the membrane is composed of two sheets of molecules arranged end-to-end (figure 3.7). Cleavage of membranes by freeze-etching, a technique that allows the microscopist to see fine detail, exposes the proteins lying within the membrane lipid bilayer. ◀◀ *Electron microscopy (section 2.4); Scanning probe microscopy (section 2.5)*

The chemical nature of membrane lipids is critical to their ability to form bilayers. Most membrane-associated lipids (e.g., the phospholipids shown in figure 3.7) are **amphipathic**: they are structurally asymmetric, with polar and nonpolar ends (figure 3.8). The polar ends interact with water and are **hydrophilic**; the nonpolar **hydrophobic** ends are insoluble in water and tend to associate with one another. In aqueous environments, amphipathic lipids can interact to form a bilayer. The outer surfaces of the bilayer are hydrophilic, whereas hydrophobic ends are buried in the interior away from the surrounding water (figure 3.7). ▶▶ *Lipids (appendix I)*

Figure 3.8 The Structure of a Phospholipid.

Phosphatidylethanolamine, a phospholipid often found in bacterial membranes.

Two types of membrane proteins have been identified based on their ability to be separated from the membrane. **Peripheral membrane proteins** are loosely connected to the membrane and can be easily removed (figure 3.7). They are soluble in aqueous solutions and make up about 20 to 30% of total membrane protein. The remaining proteins are **integral membrane proteins**. These are not easily extracted from membranes and are insoluble in aqueous solutions when freed of lipids. Integral membrane proteins, like membrane lipids, are amphipathic; their hydrophobic regions are buried in the lipid while the hydrophilic portions project from the membrane surface (figure 3.7).

Integral membrane proteins carry out some of the most important functions of the membrane. Many are transport proteins used to move materials either into or out of the cell. Others are involved in energy-conserving processes, such as the proteins found in electron transport chains. Those integral membrane proteins with regions exposed to the outside of the cell enable the cell to interact with its environment. ▶▶ *Proteins (appendix I)*

Although most aspects of the fluid mosaic model are well supported by experimentation, some are being questioned. The fluid mosaic model suggests that membrane lipids are homogeneously distributed and that integral membrane proteins are free to move laterally within the membrane. However, the presence of microdomains enriched for certain lipids and the observation that some integral proteins are present at only certain sites do not support this view. Although the term mosaic initially referred to the clusters of proteins embedded in a homogeneous lipid bilayer, it may be more accurate to use the term to refer to the patchwork of lipid microdomains found in membranes. Research is ongoing to determine the physiological role of these microdomains.

Bacterial Lipids

Bacterial membranes are similar to eukaryotic membranes in that they are lipid bilayers and many of their amphipathic lipids are phospholipids (figure 3.8). The plasma membrane is very dynamic: the lipid composition varies with environmental temperature in such a way that the membrane remains fluid during growth. For example, bacteria growing at lower temperatures have more unsaturated fatty acids in their membrane phospholipids; that is, there are one or more double covalent bonds in the long hydrocarbon chain. At higher temperatures, their phospholipids have more saturated fatty acids—those in which the carbon atoms are connected only with single covalent bonds. Other factors also affect the lipid composition of membranes. For instance, some pathogens change the lipids in their plasma membranes to protect themselves from antimicrobial peptides produced by the immune system. ▶▶ *Influences of environmental factors on growth (section 7.3); Antimicrobial peptides (section 33.3)*

Bacterial membranes usually differ from eukaryotic membranes in lacking sterols (steroid-containing lipids) such as

(a) Cholesterol (a steroid) is found in the membranes of eukaryotes.

(b) Bacteriohopanetetrol (a hopanoid) is found in many bacterial membranes.

Figure 3.9 Membrane Steroids and Hopanoids.

cholesterol (figure 3.9a). However, many bacterial membranes contain sterol-like molecules called hopanoids (figure 3.9b). **Hopanoids** are synthesized from the same precursors as steroids, and like the sterols in eukaryotic membranes, they probably stabilize the membrane. Hopanoids are also of interest to ecologists and geologists: the total mass of hopanoids stored in sediments is estimated to be around 10^{11-12} tons—about as much as the total mass of organic carbon in all living organisms (10^{12} tons)—and evidence exists that hopanoids have contributed significantly to the formation of petroleum.

Uptake of Nutrients: Getting Through the Barrier

All plasma membranes function as barriers. Yet they must also allow movement of nutrients into the cell. If a microbe does not obtain nutrients from its environment, it will quickly exhaust its supply of amino acids, nucleotides, and other molecules needed to survive. In addition, if a microbe is to thrive and reproduce, it must have a source of energy. The energy source is used to generate the cell's major energy currency: the high-energy molecule ATP. Clearly, obtaining energy and nutrient sources is one of the most important jobs an organism has, and it is primarily a function of the plasma membrane. Here we discuss nutrient uptake.

Microbiologists refer to carbon, oxygen, hydrogen, nitrogen, sulfur, and phosphorus as **macroelements** or macronutrients because they are required in relatively large amounts. They are found in organic molecules such as proteins, lipids, nucleic acids, and carbohydrates. Other macroelements are potassium, calcium, magnesium, and iron. They exist as cations and generally are associated with and contribute to the activity and stability of molecules and cell structures such as enzymes and ribosomes. Thus they are important in many cellular processes, including protein synthesis and energy conservation. ►► *Enzymes*

and ribozymes (section 10.6); Translation in bacteria (section 13.7); Electron transport chains (section 10.4)

Other elements are required in small amounts—amounts so small that in the lab they are often obtained as contaminants in water, glassware, and growth media. Likewise in nature, they are ubiquitous and usually present in adequate amounts to support the growth of microbes. Microbiologists call these elements **micronutrients** or **trace elements**. The micronutrients—manganese, zinc, cobalt, molybdenum, nickel, and copper—are needed by most cells. Micronutrients are a part of certain enzymes, and they aid in the catalysis of reactions and maintenance of protein structure.

Some microbes are able to synthesize all the organic molecules they need from the macroelements. However, some microbes are unable to synthesize certain molecules needed for survival. These molecules are called **growth factors**, and they must be obtained from the environment. There are three types of growth factors: amino acids, purines and pyrimidines, and vitamins.

What are the common features of nutrient uptake by bacteria? Bacteria can only take in dissolved molecules. Uptake mechanisms are specific; that is, the necessary substances, and not others, are acquired. It does a cell no good to take in a substance that it cannot use. Bacteria are able to transport nutrients into the cell even when the concentration of a nutrient inside the cell is higher than the concentration outside. Thus they are able to move nutrients up a concentration gradient. This is important because bacteria often live in nutrient-poor habitats. In view of the enormous variety of nutrients and the complexity of the task, it is not surprising that bacteria make use of several different transport mechanisms: passive diffusion, facilitated diffusion, primary and secondary active transport, and group translocation.

Passive Diffusion

Passive diffusion, often called diffusion or simple diffusion, is the process by which molecules move from a region of higher concentration to one of lower concentration; that is, the molecules move down the concentration gradient. The rate of passive diffusion depends on the size of the concentration gradient between a cell's exterior and its interior (figure 3.10). A large concentration gradient is required for adequate nutrient uptake by passive diffusion (i.e., the external nutrient concentration must be high while the internal concentration is low). Unless the nutrient is used immediately upon entry, the rate of diffusion decreases as more nutrient accumulates in the cell.

Most substances cannot freely diffuse across the plasma membrane. However, some gases easily diffuse across the plasma membrane, including O_2 and CO_2 . Thus they are able to enter the cell by passive diffusion. H_2O also moves across membranes by passive diffusion. This is important because it allows the cell to adjust to differences in solute concentrations. Larger molecules, ions, and polar substances must enter the cell by other mechanisms, all of which involve specialized proteins that are referred to as transport proteins. ► *How Diffusion Works*

Figure 3.10 Passive and Facilitated Diffusion. The rate of diffusion depends on the size of the solute's concentration gradient (the ratio of the extracellular concentration to the intracellular concentration). This example of facilitated diffusion involves a carrier protein that can be saturated. Sometimes facilitated diffusion is mediated by a channel. Channels often do not exhibit a saturation effect.

Transport Proteins

Bacterial cells employ a variety of transport proteins in their uptake mechanisms. These important proteins are embedded in membranes and can be classified into several types. The two major types are channels and carriers. Channels, as their name indicates, are proteins that form pores in membranes through which substances can pass; they are often involved in facilitated diffusion. Channels show some specificity for the substances that pass through them, but this is considerably less than that shown by carriers, which are far more substrate specific. Carriers are so named because they carry nutrients across the membrane.

Facilitated Diffusion

During **facilitated diffusion**, substances move across the plasma membrane with the assistance of either channels or carriers. The rate of facilitated diffusion increases with the concentration gradient much more rapidly and at lower concentrations of the diffusing molecule than that of passive diffusion (figure 3.10).

When the transporter is a carrier, the diffusion rate reaches a plateau above a specific gradient value because the carrier protein is saturated; that is, it is transporting as many solute molecules as possible. The resulting curve resembles an enzyme-substrate curve (see figure 10.17) and is different from the linear response seen with passive diffusion. An example of channel-mediated facilitated diffusion is that involving aquaporins (see figure 2.31), which transport water. Aquaporins are members of the major intrinsic protein (MIP) family of proteins. MIPs facilitate diffusion of small polar molecules, and they are observed in virtually all organisms.

Facilitated diffusion is truly diffusion, even though a transport protein is involved. A concentration gradient spanning the membrane drives the movement of molecules, and no metabolic energy input is required. If the concentration gradient disappears, net inward movement ceases. The gradient can be maintained by transforming the transported nutrient to another compound, as occurs when a nutrient is metabolized.

Considerable work has been done on the mechanism of carrier-mediated facilitated diffusion. After the solute molecule binds to the outside, the carrier is thought to change conformation and release the molecule on the cell interior (figure 3.11). The carrier subsequently changes back to its original shape and is ready to pick up another molecule. The net effect is that a hydrophilic molecule can enter the cell in response to its concentration gradient.

Facilitated diffusion has been documented in some bacteria. However, it does not seem to be the major uptake mechanism for these microbes. Recall that many bacteria live in environments where nutrient concentrations are low, and facilitated diffusion cannot concentrate nutrients inside cells. Therefore energy-dependent transport mechanisms that do concentrate nutrients are significantly more important uptake mechanisms for bacterial cells.

Figure 3.11 A Model of Facilitated Diffusion. Because there is no energy input, molecules continue to enter only as long as their concentration is greater on the outside.

Primary and Secondary Active Transport

Active transport is the transport of solute molecules to higher concentrations (i.e., against a concentration gradient) with the input of metabolic energy. Three types of active transport are observed in bacteria: primary active transport, secondary active transport, and group translocation. They differ in terms of the energy used to drive transport and on whether or not the transported molecule is modified as it enters.

Active transport resembles facilitated diffusion in that it involves carrier proteins. Recall that carrier proteins bind particular solutes with great specificity. Active transport is also characterized by the carrier saturation effect at high solute concentrations (figure 3.10). Nevertheless, active transport differs from facilitated diffusion in its use of metabolic energy and its ability to concentrate substances. Metabolic inhibitors that block energy production inhibit active transport but do not immediately affect facilitated diffusion.

Primary active transport is mediated by carriers called primary active transporters. They use the energy provided by ATP hydrolysis to move substances against a concentration gradient without modifying them. Primary active transporters are **uniporters**; that is, they move a single molecule across the membrane (figure 3.12). **ATP-binding cassette transporters (ABC transporters)** are important primary active transporters. Our focus here is on those ABC transporters that are used for import of substances. Other ABC transporters are used for export of substances, in particular proteins; these exporters are described in chapter 13. ►► *Protein translocation and secretion in bacteria (section 13.8)*

Most ABC transporters consist of two hydrophobic membrane-spanning domains associated on their cytoplasmic surfaces with two ATP-binding domains (figure 3.13). The membrane-spanning domains form a pore in the membrane, and the ATP-binding domains bind and hydrolyze ATP to drive uptake. ABC transporters employ substrate-binding proteins. The substrate-binding proteins bind the molecule to be transported and then interact with the transporter proteins to move the molecule into

Figure 3.12 Carrier Proteins Can Be Uniporters or Cotransporters.

Uniporters move a single substance into the cell. Cotransporters simultaneously move two substances across the membrane. When both substances move in the same direction, the carrier is a symporter. When the two substances move in opposite directions, the carrier is an antiporter.

Figure 3.13 ABC Transporter Function.

the cell. *E. coli* transports a variety of sugars and amino acids by this mechanism.

Secondary active transport couples the potential energy of ion gradients to transport of substances without modifying them. Secondary active transporters are cotransporters (figure 3.12). They move two substances simultaneously: the ion whose gradient powers transport and the substance being moved across the membrane. When the ion and other substance both move in the same direction, it is called **symport**. When they move in opposite directions, it is called **antiport**. ► *Cotransport (Symport and Antiport)*

Secondary active transporters include the major facilitator superfamily (MFS) proteins. MFS transporters use ion gradients, some of which are created by bacteria during their metabolic processes. For instance, electron transport during energy-conserving processes generates a proton gradient in which protons are at a higher concentration outside the cell than inside. The proton gradient can be used to do cellular work, including secondary active transport. In some cases, the proton gradient is used to create another ion gradient such as a sodium gradient. This is accomplished by an antiporter that brings protons in as sodium ions are moved out of the cell. The sodium gradient can then be used to drive uptake of nutrients by a symport mechanism. ►► *Electron transport and oxidative phosphorylation (section 11.6)*

The lactose permease of *E. coli* is a well-studied secondary active transporter. It is a single protein that transports a lactose molecule inward as a proton simultaneously enters the cell. The proton is moving down a proton gradient, and the energy released drives solute transport. X-ray diffraction studies show that the carrier protein exists in outward- and inward-facing conformations. When lactose and a proton bind to separate sites on the outward-facing conformation, the protein changes to its inward-facing conformation, and the sugar and proton are released into the cytoplasm. Thus this is an example of symport. *E. coli* also uses

proton symport to take up amino acids and some organic acids.

Bacteria often have more than one transport system for a nutrient, as can be seen with *E. coli*. This bacterium has at least five transport systems for the sugar galactose, three systems each for the amino acids glutamate and leucine, and two potassium transport complexes. When several transport systems exist for the same substance, the systems differ in such properties as their energy source, their affinity for the solute transported, and the nature of their regulation. This diversity gives the bacterium an added competitive advantage in a variable environment.

Group Translocation

The distinguishing characteristic of **group translocation** is that a molecule is chemically modified as it is brought into the cell. The best-known group translocation system is the **phosphoenolpyruvate: sugar phosphotransferase system (PTS)**, which is observed in many bacteria. The PTS transports a variety of sugars while phosphorylating them, using phosphoenolpyruvate (PEP) as the phosphate donor. PEP is an important intermediate of a biochemical pathway used by many bacteria to extract energy from organic energy sources. PEP is a high-energy molecule that can be used to synthesize ATP, the cell's energy currency. However, when it is used in PTS reactions, the energy present in PEP is used to energize uptake rather than ATP synthesis. ▶▶ *ATP* (section 10.2); *Embden-Meyerhof pathway* (section 11.4)

The transfer of phosphate from PEP to the incoming molecule involves several proteins and is an example of a **phosphorelay system**. In *E. coli* and *Salmonella*, the PTS consists of two enzymes and a low molecular weight heat-stable protein (HPr). A phosphate is transferred from PEP to enzyme II with the aid of enzyme I and HPr (figure 3.14). Enzyme II then phosphorylates the sugar molecule as it is carried across the membrane. Many different PTSs exist, and they vary in terms of the sugars they transport. The specificity lies with the type of Enzyme II used in the PTS. Enzyme I and HPr are the same in all PTSs used by a bacterium. ▶▶ *Enzymes and ribozymes* (section 10.6)

PTSs are widely distributed in bacteria. Most members of the genera *Escherichia*, *Salmonella*, and *Staphylococcus*, as well as many other facultatively anaerobic bacteria (bacteria that grow in either the presence or absence of O_2), have PTSs; some obligately anaerobic bacteria (e.g., *Clostridium*) also have PTSs. However, most aerobic bacteria lack PTSs. Many carbohydrates are transported by PTSs. *E. coli* takes up glucose, fructose, mannitol, sucrose, *N*-acetylglucosamine, cellobiose, and other carbohydrates by group translocation. Besides their role in transport, PTS proteins can bind chemical attractants, toward which bacteria move by the process of chemotaxis (p. 75). ▶▶ *Oxygen concentration* (section 7.3) 🌀 *Active Transport by Group Translocation*

Figure 3.14 Group Translocation: Bacterial PTS Transport. Two examples of the phosphoenolpyruvate: sugar phosphotransferase system (PTS) are illustrated. The following components are involved in the system: phosphoenolpyruvate (PEP), enzyme I (EI), the low molecular weight heat-stable protein (HPr), and enzyme II (EII). EIIA is attached to EIIB in the mannitol transport system and is separate from EIIB in the glucose system.

Figure 3.15 Enterobactin: A Siderophore Produced by *E. coli*. Ball-and-stick model of enterobactin complexed with Fe^{3+} .

Iron Uptake

Almost all microorganisms require iron for use in cytochromes and many enzymes. Iron uptake is made difficult by the extreme insolubility of ferric iron (Fe^{3+}) and its derivatives, which leaves little free iron available for transport. Many bacteria have overcome this difficulty by secreting **siderophores** (Greek for iron bearers). Siderophores are low molecular weight organic molecules that bind ferric iron and supply it to the cell (figure 3.15).

Microorganisms secrete siderophores when iron is scarce in the medium. Once the iron-siderophore complex has reached the cell surface, it binds to a siderophore-receptor protein. Then either the iron is released to enter the cell directly

or the whole iron-siderophore complex is transported inside by an ABC transporter. Iron is so crucial to microorganisms that they may use more than one route of iron uptake to ensure an adequate supply.

Retrieve, Infer, Apply

1. List the functions of bacterial plasma membranes. Why must their plasma membranes carry out more functions than the plasma membranes of eukaryotic cells?
2. Describe in words and with a labeled diagram the fluid mosaic model for cell membranes. What aspects of this model are currently being challenged? Why?
3. On what basis are elements divided into macroelements and trace elements?
4. Describe facilitated diffusion, primary and secondary active transport, and group translocation in terms of their distinctive characteristics and mechanisms. What advantage does a bacterium gain by using active transport rather than facilitated diffusion?
5. What are uniport, symport, and antiport?
6. What are siderophores? Why are they important?

3.4 Bacterial Cell Walls

After reading this section, you should be able to:

- Describe peptidoglycan structure
- Compare and contrast the cell walls of typical Gram-positive and Gram-negative bacteria
- Relate bacterial cell wall structure to the Gram-staining reaction

The **cell wall** is the layer that lies just outside the plasma membrane. It is one of the most important structures for several reasons: it helps maintain cell shape and protect the cell from osmotic lysis; it can protect the cell from toxic substances; and in pathogens, it can contribute to pathogenicity. Cell walls are so important that most bacteria have them. Those that do not have other features that fulfill cell wall function. Bacterial cell wall synthesis is targeted by several antibiotics. Therefore it is important to understand cell wall structure. ►► *Antibacterial drugs* (section 9.4)

Overview of Bacterial Cell Wall Structure

After Christian Gram developed the Gram stain in 1884, it soon became evident that most bacteria could be divided into two major groups based on their response to the Gram-staining procedure. Gram-positive bacteria stained purple, whereas Gram-negative bacteria were pink or red. The true structural difference between these two groups did not become clear until the advent of the transmission electron microscope. Here we describe the long-held models of Gram-positive and Gram-negative cell walls developed from these studies. More recent studies of diverse groups of bacteria have shown that these models do not hold true for all bacteria (**Microbial Diversity & Ecology 3.1**). Because of the ongoing discussions related to these new studies, we will

refer to bacteria that fit the models as being typical Gram-positive or typical Gram-negative bacteria. ►► *Differential staining* (section 2.3)

The cell walls of *Bacillus subtilis* and many other typical Gram-positive bacteria consist of a single, 20- to 80-nm-thick homogeneous layer of **peptidoglycan** (**murein**) lying outside the plasma membrane (**figure 3.16**). In contrast, the cell walls of

The typical Gram-positive cell envelope

The typical Gram-negative cell envelope

Figure 3.16 Cell Envelopes of Typical Gram-Positive and Gram-Negative Bacteria. Cell envelopes consist of the plasma membrane and any layers (e.g., cell wall) exterior to it. For simplicity, we show only the plasma membrane and cell wall. Slime layers, capsules, and S-layers are common additional layers that lie outside the cell wall. *Bacillus licheniformis* (top) has a typical Gram-positive cell wall that consists primarily of peptidoglycan (also called murein, M). *Aquaspirillum serpens* (bottom) has a typical Gram-negative cell wall consisting of a thin layer of peptidoglycan, an outer membrane (OM), and the periplasmic space (P). PM is plasma membrane.

Microbial Diversity & Ecology

3.1 Gram Positive and Gram Negative or Monoderms and Diderms?

The importance of the Gram stain in the history of microbiology cannot be overstated. The Gram stain reaction was for many years one of the critical pieces of information used by bacterial taxonomists to construct taxa, and it is still useful in identifying bacteria in clinical settings. The initial studies done to differentiate bacteria that stained Gram positive from those that stain Gram negative were done using model organisms such as *Bacillus subtilis* (Gram positive) and *Escherichia coli* (Gram negative). At the time, it was thought that all other bacteria would have similar cell wall structures. However, as the cell walls of more bacteria have been characterized, it has become apparent that it may be misleading to refer to bacteria as Gram positive or Gram negative. In other words, the long-held models of Gram-positive and Gram-negative cell walls do not hold true for all bacteria. Recently Iain Sutcliffe has proposed that microbiologists stop referring to bacteria as either Gram positive or Gram negative. He suggests that instead we should more precisely describe bacterial cell envelope architectures by focusing on the observation that some bacteria have envelopes with a single membrane—the plasma membrane as seen in typical Gram-positive bacteria—while others have envelopes with two membranes—the plasma membrane and an outer membrane as seen in typical Gram-negative bacteria. He proposed calling the former monoderms and the latter diderms.

But why make this change? Sutcliffe begins by pointing out that some bacteria staining Gram positive are actually diderms and some staining Gram negative are actually monoderms. By referring to Gram-positive-staining diderms as Gram-positive bacteria, it is too easy to mislead scientists

and many a budding microbiologist into thinking that the bacterium has a typical Gram-positive envelope. He also argues that by relating cell envelope architecture to the phylogenies of various bacterial taxa, we may gain insight into the evolution of these architectures. He notes that the phyla *Firmicutes* and *Actinobacteria* are composed almost completely of monoderm bacteria, whereas almost all other bacterial phyla consist of diderms.

There are interesting exceptions to the relationship of phylogeny and cell envelope structure. For instance, members of the genus *Mycobacterium* (e.g., *M. tuberculosis*) belong to the predominantly monoderm phylum *Actinobacteria*. Mycobacteria have cell walls that consist of peptidoglycan and an outer membrane. The outer membrane is composed of mycolic acids rather than the phospholipids and lipopolysaccharides (LPSs) found in the typical Gram-negative cells' outer membrane. ▶▶ *Suborder Corynebacterineae* (section 24.1)

Members of the genus *Deinococcus* are another interesting exception. These bacteria stain Gram positive but are diderms. Their cell envelopes consist of the plasma membrane, what appears to be a typical Gram-negative cell wall, and an outer S-layer. Their outer membrane is distinctive because it lacks LPS. Deinococci are not unique in this respect, however. It is now known that there are several taxa with outer membranes that substitute other molecules for LPS.

Source: Sutcliffe, I. C. 2010. A phylum level perspective on bacterial cell envelope architecture. *Trends Microbiol.* 18(10):464–70.

E. coli and many other typical Gram-negative bacteria have two distinct layers: a 2- to 7-nm-thick peptidoglycan layer covered by a 7- to 8-nm-thick **outer membrane**.

One important feature seen in typical Gram-negative bacteria is a space between the plasma membrane and the outer membrane. It also is sometimes observed between the plasma membrane and cell wall in typical Gram-positive bacteria. This space is called the **periplasmic space**. The substance that occupies the periplasmic space is the periplasm.

Peptidoglycan Structure

The feature common to nearly all bacterial cell walls is the presence of peptidoglycan, which forms an enormous mesh-like structure often referred to as the peptidoglycan sacculus. Peptidoglycan is composed of many identical subunits. Each subunit within the sacculus contains two sugar derivatives,

N-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM), and several different amino acids. The amino acids form a short peptide consisting of four alternating D- and L-amino acids; the peptide is connected to the carboxyl group of NAM (figure 3.17). Three of the amino acids are not found in proteins: D-glutamic acid, D-alanine, and *meso*-diaminopimelic acid. The presence of D-amino acids protects against degradation by most peptidases, which recognize only the L-isomers of amino acid residues. The peptidoglycan subunit of many bacteria is shown in figure 3.17. ▶▶ *Carbohydrates* (appendix I); *Proteins* (appendix I); *Protein structure* (section 13.2)

The peptidoglycan sacculus is formed by linking the sugars of the peptidoglycan subunits together to form a strand; the strands are then cross-linked to each other by covalent bonds formed between the peptides extending from each strand. As seen in figure 3.18, the backbone of each strand is composed of

Figure 3.17 Peptidoglycan Subunit Composition. Shown is the peptidoglycan subunit of *E. coli*, many other typical Gram-negative bacteria, and many typical Gram-positive bacteria before it has been inserted into the existing peptidoglycan polymer. NAG is N-acetylglucosamine. NAM is N-acetylmuramic acid. The pentapeptide side chain is composed of alternating D- and L-amino acids; it terminates with two D-alanines. The amino acids are shown in different shades of color for clarity.

alternating NAG and NAM residues. The strand is helical, and the peptides extend out from the backbone in different directions. Many bacteria cross-link the strands by connecting the carboxyl group of the D-alanine at position 4 directly to the amino group of diaminopimelic acid (position 3) of the other strand (the position 5 D-alanine is removed as the cross-link is formed). Other bacteria use a **peptide interbridge** instead (figure 3.19). With or without an interbridge, cross-linking results in one dense, interconnected network of peptidoglycan strands (figure 3.20). ►► **Synthesis of peptidoglycan (section 12.4)**

The peptidoglycan sacculus is strong but elastic. It is able to stretch and contract in response to osmotic pressure. This is due

Figure 3.18 A Helical Peptidoglycan Strand. Because of its helical nature, the amino acid chains project out in different directions from the NAM-NAG backbone. Here the chains are shown projecting out at 90° angles. Some studies suggest that the angle is actually 120°.

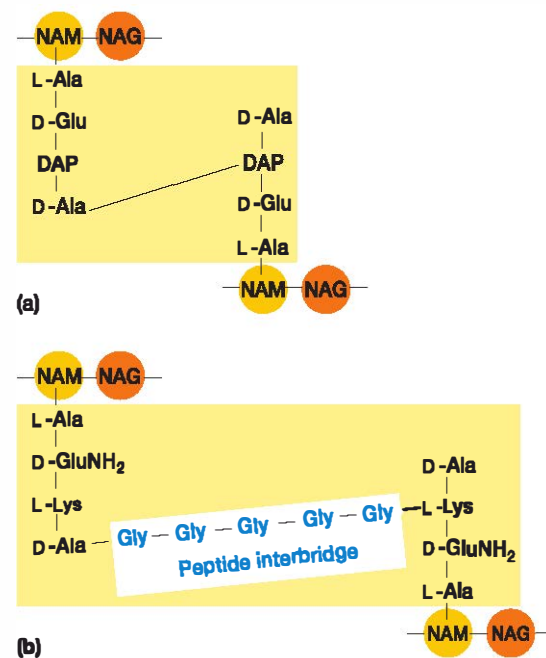

Figure 3.19 Peptidoglycan Cross-Links. (a) *E. coli* peptidoglycan with direct cross-linking, typical of many Gram-negative bacteria. (b) *Staphylococcus aureus* peptidoglycan. *S. aureus* stains Gram positive. NAM is N-acetylmuramic acid. NAG is N-acetylglucosamine. Gly is glycine. D-GluNH₂ is D-glutamic acid with an NH₂ group attached to the α carbon (the carbon next to the carboxyl group).

Figure 3.20 An Isolated Peptidoglycan Sacculus. The peptidoglycan sacculus from *Bacillus megaterium*. The latex spheres have a diameter of 0.25 μm.

to the rigidity of the backbone coupled with the flexibility of the cross-links. Peptidoglycan sacculi are also rather porous, allowing globular proteins having a molecular weight as large as 50,000 to pass through, depending on whether the sacculus is relaxed or stretched; thus only extremely large proteins are unable to pass through peptidoglycan.

Variants of peptidoglycan are often characteristic of particular groups and are therefore of some taxonomic value. Most typical Gram-negative bacteria have the amino acid composition and cross-linking shown in figure 3.19a. This variant is also observed in members of genera such as *Bacillus*, *Clostridium*, *Corynebacterium*, and *Nocardia*, which stain Gram positive. Other typical Gram-positive bacteria substitute the diamino acid lysine for *meso*-diaminopimelic acid (figure 3.21) and cross-link chains via interpeptide bridges. These interpeptide

Figure 3.21 Diamino Acids Present in Peptidoglycan. (a) L-lysine. (b) *meso*-diaminopimelic acid, (c) D-ornithine.

bridges can vary considerably (figure 3.22). Peptidoglycan can also vary in terms of the length of the peptidoglycan strands and the amount of cross-linking. Bacteria that stain Gram positive tend to have much more cross-linking, whereas those that stain Gram negative have considerably less.

Typical Gram-Positive Cell Walls

Most bacteria that stain Gram positive belong to the phyla *Firmicutes* and *Actinobacteria*, and most of these bacteria have thick cell walls composed of peptidoglycan and large amounts of other polymers such as teichoic acids (figure 3.23). **Teichoic acids** are polymers of glycerol or ribitol joined by phosphate groups (figure 3.24). The teichoic acids are covalently connected to peptidoglycan or to plasma membrane lipids; in the latter case,

Figure 3.22 Examples of Peptidoglycan Cross-Links. Most variation in peptidoglycan structure occurs in the composition of the peptide chain and the method by which peptidoglycan strands are cross-linked. (a) Examples of interpeptide bridges that link D-alanine in position 4 with L-lysine in position 3. The bracket contains six typical bridges: (1) *Staphylococcus aureus*, (2) *S. epidermidis*, (3) *Micrococcus roseus* and *Streptococcus thermophilus*, (4) *Lactobacillus viridescens*, (5) *Streptococcus salivarius*, and (6) *Leuconostoc cremoris*. The arrows indicate the polarity of peptide bonds running in the C to N direction. (b) An interpeptide bridge observed in *Corynebacterium poinsettiae*. The bridge extends between positions 2 and 4 and consists of the D-diamino acid ornithine. Note that L-homoserine (L-Hsr) is in position 3 rather than *meso*-diaminopimelic acid or L-lysine.

Figure 3.23 Typical Gram-Positive Cell Wall. This component of the cell envelope lies just outside the plasma membrane.

Figure 3.24 Teichoic Acid Structure. The segment of a teichoic acid made of phosphate, glycerol, and a side chain, R. R may represent D-alanine, glucose, or other molecules.

they are called lipoteichoic acids. Teichoic acids extend to the surface of the peptidoglycan. They are negatively charged and help give the cell wall its negative charge. Teichoic acids are not present in other bacteria.

The functions of teichoic acids are still unclear, despite the fact that they may constitute up to 50% of the mass of the cell wall. There is increasing evidence that they help create and maintain the structure of the cell envelope and protect the cell from harmful substances in the environment (e.g., antibiotics and host defense molecules). In addition, some teichoic acids may be involved in binding pathogenic species to host tissues, thus initiating the infectious disease process.

The periplasmic space lies between the plasma membrane and the cell wall, and is so narrow that it is often not visible. The periplasm has relatively few proteins; this is probably because the peptidoglycan sacculus is porous and many proteins translocated across the plasma membrane pass through the sacculus. Some secreted proteins are enzymes called **exoenzymes**. Exoenzymes often serve to degrade polymeric nutrients that would otherwise be too large for transport across the plasma membrane. Those proteins that remain in the periplasmic space are usually attached to the plasma membrane.

In addition to the polymers embedded in the peptidoglycan sacculus, there are often proteins associated with its surface. These proteins are involved in interactions of the cell with its environment. Some are noncovalently bound to teichoic acids

or other cell wall polymers. Other surface proteins are covalently attached to the peptidoglycan. Membrane-bound enzymes called sortases catalyze the formation of the covalent bonds that join these proteins to the peptidoglycan. Many covalently attached proteins have roles in virulence. For example, the M protein of pathogenic streptococci aids in adhesion to host tissues and interferes with host defenses.

Typical Gram-Negative Cell Walls

As just noted, most bacteria that stain Gram positive belong to the phyla *Firmicutes* and *Actinobacteria*. With a few exceptions, the bacteria belonging to the remaining phyla stain Gram negative (Microbial Diversity & Ecology 3.1). Even a brief inspection of figure 3.16 shows that typical Gram-negative cell walls are much more complex than typical Gram-positive walls. One of the most striking differences is the paucity of peptidoglycan. The peptidoglycan layer is very thin (2 to 7 nm, depending on the bacterium) and sits within the periplasmic space.

The periplasmic space is usually 30 to 70 nm wide. Some studies indicate that it may constitute about 20 to 40% of the total cell volume. Thus it is much larger than that observed in typical Gram-positive cells. When cell walls are disrupted carefully or removed without disturbing the underlying plasma membrane, periplasmic enzymes and other proteins are released and may be

Figure 3.25 Typical Gram-Negative Cell Wall. Notice that these bacteria are bounded by two membranes, the plasma membrane and the outer membrane of the cell wall.

MICRO INQUIRY How does the outer membrane of the cell wall differ from the plasma membrane?

easily studied. Some periplasmic proteins participate in nutrient acquisition—for example, hydrolytic enzymes and transport proteins. Some periplasmic proteins are involved in energy conservation. For instance, some bacteria have electron transport proteins in their periplasm (e.g., denitrifying bacteria, which convert nitrate to nitrogen gas). Other periplasmic proteins are involved in peptidoglycan synthesis and modification of toxic compounds that could harm the cell. ►► *Anaerobic respiration* (section 11.7), *Nitrogen cycle* (section 28.1)

The outer membrane lies outside the thin peptidoglycan layer. It is linked to the cell by Braun's lipoprotein, the most abundant protein in the outer membrane (figure 3.25). This small lipoprotein is covalently joined to the underlying peptidoglycan and is embedded in the outer membrane by its hydrophobic end.

Possibly the most unusual constituents of the outer membrane are its **lipopolysaccharides (LPSs)**. These large, complex molecules contain both lipid and carbohydrate, and consist of three parts: (1) lipid A, (2) the core polysaccharide, and (3) the O side chain. The LPS from *Salmonella* spp. has been studied most,

and its general structure is described here (figure 3.26). The **lipid A** region contains two glucosamine sugar derivatives, each with three fatty acids and phosphate or pyrophosphate attached. The fatty acids of lipid A are embedded in the outer membrane, while the remainder of the LPS molecule projects from the surface. The **core polysaccharide** is joined to lipid A and is constructed of 10 sugars, many of them unusual in structure. The O side chain or **O antigen** is a polysaccharide chain extending outward from the core. It has several peculiar sugars and varies in composition between bacterial strains.

LPS has many important functions. (1) It contributes to the negative charge on the bacterial surface because the core polysaccharide usually contains charged sugars and phosphate (figure 3.26). (2) It helps stabilize outer membrane structure because lipid A is a major constituent of the exterior leaflet of the outer membrane. (3) It helps create a permeability barrier. The geometry of LPS (figure 3.26b) and interactions between neighboring LPS molecules are thought to restrict the entry of bile salts, antibiotics, and other toxic substances that might

Figure 3.26 Lipopolysaccharide Structure. (a) A simplified diagram of LPS. Abbreviations: GlcN, glucosamine; Hep, heptulose; KDO, 2-keto-3-deoxyoctonate; P, phosphate. Lipid A is buried in the outer membrane. (b) Molecular model of a lipopolysaccharide. The lipid A and core polysaccharide are straight; the O side chain is bent at an angle in this model.

kill or injure the bacterium. (4) LPS also plays a role in protecting pathogenic bacteria from host defenses. The O side chain of LPS is also called the O antigen because it elicits an immune response by an infected host. This response involves the production of antibodies that bind the strain-specific form of LPS that elicited the response. For example, microbiologists refer to specific strains of Gram-negative bacteria using the O antigen, such as *E. coli* O157; here the O side chain is the antigenic type number 157. Unfortunately, many bacteria can rapidly change the antigenic nature of their O side chains, thus thwarting host defenses. (5) Importantly, the lipid A portion of LPS can act as a toxin and is called endotoxin; it causes some of the symptoms that arise in infections by Gram-negative pathogens. If LPS or lipid A enters the bloodstream, a form of septic shock develops for which there is no direct treatment. ►► *Endotoxins (section 35.2); Antibodies (section 34.7)*

Despite the role of LPS in creating a permeability barrier, the outer membrane is more permeable than the plasma membrane and permits the passage of small molecules such as glucose and other monosaccharides. This is due to the presence of **porin proteins**. Most porin proteins cluster together to form a trimer in the outer membrane (figure 3.25 and figure 3.27). Each porin protein spans the outer membrane and is more or less tube-shaped; its narrow, water-filled channel allows passage of molecules smaller than about 600 daltons. However,

larger molecules such as vitamin B₁₂ cross the outer membrane through the action of specific outer membrane carrier proteins that deliver the molecule to ABC transporters.

Mechanism of Gram Staining

The difference between typical Gram-positive bacteria and typical Gram-negative bacteria is due to the physical nature of their cell walls. If the cell wall is removed, typical Gram-positive bacteria stain Gram negative. Furthermore, bacteria that never make cell walls, such as the mycoplasmas, also stain Gram negative. ◀◀ *Differential staining (section 2.3)*

During the Gram-staining procedure, bacteria are first stained with crystal violet, a dye with a positive charge that is attracted to the bacterial cell's net negative charge, and next treated with iodine. Iodine is a mordant that interacts with the crystal violet, forming an insoluble complex and thus promoting dye retention. When bacteria are treated with ethanol in the decolorization step, the alcohol is thought to shrink the pores of the thick peptidoglycan found in the cell walls of typical Gram-positive bacteria, causing the peptidoglycan to act as a permeability barrier that prevents loss of crystal violet. Thus the dye-iodine complex is retained during the decolorization step and the bacteria remain purple, even after the addition of a second dye, required by the procedure. In contrast, the peptidoglycan in

Figure 3.27 Porin Proteins. Two views of the OmpF porin of *E. coli*. (a) Structure of a trimeric porin observed when looking down at the outer surface of the outer membrane (i.e., top view). The center of each porin monomer is a water-filled channel. Each OmpF monomer can be divided into three loops: the green loop forms the channel, the blue loop interacts with other porin proteins to help form the trimer, and the orange loop narrows the channel. The arrow indicates the area of a porin molecule viewed from the side in panel (b). Side view of a porin monomer showing the β -barrel structure characteristic of porin proteins.

MICRO INQUIRY Are these transporter proteins categorized as channels or carriers?

typical Gram-negative cell walls is very thin, not as highly cross-linked, and has larger pores. Alcohol treatment also may extract enough lipid from the outer membrane to increase the cell wall's porosity further. For these reasons, alcohol more readily removes the crystal violet-iodine complex, decolorizing the cells. The counterstain safranin, also a dye with a net negative charge, easily stains the decolorized cells so that they appear red or pink.

Cell Walls and Osmotic Protection

Microbes have several mechanisms for responding to changes in osmotic pressure. This pressure arises when the concentration of solutes inside the cell differs from that outside, and the responses work to equalize the solute concentrations. However, in certain situations, osmotic pressure can exceed the cell's ability to acclimate. In these cases, additional protection is provided by the cell wall. When cells are in hypotonic solutions—

ones in which the solute concentration is less than that in the cytoplasm—water diffuses into the cell, causing it to swell. Without the peptidoglycan layer of the cell wall, the pressure on the plasma membrane would become so great that the membrane would be disrupted and the cell would burst—a process called **lysis**. Conversely, in hypertonic solutions, water flows out and the cytoplasm shrivels up—a process called **plasmolysis**.

The protective nature of peptidoglycan is most clearly demonstrated when bacterial cells are treated with lysozyme or penicillin. The enzyme **lysozyme** attacks peptidoglycan by hydrolyzing the bond that connects *N*-acetylmuramic acid with *N*-acetylglucosamine (figure 3.17; see also figure 33.4). Penicillin works by a different mechanism. It inhibits the enzyme transpeptidase, which is responsible for making the cross-links between peptidoglycan chains. If bacteria are treated with either of these substances while in a hypotonic solution, they lyse. However, if they are in an isotonic solution, they can survive and grow normally. Treatment of typical Gram-positive bacteria with lysozyme or penicillin results in the complete loss of the cell wall, and the cell becomes a protoplast. When typical Gram-negative bacteria are exposed to lysozyme or penicillin, the peptidoglycan sacculus is destroyed, but the outer membrane remains. These cells are called **spheroplasts**. Because they lack a complete cell wall, both protoplasts and spheroplasts are osmotically sensitive. If they are transferred to a hypotonic solution, they lyse due to uncontrolled water influx (figure 3.28). ►► *Antibacterial drugs (section 9.4)*

Bacteria That Lack Peptidoglycan or Cell Walls

Peptidoglycan is a signature molecule for bacteria. No other organisms have been found to synthesize it. However, some walled bacteria that stain Gram negative do not have peptidoglycan in their cell walls: members of the phyla *Chlamydiae* and *Planctomycetes*. Both have an outer membrane like other Gram-negative bacteria, but there is no peptidoglycan layer between the plasma membrane and outer membrane. *Chlamydia* are intracellular parasites that cause disease in a variety of organisms, including humans. They also have complex life cycles in which they change from replicative forms to infective forms. *Planctomycetes* are of interest because some have cytoplasmic compartments surrounded by lipid membranes. Why these bacteria lack peptidoglycan is still an unanswered question. ►► *Phylum Planctomycetes (section 21.5); Phylum Chlamydiae (section 21.6)*

Figure 3.28 Protoplast Formation and Lysis. Protoplast formation induced by incubation with penicillin in an isotonic medium. Transfer to hypotonic medium will result in lysis.

Despite their lack of peptidoglycan, chlamydia and planctomycetes maintain a characteristic shape. This is not true of mycoplasmas, which lack a cell wall altogether; they tend to be pleomorphic (see figure 21.4). Mycoplasmas also are osmotically sensitive. Despite this, they often can grow in dilute media or terrestrial environments because their plasma membranes are more resistant to osmotic pressure than those of walled bacteria. The precise reason for this is not clear, although the presence of sterols in the membranes of many species may provide added strength.

Retrieve, Infer, Apply

1. Describe in detail the composition and structure of peptidoglycan. Why does peptidoglycan contain the unusual D-isomers of alanine and glutamic acid rather than the L-isomers observed in proteins?
2. List the major molecules that make up typical Gram-positive and Gram-negative cell walls and note which molecules are unique to each type of cell wall. How do these molecules contribute to the functions of the cell wall?
3. When protoplasts and spheroplasts are made, the shape of the cell becomes spherical regardless of the original cell shape. Why does this occur?
4. The cell walls of most members of the phyla *Firmicutes* and *Actinobacteria* lack porins. Why is this the case?
5. What two mechanisms allow the passage of nutrients across the outer membrane of typical Gram-negative bacteria?

3.5 Cell Envelope Layers Outside the Cell Wall

After reading this section, you should be able to:

- Compile a list of the structures found in all the layers of bacterial cell envelopes, noting the functions and the major component molecules of each

Figures 3.23 and 3.25 show the bacterial envelope as consisting solely of the plasma membrane and cell wall. However, many bacteria have another layer in their cell envelopes that lies outside the cell wall. This layer is given different names depending on its makeup and how it is organized.

Capsules and Slime Layers

Capsules are layers that are well organized and not easily washed off (figure 3.29). They are most often composed of polysaccharides, but some are constructed of other materials. For example, *Bacillus anthracis* has a proteinaceous capsule composed of poly-D-glutamic acid. Capsules are clearly visible in the light microscope when negative stains or specific capsule stains are employed; they also can be studied with the electron microscope.

Although capsules are not required for growth and reproduction in laboratory cultures, they confer several advantages when bacteria grow in their normal habitats. They help pathogenic bacteria resist phagocytosis by host phagocytes. *Streptococcus pneumoniae* provides a dramatic example. When

K. pneumoniae

Figure 3.29 Bacterial Capsules. *Klebsiella pneumoniae* with its capsule stained for observation in the light microscope ($\times 1,500$).

it lacks a capsule, it is phagocytosed easily and does not cause disease. On the other hand, the capsulated variant quickly kills mice. Capsules can also protect against desiccation because they contain a great deal of water. They exclude viruses and most hydrophobic toxic materials such as detergents.

A **slime layer** is a zone of diffuse, unorganized material that is removed easily. It is usually composed of polysaccharides but is not as easily observed by light microscopy. Gliding bacteria often produce slime, which in some cases has been shown to facilitate motility (section 3.8).

The term **glycocalyx** refers to a layer consisting of a network of polysaccharides extending from the surface of the cell. The term can encompass both capsules and slime layers because they usually are composed of polysaccharides. The glycocalyx aids in attachment to solid surfaces, including tissue surfaces in plant and animal hosts (figure 3.30). ►► **Virulence factors** (section 35.2)

Figure 3.30 Bacterial Glycocalyx. Bacteria connected to each other and to the intestinal wall by their glycocalyxes, the extensive networks of fibers extending from the cells ($\times 17,500$).

Figure 3.31 The S-Layer. An electron micrograph of the S-layer of the bacterium *Deinococcus radiodurans* after shadowing.

S-Layers

Many bacteria have a regularly structured layer called an **S-layer** on their surface. The S-layer has a pattern something like floor tiles and is composed of protein or glycoprotein (**figure 3.31**). In typical Gram-negative bacteria, the S-layer adheres directly to the outer membrane; it is associated with the peptidoglycan surface of typical Gram-positive cell walls.

S-layers are of considerable interest not only for their biological roles but also in the growing field of nanotechnology. Their biological roles include protecting the cell against ion and pH fluctuations, osmotic stress, enzymes, or predatory bacteria. The S-layer also helps maintain the shape and envelope rigidity of some cells, and it can promote cell adhesion to surfaces. Finally, the S-layer seems to protect some bacterial pathogens against host defenses, thus contributing to their virulence. The potential use of S-layers in nanotechnology is due to the ability of S-layer proteins to self-assemble; that is, the S-layer proteins contain the information required to spontaneously associate and form the S-layer without the aid of any additional enzymes or other factors. Thus S-layer proteins could be used as building blocks for the creation of technologies such as drug-delivery systems and novel detection systems for toxic chemicals or bioterrorism agents.

Retrieve, Infer, Apply

1. What is the difference between a capsule and a slime layer? Why does the term glycocalyx usually encompass both?
2. S-layers and some capsules are composed of proteins. How does an S-layer differ from a proteinaceous capsule?

3.6 Bacterial Cytoplasm

After reading this section, you should be able to:

- Create a table or concept map that identifies the components of the bacterial cytoplasm and describes their structure, molecular makeup, and functions

The plasma membrane and everything within is called the **protoplast**. The **cytoplasm** is the material bounded by the plasma membrane; thus the cytoplasm is a major part of the protoplast. For many years, bacterial cells were thought of as bags of water in which structures such as inclusions, ribosomes, the nucleoid, and plasmids floated. But the exciting discovery of cytoskeletal proteins in bacterial cells has forever changed that view. The bacterial cytoskeleton is less complex than that of eukaryotes. However, it is now clear that the bacterial cytoskeleton helps organize the cytoplasm. In this section, we consider the bacterial cytoskeleton and then a variety of other structures found in the cytoplasm.

Bacterial Cytoskeleton

Eukaryotes possess three cytoskeletal elements: actin filaments, microtubules, and intermediate filaments. Actin filaments are made from actin, and microtubules are made from tubulin. Intermediate filaments are composed of a mixture of one or more members of different classes of proteins. Homologues of all three types of eukaryotic proteins have been identified in bacteria (**table 3.2**). The bacterial cytoskeletal proteins are structurally similar to their eukaryotic counterparts and carry out similar functions: they participate in cell division, localize proteins to certain sites in the cell, and determine cell shape (**table 3.2**). In addition, some cytoskeletal proteins appear to be unique to bacteria. Thus it is likely that the evolution of the cytoskeleton was an early event in the history of life on Earth. ▶▶ *Cytoplasm of eukaryotes* (section 5.3); *Bacterial cell cycle* (section 7.2)

The cytoskeletons of *Escherichia coli*, *Bacillus subtilis*, and *Caulobacter crescentus* are the best studied and are the focus of our discussion. These three organisms are important bacterial model systems for several reasons. *E. coli* is a Gram-negative rod that has been extensively studied and can be easily manipulated. *B. subtilis* is a Gram-positive rod found in soil. It is an endospore-forming bacterium, making it a good model for cellular differentiation (section 3.9). Both were models for cell wall structure as described in section 3.4. *C. crescentus* is a curved rod found in aquatic habitats. It is interesting in part because it exhibits a complex life cycle that includes two different stages: a motile swarmer cell and a sessile, stalked cell that attaches to surfaces by a holdfast (*see figure 22.10*). ▶▶ *The Caulobacteraceae and Hyphomicrobiaceae* (section 22.1)

The best studied bacterial cytoskeletal proteins are FtsZ, MreB, and CreS (also known as crescentin). FtsZ was one of the first bacterial cytoskeletal proteins identified and has since been found in most bacteria. FtsZ is a homologue of the eukaryotic protein tubulin. It forms a ring at the center of a dividing cell and is required for the formation of the septum that will separate the daughter cells (**figure 3.32a**). MreB and its relative

Table 3.2 Bacterial Cytoskeletal Proteins

| Type | Function | Comments |
|---|---|---|
| Tubulin Homologues | | |
| FtsZ | Cell division | Widely observed in bacteria and archaea |
| BtubA/BtubB | Unknown | Observed only in <i>Prostheobacter</i> spp.; thought to be encoded by eukaryotic tubulin genes obtained by horizontal gene transfer |
| TubZ | Possibly plasmid segregation | Encoded by large plasmids observed in members of the genus <i>Bacillus</i> |
| Actin Homologues | | |
| MamK | Positioning magnetosomes | Observed in magnetotactic species |
| MreB/Mbl | Helps determine cell shape, may be involved in chromosome segregation, localizes proteins | Most rod-shaped bacteria |
| ParM | Plasmid segregation | Plasmid encoded |
| Intermediate Filament Homologues | | |
| CreS (crescentin) | Induces curvature in curved rods | <i>Caulobacter crescentus</i> |
| Unique Bacterial Cytoskeletal Proteins | | |
| MinD | Prevents polymerization of FtsZ at cell poles | Many rod-shaped bacteria |
| ParA | Segregates chromosomes and plasmids | Observed in many species, including <i>Vibrio cholerae</i> , <i>C. crescentus</i> , and <i>Thermus thermophilus</i> |

(a) FtsZ

(b) Mbl

(c) Mbl

(d) Crescentin

Figure 3.32 The Bacterial Cytoskeleton. (a) FtsZ protein in a chain of *Bacillus subtilis* cells; FtsZ-green fluorescent (GFP) fusion protein viewed by fluorescence microscopy. (b) The MreB-like cytoskeletal protein (Mbl) of *B. subtilis*; Mbl-GFP in live cells was examined by fluorescence microscopy. With this method, Mbl seems to form helices (arrows). More sensitive methods show that Mbl forms patches that move perpendicular to the long axis of the cell. (c) Three of the cells from (b) are shown at a higher magnification. (d) CreS (crescentin), in red, of *Caulobacter crescentus*. The DNA in the cells was stained blue with DAPI.

Mbl are actin homologues. Their major function is to determine cell shape in rod-shaped cells; MreB is not found in cocci. MreB and Mbl determine cell shape by properly positioning the machinery needed for peptidoglycan synthesis (figure 3.32*b, c*). CreS (crescentin) was discovered in *C. crescentus* and is responsible for its curved shape (figure 3.32*d*). CreS is a homologue of lamin and keratin, two intermediate filament proteins. ►► *Cellular growth and determination of cell shape* (section 7.2)

Intracytoplasmic Membranes

Although members of *Bacteria* do not contain complex membranous organelles like mitochondria or chloroplasts, internal membranous structures are observed in some bacteria (figure 3.33).

(a)

(b)

Figure 3.33 Internal Bacterial Membranes. Membranes of nitrifying and photosynthetic bacteria. (a) *Nitrocystis oceanus* with parallel membranes traversing the whole cell. Note nucleoid (n) with fibrillar structure. (b) *Ectothiorhodospira mobilis* with an extensive intracytoplasmic membrane system ($\times 60,000$).

These can be extensive and complex in photosynthetic bacteria and in bacteria with very high respiratory activity, such as the nitrifying bacteria. The internal membranes of the photosynthetic cyanobacteria are called thylakoids and are analogous to the thylakoids of chloroplasts. ►► *Photosynthetic bacteria* (section 21.4); *Nitrifying bacteria* (section 22.1); *Organelles involved in energy conservation* (section 5.6)

The internal membranous structures observed in bacteria may be aggregates of spherical vesicles, flattened vesicles, or tubular membranes (see figure 22.3). They are often connected to the plasma membrane and are thought to arise from it by invagination. However, these internal membranes differ from the plasma membrane by being enriched for proteins and other molecules involved in energy conservation. For instance, the thylakoids of cyanobacteria contain the chlorophyll and photosynthetic reaction centers responsible for converting light energy into ATP. Thus the function of internal membranes may be to provide a larger membrane surface for greater metabolic activity.

The membrane-bound organelle called the anammoxosome is observed in some members of the phylum *Planctomycetes* and deserves additional comment (see figure 21.14). This organelle is the site of anaerobic ammonia oxidation and is unique to these bacteria. The anammoxosome membrane contains an unusual group of lipids called ladderane lipids (figure 3.34). Ladderane lipids are defined by the presence of two or more fused cyclobutane rings. They pack together very tightly, and this characteristic is thought to be important to anammoxosome function.

Inclusions

Inclusions are common in all cells. They are formed by the aggregation of substances that may be either organic or inorganic. The first bacterial inclusions were discovered in the late 1800s. Since then much has been learned about their structure and function. Inclusions can take the form of granules, crystals, or globules; some are amorphous. Some inclusions lie free in the cytoplasm. Other inclusions are enclosed by a shell that is single-layered and may consist of proteins or of both proteins and phospholipids. Some inclusions are surrounded by invaginations of the plasma membrane. Many

Figure 3.34 Ladderane Lipids. These lipids are unique to planctomycetes.

inclusions are used for storage (e.g., of carbon compounds, inorganic substances, and energy) or to reduce osmotic pressure by tying up molecules in particulate form. The quantity of inclusions used for storage varies with the nutritional status of the cell. Some inclusions are so distinctive that they are increasingly being referred to as microcompartments. A brief description of several important inclusions follows.

Storage Inclusions

Cells have a wide variety of storage inclusions. Many are formed when one nutrient is in ready supply but another nutrient is not. Some store end products of metabolic processes. In some cases, these end products are used by the microbe when it is in different environmental conditions. The most common storage inclusions are glycogen inclusions, polyhydroxyalkonate granules, sulfur globules, and polyphosphate granules. Some storage inclusions are observed only in certain organisms, such as the cyanophycin granules in cyanobacteria. ►► *Phylum Cyanobacteria* (section 21.4)

Carbon is often stored as polyhydroxyalkonate (PHA) granules. Several types of PHA granules have been identified, but the most common contain **poly- β -hydroxybutyrate (PHB)**. (figure 3.35). The structure of PHB inclusions has been well studied, and PHB granules are now known to be surrounded by a single-layered shell composed of proteins and a small amount of phospholipids (figure 3.35b). Much of the interest in PHB and other PHA granules is due to their industrial use in making biodegradable plastics. ►► *Biopolymers* (section 42.1)

Polyphosphate granules and sulfur globules are inorganic inclusions observed in many organisms. **Polyphosphate granules** store the phosphate needed for synthesis of important cell constituents such as nucleic acids. In some cells, they act as an energy reserve, and polyphosphate also can serve as an energy source in some reactions, when the bond linking the final phosphate in the polyphosphate chain is hydrolyzed. Sulfur globules are formed by bacteria that use reduced sulfur-containing compounds as a source of electrons during their energy-conserving metabolic processes (figure 3.36). For example, some photosynthetic bacteria can use hydrogen sulfide (rather than water) as an electron donor and accumulate the resulting sulfur either externally or internally. ►► *Light reactions in anoxygenic photosynthesis* (section 11.11); *Class Gammaproteobacteria* (section 22.3)

Microcompartments

Some bacterial inclusions are unique and serve functions other than simply storing substances for later use by the cell. These inclusions are called microcompartments. Microcompartments share several characteristics. They are relatively large polyhedrons formed by one or more different proteins. Enclosed within the protein shell are one or more enzymes. Microcompartments include the ethanolamine utilization (Eut) microcompartment, the propandiol utilization (Pdu) microcompartment, and carboxysomes. We focus here on carboxysomes as they are the best studied.

(a)

(b)

Figure 3.35 PHB Inclusions in Bacteria. (a) Electron micrograph of *Bacillus megaterium* ($\times 30,500$). PHB is a polymer of β -hydroxybutyrate molecules joined by ester bonds between the carboxyl and hydroxyl groups of adjacent molecules. PHB inclusions are around 0.2 to 0.7 μm in diameter. They are seen as empty holes by electron microscopy because PHB is hydrophobic and is dissolved by the solvents used to prepare specimens. PHB, poly- β -hydroxybutyrate inclusion; CW, cell wall; N, nucleoid; PM, plasma membrane; and R, ribosomes. (b) Structure of a PHB granule. PHB is enclosed by a shell composed of several different proteins, including the PHB-synthesizing enzyme (red sphere) and the PHB-degrading enzyme (green sphere). Yellow spheres represent the phospholipids that are also found in the shell. Note that these phospholipids do not form a phospholipid bilayer.

Carboxysomes are present in many cyanobacteria and other CO_2 -fixing bacteria (figure 3.37). Their polyhedral coat is composed of about six different proteins and is about 100 nm in diameter. Enclosed by the shell is the enzyme carbonic anhydrase, which converts carbonic acid into CO_2 . Recall that

Figure 3.36 Sulfur Globules. *Chromatium vinosum*, a purple sulfur bacterium, with intracellular sulfur globules, bright-field microscopy ($\times 2,000$).

Figure 3.37 Carboxysomes. Carboxysomes in the bacterium *Halothiobacillus neapolitanus*. This is one image of a tilt series taken for electron cryotomography. Each carboxysome is approximately 100 nm in diameter.

biological membranes allow the free diffusion of CO_2 . However, the carboxysome shell prevents CO_2 from escaping so it can accumulate within. Also enclosed within the polyhedron is the enzyme ribulose-1, 5-bisphosphate carboxylase/oxygenase (RubisCO). RubisCO is the critical enzyme for CO_2 fixation, the process of converting CO_2 into sugar. Thus the carboxysome serves as a site for CO_2 fixation. As such, it is critical that carboxysomes be distributed to both daughter cells during cell division. A recent study has demonstrated that ParA, a cytoskeletal protein (table 3.2), helps ensure appropriate segregation of carboxysomes. ►► *CO_2 fixation (section 12.3)*

Other Inclusions

Inclusions can be used for functions other than storage or as microcompartments. Two of the most remarkable inclusions are gas vacuoles and magnetosomes. Both are involved in bacterial movement.

Figure 3.38 Gas Vacuoles and Gas Vesicles. A freeze-fracture preparation of *Anabaena flosaquae* ($\times 89,000$) showing gas vesicles and gas vacuoles. Clusters of the cylindrical vesicles form gas vacuoles. Both longitudinal and cross-sectional views of gas vesicles are indicated by arrows.

The **gas vacuole** provides buoyancy to some aquatic bacteria, many of which are photosynthetic. Gas vacuoles are aggregates of enormous numbers of small, hollow, cylindrical structures called **gas vesicles** (figure 3.38). Gas vesicle walls are composed entirely of a single small protein. These protein subunits assemble to form a rigid cylinder that is impermeable to water but freely permeable to atmospheric gases. Cells with gas vacuoles can regulate their buoyancy to float at the depth necessary for proper light intensity, oxygen concentration, and nutrient levels. They descend by simply collapsing vesicles and float upward when new ones are constructed.

Aquatic magnetotactic bacteria use **magnetosomes** to orient themselves in Earth's magnetic field. Magnetosomes are intracellular chains of magnetite (Fe_3O_4) particles (figure 3.39). They are around 35 to 125 nm in diameter and enclosed within invaginations of the plasma membrane. The invaginations have been shown to contain distinctive proteins that are not found in the rest of the plasma membrane. Each iron particle is a tiny magnet: the Northern Hemisphere bacteria use their magnetosome chain to determine northward and downward directions, and swim down to nutrient-rich sediments or locate the optimum depth in freshwater and marine habitats. Magnetotactic bacteria in the Southern Hemisphere generally orient southward and downward, with the same result. For the cell to move properly within a magnetic field, magnetosomes must be arranged in a chain. A cytoskeletal protein called MamK is currently thought to be responsible for establishing a framework upon which the chain can form (figure 3.39b).

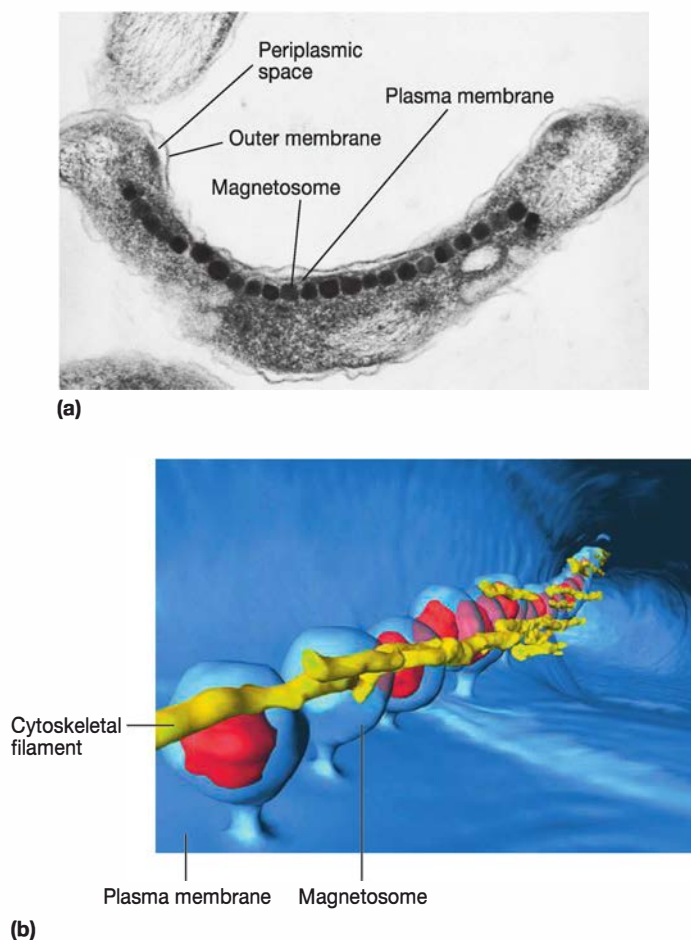

Figure 3.39 Magnetosomes. (a) Transmission electron micrograph of the magnetotactic bacterium *Magnetospirillum magnetotacticum* ($\times 123,000$). (b) An electron cryotomography three-dimensional reconstruction of the magnetosomes of *M. magneticum*.

Bacterial Ribosomes

Ribosomes are the site of protein synthesis, and large numbers of them are found in nearly all cells. The cytoplasm of bacterial cells is often packed with ribosomes, and other ribosomes may be loosely attached to the plasma membrane. The cytoplasmic ribosomes synthesize proteins destined to remain within the cell, whereas plasma membrane-associated ribosomes make proteins that will reside in the cell envelope or are transported to the outside.

Translation, the process of protein synthesis, is amazingly complex and is discussed in detail in chapter 13. This complexity is evidenced in part by the structure of ribosomes, which are made of numerous proteins and several ribonucleic acid (RNA) molecules. The ribosomes of all three domains of life share similarities. However, there are important differences. Here we focus strictly on bacterial ribosomes. We compare bacterial and archaeal ribosomes in chapter 4 and compare all three types of ribosomes in chapter 5.

Bacterial ribosomes are called 70S ribosomes and are constructed of a 50S and a 30S subunit (**figure 3.40**). The S in 70S and similar values stands for **Svedberg unit**. This is the unit of the sedimentation coefficient, a measure of sedimentation velocity in a centrifuge; the faster a particle travels when centrifuged, the greater its Svedberg value or sedimentation coefficient. The sedimentation coefficient is a function of a particle's molecular weight, volume, and shape. Heavier and more compact particles normally have larger Svedberg numbers and sediment faster.

Bacterial ribosomes are composed primarily of ribosomal RNA (rRNA) molecules. The small subunit contains 16S rRNA; 23S and 5S rRNA molecules are in the large subunit. Approximately 55 proteins make up the rest of the mass of the ribosome: 21 in the small subunit, and 34 in the large subunit.

Nucleoid

The **nucleoid** is an irregularly shaped region that contains the cell's chromosome and numerous proteins (**figure 3.41**). The chromosomes of most bacteria are a single circle of double-stranded **deoxyribonucleic acid (DNA)**, but some bacteria have a linear chromosome, and some bacteria, such as *Vibrio cholerae* and *Borrelia burgdorferi* (the causative agents of cholera and Lyme disease, respectively), have more than one chromosome.

Bacterial chromosomes are longer than the length of the cell. An important and still unanswered question is how these microbes manage to fit their chromosomes into the relatively small space occupied by the nucleoid. For instance, *E. coli*'s circular chromosome measures approximately $1,400\ \mu\text{m}$, or about 230–700 times longer than the cell (**figure 3.41b**). Thus the chromosome must be organized and packaged in a manner that decreases its overall size. Supercoiling is thought to be important. It produces a dense, central core of DNA with loops of DNA extending out from the core. Several nucleoid-associated proteins (NAPs) cause the chromosome to bend and fold, thereby also helping to pack the DNA into a smaller space. One NAP found in many bacteria is the protein HU. During cell division, bacterial chromosomes are further compacted by proteins called condensins. This extra level of packing is important for proper segregation of daughter chromosomes during cell division.

For most bacteria, the nucleoid is simply a region in the cytoplasm; it is not separated from other components of the cytoplasm by a membrane. However, there are a few exceptions. Membrane-bound DNA-containing regions are present in at least two genera of the unusual bacterial phylum *Planctomycetes* (see **figure 21.14**). *Pirellula* has a single membrane that surrounds a region called the pirellulosome, which contains a fibrillar nucleoid and ribosome-like particles. The nuclear body of *Gemmata obscuriglobus* is bounded by two membranes. More work is required to determine the functions of these membranes and how widespread this phenomenon is. ►► *Phylum Planctomycetes* (section 21.5)

Figure 3.40 Bacterial Ribosomes. (a–c) Schematic representation of the two subunits and the complete 70S ribosome of *E. coli*. (d) Molecular structure of the 70S ribosome of *Thermus thermophilus*. The 50S subunit (LSU) includes 23S rRNA (gray) and 5S rRNA (lavender), while 16S rRNA (turquoise) is found in the 30S subunit (SSU). A molecule of tRNA (gold) is shown in the A site. To generate this ribbon diagram, crystals of purified bacterial ribosomes were prepared and exposed to X rays, and the resulting diffraction pattern analyzed.

Table 3.3 Major Types of Bacterial Plasmids

| Type | Function | Example | Size (kbp) | Hosts | Phenotypic Features ¹ |
|---|---|----------|------------|--|--|
| Conjugative Plasmids² | Transfer of DNA from one cell to another | F factor | 95–100 | <i>E. coli</i> , <i>Salmonella</i> , <i>Citrobacter</i> | Sex pilus, conjugation |
| R Plasmids | Carry antibiotic-resistance genes | RP4 | 54 | <i>Pseudomonas</i> and many other Gram-negative bacteria | Sex pilus, conjugation, resistance to Amp, Km, Nm, Tet |
| Col Plasmids | Produce bacteriocins, substances that destroy closely related species | ColE1 | 9 | <i>E. coli</i> | Colicin E1 production |
| Virulence Plasmids | Carry virulence genes | Ti | 200 | <i>Agrobacterium tumefaciens</i> | Tumor induction in plants |
| Metabolic Plasmids | Carry genes for enzymes | CAM | 230 | <i>Pseudomonas</i> | Camphor degradation |

¹ Abbreviations used for resistance to antibiotics: Amp, ampicillin; Gm, gentamycin; Km, kanamycin; Nm, neomycin; Tet, tetracycline.

² Many R plasmids, metabolic plasmids, and others are also conjugative.

Plasmids

In addition to the genetic material present in the nucleoid, many bacteria contain extrachromosomal DNA molecules called plasmids. Indeed, most of the bacterial genomes sequenced thus far include plasmids. In some cases, numerous different plasmids within a single species have been identified. For instance, *B. burgdorferi* carries 12 linear and nine circular plasmids. Plasmids play many important roles in the lives of the organisms that have them. They also have proved invaluable to microbiologists and molecular geneticists in constructing and transferring new genetic combinations and in cloning genes, as described in chapter 17.

Plasmids are small, double-stranded DNA molecules that can exist independently of the chromosome. Both circular and linear plasmids have been documented, but most known plasmids are circular. Plasmids have relatively few genes, generally less than 30. Their genetic information is not essential to the bacterium, and cells that lack them usually function normally. However, many plasmids carry genes that confer a selective advantage to the bacterium in certain environments.

Plasmids use the cell's DNA-synthesizing machinery to replicate, but their replication is not linked to any particular stage of the cell cycle. Thus regulation of plasmid and chromosomal replication are independent. However, some plasmids are able to integrate into the chromosome. Such plasmids are called **episomes** and when integrated are replicated as part of the chromosome. Plasmids are inherited stably during cell division, but they are not always equally apportioned into daughter cells and sometimes are lost. The loss of a plasmid is called **curing**. It can occur spontaneously or be induced by treatments that inhibit plasmid replication but not host cell reproduction. Some commonly used curing treatments are acridine mutagens, ultraviolet and ionizing radiation, thymine starvation, antibiotics, and growth above optimal temperatures.

Plasmids may be classified in terms of their mode of existence, spread, and function. A brief summary of the types of bacterial plasmids and their properties is given in **table 3.3**. These various types of plasmids can also differ in terms of the number of copies found within the cell. Single-copy plasmids produce only one copy per host cell. Multi-copy plasmids may be present at concentrations of 40 or more per cell.

Retrieve, Infer, Apply

1. Briefly describe the nature and function of the cytoplasm, and the regions and structures within it.
2. List the most common kinds of inclusions. How are they similar to eukaryotic organelles such as mitochondria and chloroplasts? How do they differ?
3. How do plasmids differ from chromosomes? What is an episome?
4. Explain the importance of each of the following plasmids: conjugative plasmid, R plasmid, Col plasmid, virulence plasmid, and metabolic plasmid.

3.7 External Structures

After reading this section, you should be able to:

- Distinguish pili (fimbriae) and flagella
- Illustrate the various patterns of flagella distribution

Bacteria must constantly respond to their changing environments. Sometimes, it is advantageous to attach to a surface. Other times, it is better to move toward or away from something in the environment. Many bacteria have structures that extend beyond the cell envelope and are involved in either attachment

Figure 3.42 Flagella and Fimbriae. The long flagella and numerous shorter fimbriae are evident in this electron micrograph of the bacterium *Proteus vulgaris* ($\times 39,000$).

to surfaces or motility. In addition, these external structures can function in protection and horizontal gene transfer. Several are discussed in this section.

Bacterial Pili and Fimbriae

Many bacteria have fine, hairlike appendages that are thinner and typically shorter than flagella. These are usually called **fimbriae** (s., **fimbria**) or **pili** (s., **pilus**). The terms are synonymous, although certain structures are always called pilus (e.g., sex pilus), while others are always called fimbriae. We will use the terms interchangeably, except in those instances. A cell may be covered with up to 1,000 fimbriae, but they are only visible in an electron microscope due to their small size (**figure 3.42**). They are slender tubes composed of helically arranged protein subunits and are about 3 to 10 nm in diameter and up to several micrometers long. Several different types of fimbriae have been identified in typical Gram-negative bacteria. Most function to attach cells to solid surfaces such as rocks in streams and host tissues. One type, called type IV pili, are involved in motility (section 3.8) and the uptake of DNA during the process of bacterial transformation. Typical Gram-positive bacteria have at least two types of pili; both are involved in attaching the bacteria to surfaces. ►► *Bacterial transformation* (section 16.7)

Many bacteria have up to 10 **sex pili** (s., **sex pilus**) per cell. These hairlike structures differ from other pili in the following ways. Sex pili often are larger than other pili (around 9 to 10 nm in diameter). They are genetically determined by conjugative plasmids and are required for conjugation. Some bacterial viruses attach specifically to sex pili at the start of their multiplication cycle. ►► *Bacterial conjugation* (section 16.6)

Bacterial Flagella

Many motile bacteria move by use of **flagella** (s., **flagellum**), threadlike locomotor appendages extending outward from the plasma membrane and cell wall. Although the main function of flagella is motility, they can have other roles. They can be involved in attachment to surfaces, and in some bacteria, they are virulence factors. ►► *Microbial growth on solid media* (section 7.5)

Bacterial flagella are slender, rigid structures about 20 nm across and up to 20 μm long. Flagella are so thin they cannot be observed directly with a bright-field microscope but must be stained with techniques designed to increase their thickness. The detailed structure of a flagellum can only be seen in the electron microscope.

Bacterial species often differ in their patterns of flagella distribution, and these patterns are useful in identifying bacteria. **Monotrichous** bacteria (*trichous* means hair) have one flagellum; if it is located at an end, it is said to be a **polar flagellum** (**figure 3.43a**). **Amphitrichous** bacteria (*amphi* means on both sides) have a single flagellum at each pole. In contrast, **lophotrichous** bacteria (*lopho* means tuft) have a cluster of flagella at one or both ends (**figure 3.43b**). Flagella are spread evenly over the whole surface of **peritrichous** (*peri* means around) bacteria (**figure 3.43c**).

Transmission electron microscope studies have shown that the bacterial flagellum is composed of three parts (**figure 3.44**). (1) The longest and most obvious portion is the **filament**, which extends from the cell surface to the tip. (2) The **basal body** is embedded in the cell envelope; and (3) a short, curved segment, the **hook**, links the filament to its basal body and acts as a flexible coupling. The filament is a hollow, rigid cylinder constructed of subunits of the protein **flagellin**, which ranges in molecular mass from 30,000 to 60,000 daltons, depending on the bacterial species. The filament ends with a capping protein. Some bacteria have sheaths surrounding their flagella. For example, *Vibrio cholerae* flagella have lipopolysaccharide sheaths.

The hook and basal body are quite different from the filament (**figure 3.44**). Slightly wider than the filament, the hook is made of different protein subunits. The basal body is the most complex part of a flagellum. The basal bodies of *E. coli* and most other typical Gram-negative bacteria have four rings: L, P, MS, and C, which are connected to a central rod (**figure 3.44a**). The L, P, and MS rings are embedded in the cell envelope, and the C ring is on the cytoplasmic side of the MS ring. Typical Gram-positive bacteria have only two rings: an inner ring connected to the plasma membrane and an outer one probably attached to the peptidoglycan (**figure 3.44b**).

The synthesis of bacterial flagella is complex and involves at least 20 to 30 genes. Besides the gene for flagellin, 10 or more genes code for hook and basal body proteins; other genes are concerned with the control of flagellar construction or function. How the cell regulates or determines the exact location of flagella is not known.

Many components of the flagellum lie outside the cell envelope and are transported out of the cell for assembly.

Figure 3.43 Flagellar Distribution. Examples of various patterns of flagellation as seen in the light microscope. (a) Monotrichous polar (*Pseudomonas*). (b) Lophotrichous (*Spirillum*). (c) Peritrichous (*Proteus vulgaris*, $\times 600$).

Figure 3.44 The Ultrastructure of Bacterial Flagella. Flagellar basal bodies and hooks in (a) typical Gram-negative and (b) typical Gram-positive bacteria.

Interestingly, the basal body is a specialized version of the type III protein secretion system observed in typical Gram-negative bacteria. Type III secretion systems have a needlelike structure through which proteins are secreted. In the flagellar type III secretion system, the filament replaces the needle. Individual flagellin subunits are transported through the hollow filament. When the subunits reach the tip, they spontaneously aggregate under the direction of a protein called the filament cap; thus the filament grows at its tip rather than at the base (**figure 3.45**). Filament synthesis, like S-layer formation, is an

example of **self-assembly**. ►► *Protein maturation and secretion (section 13.8)*

1. What are the functions of fimbriae (pili) and sex pili?
2. What terms are used to describe the different flagella distribution patterns observed among bacteria?
3. What is self-assembly? Why does it make sense that the filament of a flagellum is assembled in this way?

Figure 3.45 Growth of Flagellar Filaments. Flagellin subunits travel through the flagellar core and attach to the growing tip. Their attachment is directed by the filament cap protein.

3.8 Bacterial Motility and Chemotaxis

After reading this section, you should be able to:

- Compare and contrast flagellar swimming motility, spirochete flagellar motility, and twitching and gliding motility
- State the source of energy that powers flagellar motility
- Explain why bacterial chemotaxis is referred to as a “biased random walk”

As we note in section 3.7, several structures extending beyond bacterial cell envelopes contribute to motility. Five major methods of movement have been observed: swimming movement conferred by flagella; flagella-mediated swarming; corkscrew movement of spirochetes; twitching motility associated with type IV pili; and gliding motility.

Motile bacteria do not move aimlessly. Rather, motility is used to move toward nutrients such as sugars and amino acids and away from many harmful substances and bacterial waste products. Movement toward chemical attractants and away from repellents is known as chemotaxis. Motile bacteria also can move in response to environmental cues such as temperature (thermotaxis), light (phototaxis), oxygen (aerotaxis), osmotic pressure (osmotaxis), and gravity.

Flagellar Movement

Swimming

The filament of a bacterial flagellum is in the shape of a rigid helix, and the cell moves when this helix rotates like a propeller on a boat. The flagellar motor can rotate very rapidly. The *E. coli*

motor rotates 270 revolutions per second (rps); *Vibrio alginolyticus* averages 1,100 rps. When bacteria are in an aquatic environment, flagellar rotation results in two types of movement: a smooth swimming movement often called a **run**, which actually moves the cell from one spot to another, and a **tumble**, which serves to reorient the cell. Often, the direction of flagellar rotation determines whether a run or a tumble occurs. For many bacteria with monotrichous, polar flagella, counterclockwise rotation results in a run (figure 3.46). When rotation is reversed, the cell tumbles. Peritrichously flagellated bacteria operate in a somewhat similar way. To move forward in a run, the flagella rotate counterclockwise. As they do so, the flagella bend at their hooks to form a rotating bundle that propels the cell forward. Clockwise rotation of the flagella disrupts the bundle and the cell tumbles.

The motor that drives flagellar rotation is located at the base of the flagellum. Torque generated by the motor is transmitted to the hook and filament. The motor is composed of two components: the rotor and the stator. It is thought to function like an electrical motor, where the rotor turns in the center of a ring of electromagnets, the stator. In typical Gram-negative bacteria, the rotor is composed of the MS ring and the C ring (figure 3.47). The C ring protein, FliG, is particularly important because it is thought to interact with the stator. The stator is composed of the proteins MotA and MotB, which form a channel through the plasma membrane. MotB also anchors MotA to cell wall peptidoglycan.

As with all motors, the flagellar motor must have a power source that allows it to generate torque and cause flagellar rotation. The power used by most flagellar motors is a difference in charge and pH across the plasma membrane. This difference is

Figure 3.46 Flagellar Motility. The relationship of flagellar rotation to bacterial movement. Parts (a) and (b) describe the motion of monotrichous, polar bacteria. Parts (c) and (d) illustrate the movements of peritrichous organisms.

called the proton motive force (PMF). PMF is largely created by the metabolic activities of organisms, as described in chapter 11. One important metabolic process is the transfer of electrons from an electron donor to a terminal electron acceptor via a chain of electron carriers called the electron transport chain (ETC). In bacterial cells, most components of the ETC are located in the plasma membrane. As electrons are transported down the ETC, protons are transported from the cytoplasm to the outside of the cell. Because there are more protons outside the cell than inside, the outside has more positively charged ions (the protons) and a lower pH. PMF is a type of potential energy that can be used to do work: mechanical work, as in the case of flagellar rotation; transport work, the movement of materials into or out of the cell; or chemical work such as the synthesis of ATP, the cell's energy currency.

How can PMF be used to power the flagellar motor? The channels created by the MotA and MotB proteins allow protons to move across the plasma membrane from the outside to the inside (figure 3.47). Thus the protons move down the charge and

Figure 3.47 Mechanism of Flagellar Movement. (a) This diagram of a flagellum shows some of the more important components and the flow of protons that drives rotation. Five of the many flagellar proteins are labeled. (b) A three-dimensional electron cryotomographic reconstruction of the flagellar motor.

MICRO INQUIRY Would this flagellum be found in a typical Gram-negative or Gram-positive bacterium?

pH gradient. This movement releases energy that is used to rotate the flagellum. In essence, the entry of a proton into the channel is like the entry of a person into a revolving door. The "power" of the proton generates torque, rather like a person pushing the revolving door. Indeed, the speed of flagellar rotation is

proportional to the magnitude of the PMF. ►► *Electron transport and oxidative phosphorylation* (section 11.6)

The flagellum is a very effective swimming device. From the bacterium's point of view, swimming is quite a difficult task because the surrounding water seems as viscous as molasses. The cell must bore through the water with its corkscrew-shaped flagella, and if flagellar activity ceases, it stops almost instantly. Despite such environmental resistance to movement, bacteria can swim from 20 to almost 90 μm per second. This is equivalent to traveling from 2 to over 100 cell lengths per second. In contrast, an exceptionally fast human might be able to run around 5 to 6 body lengths per second.

Swarming

An increasing number of bacterial species has been found to exhibit an interesting type of motility called swarming. This motility occurs on moist surfaces and is a type of group behavior in which cells move in unison across the surface. Most bacteria that swarm have peritrichous flagella. Many also produce and secrete molecules that help them move across the substrate. When bacteria that swarm are cultured in the laboratory on appropriate solid media, they produce characteristic colony morphologies (figure 3.48).

Spirochete Motility

Spirochetes have flagella that work in a distinctive manner. In many spirochetes, multiple flagella arise from each end of the

cell, intertwine, and wind around the cell (figure 3.49). The flagella do not extend outside the cell wall but rather remain in the periplasmic space and are covered by the outer membrane. They are called periplasmic flagella and are thought to rotate like the external flagella of other bacteria, causing the corkscrew-shaped outer membrane to rotate and move the cell through the surrounding liquid, even very viscous liquids. Flagellar rotation may also flex or bend the cell and account for the creeping or crawling movement observed when spirochetes are in contact with a solid surface. ►► *Phylum Spirochaetes* (section 21.7)

Twitching and Gliding Motility

Twitching and gliding motility occur when cells are on a solid surface. Both types of motility can involve type IV pili, the production of slime, or both. Thus they are considered together. The gliding motility of *Flavobacterium* spp. and *Mycoplasma* spp. are distinctive and are considered in detail in chapter 21. ►► *Phylum Bacteroidetes* (section 21.8); *Class Mollicutes* (*Phylum Tenericutes*) (section 21.3)

Type IV pili are present at one or both poles of some bacteria and are involved in twitching motility and in the gliding motility of some bacteria. **Twitching motility** is characterized by short, intermittent, jerky motions of up to several micrometers in length and is normally seen on very moist surfaces. The pili are thought to alternately extend and retract to move bacteria during twitching motility. The extended

Figure 3.48 Swarming Bacteria Often Produce Distinctive Patterns on a Solid Growth Medium. These bacterial cells swarmed out from the center of the plate and produced a branching pattern called dendrites.

(a)

(b)

Figure 3.49 Spirochete Flagella. (a) Numerous flagella arise from each end of the spirochete. These intertwine and wind around the cell, usually overlapping in the middle. (b) Electron cryotomographic surface view of the spirochete *Treponema denticola* showing three flagella arising from the tip of the cell.

pilus contacts the surface at a point some distance from the cell body. When the pilus retracts, the cell is pulled forward. Hydrolysis of ATP likely powers the extension/retraction process.

Gliding motility is smooth and varies greatly in rate (from 2 to over 600 μm per minute) and in the nature of the motion. Although first observed over 100 years ago, the mechanism by which many bacteria glide remains a mystery. Some glide along in a direction parallel to the longitudinal axis of their cells. Others travel with a screwlike motion or even move in a direction perpendicular to the long axis of the cells. Still others rotate around their longitudinal axis while gliding. Such diversity in gliding movement correlates with the observation that more than one mechanism for gliding motility exists. Some types involve type IV pili, some involve slime, and some involve mechanisms that have not yet been elucidated.

The motility of the bacterium *Myxococcus xanthus* is well studied because it exhibits two types of motility. One type is called social (S) motility because it occurs when large groups of cells move together in a coordinated fashion. It is mediated by type IV pili, as we have just described. The other type of motility is by gliding and is called adventurous (A) motility; it is observed when single cells move independently. A recent study suggests that proteins similar to MotA and MotB of the flagellar motor function as the motors for gliding motility. They are thought to be in the cytoplasmic membrane (like flagellar motors) and are associated with other proteins, forming relatively large protein complexes. Additional proteins connect the motors to MreB, a cytoskeletal protein (section 3.6). Other proteins connect the motors to the substrate along which the cell glides. The

motors are powered by PMF. How the action of the motor complexes are translated into gliding motility is still unknown. However, some researchers have suggested that the surface of the cell is deformed by these protein complexes, creating pressure waves in the slime secreted by the bacterium. This propels the cell forward in a manner not unlike that observed when snails crawl. ►► *Order Myxococcales (section 22.4)*

Chemotaxis

As noted earlier, bacteria exhibit taxes to a variety of stimuli, including light and oxygen. The movement of cells toward chemical attractants or away from chemical repellents (**chemotaxis**) is the best-studied type of taxis. Chemotaxis is readily observed in Petri dish cultures. If bacteria are placed in the center of a dish of semisolid agar containing an attractant, the bacteria will exhaust the local supply of the nutrient and swim outward following the attractant gradient they have created. The result is an expanding ring of bacteria (**figure 3.50a**). When a disk of repellent is placed in a Petri dish of semisolid agar and bacteria, the bacteria will swim away from the repellent, creating a clear zone around the disk (**figure 3.50b**).

Attractants and repellents are detected by **chemoreceptors**, proteins that bind chemicals and transmit signals to other components of the chemosensing system. The chemosensing systems are very sensitive and allow the cell to respond to very low levels of attractants (about 10^{-8} M for some sugars). In typical Gram-negative bacteria, the chemoreceptor proteins are located in the plasma membrane. Some receptors also participate in the initial stages of sugar transport into the cell.

Figure 3.50 Positive and Negative Bacterial Chemotaxis. (a) Positive chemotaxis can be demonstrated on an agar plate that contains various nutrients; positive chemotaxis by *E. coli* is shown on the left. The outer ring is composed of bacteria consuming serine. The second ring was formed by *E. coli* consuming aspartate, a less powerful attractant. (b) Negative chemotaxis by *E. coli* in response to the repellent acetate. The bright disks are plugs of concentrated agar containing acetate that have been placed in dilute agar inoculated with *E. coli*. Acetate concentration increases from zero at the top right to 3 M at top left. Note the increasing size of bacteria-free zones with increasing acetate. The bacteria have migrated for 30 minutes.

Figure 3.51 Directed Movement in Bacteria. (a) Random movement of a bacterium in the absence of a concentration gradient. Tumbling frequency is fairly constant. (b) Movement in an attractant gradient. Tumbling frequency is reduced when the bacterium is moving up the gradient. Therefore runs in the direction of increasing attractant are longer.

The chemotactic behavior of bacteria has been studied using the tracking microscope, a microscope with a moving stage that automatically keeps an individual bacterium in view. In the absence of a chemical gradient, bacteria move randomly, switching back and forth between a run and a tumble. During a run, the bacterium swims in a straight or slightly curved line. After a few seconds, the bacterium stops and tumbles. The tumble randomly reorients the bacterium so that it often is facing in a different direction. Therefore when it begins the next run, it usually goes in a different direction (figure 3.51a). In contrast, when the bacterium is exposed to an attractant, it tumbles less frequently (or has longer runs) when traveling toward the attractant. Although the tumbles can still orient the bacterium away from the attractant, over time the bacterium gets closer and closer to the attractant (figure 3.51b). The opposite response occurs with a repellent. Tumbling frequency decreases (the run time lengthens) when the bacterium moves away from the repellent.

Clearly, the bacterium must have some mechanism for sensing that it is getting closer to the attractant (or moving away from the repellent). The behavior of the bacterium is shaped by temporal changes in chemical concentration. The bacterium is able to compare the current concentration with the concentration a few seconds earlier. If the concentration of the attractant is increasing, tumbling is suppressed. Likewise, the bacterium moves away from a repellent because it senses that the concentration of the repellent is decreasing. The bacterium's chemoreceptors play a critical role in this process. The molecular events that enable bacterial cells to sense a chemical gradient and respond appropriately are presented in chapter 14.

Retrieve, Infer, Apply

1. Describe the way many flagella operate to move a bacterium.
2. How does swimming differ from swarming?
3. Explain in a general way how bacteria move toward substances such as nutrients and away from toxic materials.
4. Suggest why chemotaxis is sometimes called a "biased random walk."

3.9 Bacterial Endospores

After reading this section, you should be able to:

- Describe the structure of a bacterial endospore
- Explain why bacterial endospores are of particular concern to the food industry and why endospore-forming bacteria are important model organisms
- Describe in general terms the process of sporulation
- Describe those properties of endospores that are thought to contribute to its resistance to environmental stresses
- Describe the three stages that transform an endospore into an active vegetative cell

Endospores, dormant cells formed within a so-called mother cell, are fascinating bacterial structures only produced by certain members of the genera *Bacillus* and *Clostridium* (rods), and *Sporosarcina* (cocci) within the phylum *Firmicutes*. There are several reasons why endospores have long held the interest of microbiologists. The primary reason is that endospores are extraordinarily resistant to environmental stresses such as heat, ultraviolet radiation, gamma radiation, chemical disinfectants, and desiccation. In fact, some endospores have remained viable for around 100,000 years. Another important reason is that several species of endospore-forming bacteria are dangerous pathogens. For example, *Clostridium botulinum* causes botulism, a food-borne disease that results from ingestion of botulinum toxin, the deadliest toxin known. In order to prevent botulism, food must be prepared and stored properly. The extreme heat resistance of *C. botulinum*'s endospores is a major concern of the food industry. *Bacillus anthracis* causes the deadly disease inhalational anthrax, which occurs when spores are inhaled and germinate in the lungs. *B. anthracis* spores can be produced in a laboratory and used as a bioterrorism agent, as was done in 2001 in the United States (p. 22). Other medically important endospore-forming bacteria include *C. tetani* (causes tetanus) and *C. perfringens* (causes gas gangrene and food poisoning). Clearly, endospores are of great practical importance in food, industrial, and medical microbiology. Endospores also are of considerable interest to scientists because of their complex structures and the equally complex process that generates them. Over the decades, microbiologists have asked many questions about endospores and endospore formation. (1) How are endospores structurally different from vegetative cells? (2) What makes them so resistant to harsh environmental conditions? (3) What triggers endospore formation? (4) What are the steps in endospore formation and how is the process regulated? (5) How do spores convert back to vegetative cells? In this section, we relate

Figure 3.52 Bacterial Endospores. (a) A schematic showing the various layers of an endospore. They are not drawn to scale. (b) A colored cross section of a *Bacillus subtilis* cell undergoing sporulation. The oval in the center is an endospore that is almost mature; when it reaches maturity, the mother cell will lyse to release it.

some of the answers to these questions. We save the consideration of regulating spore formation for chapter 14. ►► *Sporulation in Bacillus subtilis* (section 14.5)

Endospore Structure and Resistance

Electron microscopy has been an important tool for dissecting endospore structure. Electron micrographs show that the spore consists of a core surrounded by several layers that vary significantly in composition. The core has normal cell structures such as ribosomes and a nucleoid but has very low water content (figure 3.52). The core is surrounded by an inner membrane, which is in turn covered by the core wall (also called the germ cell wall, as it contains the peptidoglycan that will form the wall of the vegetative cell that grows out of the spore following germination). Next is the cortex, which may occupy as much as half the spore volume. It is made of peptidoglycan that is less cross-linked than that in vegetative cells. The cortex is surrounded by a phospholipid bilayer called the outer membrane. Outside of the outer membrane is the coat. It is composed of more than 50 different proteins, which are highly cross-linked to each other. Finally, many endospore-forming bacteria produce spores enclosed by a thin, delicate covering called the exosporium.

The ability of the spore to survive heat, radiation, and damaging chemicals requires that its enzymes and DNA be protected.

The various layers of the spore contribute to this resistance in several ways. The spore coat protects the spore from chemicals and various lytic enzymes such as lysozyme. The inner membrane is extremely impermeable to various chemicals, including those that cause DNA damage. The core has very low water content, high amounts of dipicolinic acid complexed with calcium ions (Ca-DPA), and a slightly lower pH, all of which contribute to the spore's resistance to harsh conditions. Evidence exists that the water content of the core is low enough to prevent rotation of enzymes and other proteins present. However, it is not low enough to prevent denaturation of the proteins. It has been suggested that the immobilization of the proteins prevents them from interacting with each other and becoming entangled. Thus, even though they may become denatured, they are able to refold to their proper active structure as the spore germinates. The spore's DNA is protected by two main mechanisms. Ca-DPA complexes are inserted between the nitrogenous bases of DNA, which helps stabilize it. The DNA is further stabilized by small, acid-soluble DNA-binding proteins (SASPs), which saturate spore DNA. There are several types of SASPs; the α/β type plays a major role in environmental resistance.

Sporulation: Making Endospores

Endospore-forming bacteria are common in soil, where they must be able to withstand fluctuating levels of nutrients. Sporulation (endospore formation) normally commences when growth ceases due to lack of nutrients. Thus it is a survival mechanism that allows the bacterium to produce a dormant cell that can survive until nutrients are again available and vegetative growth can resume. These bacteria cycle between two states: vegetative growth and survival as an endospore. Vegetative growth is the normal, continuous cycle of growth and division. By contrast, sporulation is a complex process that occurs in a highly organized fashion over several hours. The mature endospore is located in a characteristic location in the mother cell (referred to as the sporangium), depending on the species of bacteria. Endospores may be centrally located, close to one end (subterminal), or terminal (figure 3.53). Sometimes an endospore is so large that it swells the sporangium. One of the best-studied

Figure 3.53 Examples of Endospore Location and Size.

Figure 3.54 Endospore Formation. The stages are indicated by Roman numerals.

endospore formers is *Bacillus subtilis*, which is an important model organism.

Sporulation may be divided into seven stages (figure 3.54). The cell's DNA is replicated (stage I), followed by an inward folding of the cell membrane to enclose part of the DNA and produce the forespore septum (stage II). The mother cell membrane continues to grow and engulfs the immature endospore in a second membrane (stage III). Next, cortex is laid down in the space between the two membranes, and both calcium and dipicolinic acid are accumulated (stage IV). Protein coats are formed around the cortex (stage V), and maturation of the endospore occurs (stage VI). Finally, lytic enzymes destroy the sporangium, releasing the spore (stage VII). Sporulation requires about 10 hours in *Bacillus megaterium*. 🌀 *Bacterial Spore Formation*

Endospore to Vegetative Cell

The transformation of dormant spores into active vegetative cells is almost as complex as sporulation. It occurs in three stages: (1) activation, (2) germination, and (3) outgrowth (figure 3.55). Activation is a process that prepares spores for germination and can result from treatments such as heating.

This is followed by germination, the breaking of the spore's dormant state. It begins when proteins called germinant receptors, located in the inner membrane, detect small molecules

Figure 3.55 Endospore Germination. *Clostridium pectinovorum* emerging from the spore during germination.

such as sugars and amino acids. Upon detection of these molecules, a series of events occur, including release of the Ca-DPA complexes, breakdown of the peptidoglycan in the cortex, and water uptake. Eventually water levels inside the germinating spore reach those characteristic of vegetative cells and enzymes in the core become active. This allows the spore to begin synthesizing the various molecules it needs to initiate spore outgrowth and return to a vegetative state.

Retrieve, Infer, Apply

1. Describe the structure of the bacterial endospore using a labeled diagram.
2. Briefly describe endospore formation and germination. What is the importance of the endospore?
3. What features of the endospore contribute to its resistance to harsh conditions?

Key Concepts

3.1 The “Prokaryote” Controversy

- Bacteria and archaea are often considered to be related because they share a common cell architecture. However, they are now known to have distinct characteristics and evolutionary lineages.
- Recent discoveries that challenge traditional notions of what a prokaryote is include the discovery of membrane-bound organelles in some bacteria and cytoskeletal elements in both bacteria and archaea.

3.2 A Typical Bacterial Cell

- Rods (bacilli) and cocci (spheres) are common bacterial shapes. In addition, bacteria may be comma-shaped (vibrio), spiral (spirillum and spirochetes), or filamentous; they may form buds and stalks; or they may have no characteristic shape (pleomorphic) (**figures 3.1 and 3.2**).
- Some cells remain together after division to form pairs, chains, and clusters of various sizes and shapes.
- Frequently observed bacterial cell structures include a cell wall, plasma membrane, cytoplasm, nucleoid, fimbriae, inclusions, capsule, ribosomes, and flagella (**figure 3.6**). **Table 3.1** summarizes the major functions of these structures.

3.3 Bacterial Plasma Membranes

- The cell envelope consists of the plasma membrane and all external coverings, including the cell wall and other layers (e.g., capsules).
- The bacterial plasma membrane fulfills many roles, including acting as a semipermeable barrier, carrying out respiration and photosynthesis, and detecting and responding to chemicals in the environment.
- The fluid mosaic model proposes that cell membranes are lipid bilayers in which integral membrane proteins are buried. Peripheral membrane proteins are loosely associated with the membrane (**figure 3.7**).
- Bacterial membranes are bilayers composed of phospholipids constructed of fatty acids connected to glycerol by ester linkages (**figure 3.8**). Bacterial membranes usually lack sterols but often contain hopanoids (**figure 3.9**).

- Microorganisms require nutrients, materials that are used in energy conservation and biosynthesis. Macronutrients are needed in relatively large quantities. Micronutrients (trace elements) are used in very small amounts.
- In passive diffusion, a substance moves through the membrane on its own. Movement is down a concentration gradient and does not require an input of energy. Only a few substances enter cells by passive diffusion.
- Transport proteins are divided into two major types: channels and carriers. Channels create a pore through which a substance moves. Carriers are so called because they carry the molecule across the membrane.
- In facilitated diffusion, a transport protein (either a channel or a carrier) helps move substances in the direction of decreasing concentration; no metabolic energy is required (**figure 3.11**). Facilitated diffusion is not an important uptake mechanism for bacterial cells.
- Active transport systems use metabolic energy and carrier proteins to concentrate substances by transporting them against a gradient. ATP is used as an energy source by ABC transporters, a type of primary active transporter (**figure 3.13**). ABC transporters are uniporters (one substance is transported). Gradients of ions drive solute uptake in secondary active transport systems. Secondary active transporters are either symporters (two substances are transported in the same direction) or antiporters (two substances are transported in opposite directions) (**figure 3.12**).
- Group translocation is a type of active transport in which bacterial cells transport organic molecules while modifying them (**figure 3.14**).
- The secretion of siderophores, which bind ferric iron, enables the accumulation of iron within bacterial cells (**figure 3.15**).

3.4 Bacterial Cell Walls

- The vast majority of bacteria have a cell wall outside the plasma membrane to help maintain their shape and protect them from osmotic stress.
- Bacterial walls are chemically complex and usually contain peptidoglycan (**figures 3.16–3.22**). Typical

Gram-positive walls have thick, homogeneous layers of peptidoglycan and teichoic acids (**figures 3.23 and 3.24**). Typical Gram-negative bacteria have a thin peptidoglycan layer surrounded by a complex outer membrane containing lipopolysaccharides (LPSs) and other components (**figures 3.25 and 3.26**). The lipid A portion of LPS is also called endotoxin. Its release into the human body can lead to septic shock.

- The mechanism of the Gram stain is thought to depend on the thickness of peptidoglycan. The thick peptidoglycan of typical Gram-positive bacteria binds crystal violet tightly, preventing its loss during the ethanol wash.

3.5 Cell Envelope Layers Outside the Cell Wall

- Capsules, slime layers, and glycocalyxes are layers of material lying outside the cell wall. They can protect cells from certain environmental conditions, allow cells to attach to surfaces, and protect pathogenic bacteria from host defenses (**figures 3.29 and 3.30**).
- S-layers are the external-most layer in some bacteria. They are composed of proteins or glycoprotein and have a characteristic geometric shape (**figure 3.31**).

3.6 Bacterial Cytoplasm

- The bacterial cytoplasm contains proteins that are similar in structure and function to the cytoskeletal proteins observed in eukaryotes (**figure 3.32 and table 3.2**).
- Some bacteria have simple internal membrane systems containing photosynthetic and respiratory machinery (**figure 3.33**).
- Inclusions are observed in all cells. Most are used for storage (e.g., PHB inclusions and polyphosphate granules) (**figures 3.35 and 3.36**), but some are used for other purposes (e.g., magnetosomes and gas vacuoles) (**figures 3.38 and 3.39**). Microcompartments such as carboxysomes contain enzymes that catalyze important reactions (e.g., CO₂ fixation; **figure 3.37**).
- Bacterial ribosomes are 70S in size. They are composed of numerous proteins and several rRNA molecules (**figure 3.40**).
- The genetic material of bacterial cells is located in an area within the cytoplasm called the nucleoid. The nucleoid is not usually enclosed by a membrane (**figure 3.41**). In most bacteria, the nucleoid contains a single chromosome. The chromosome usually consists of a double-stranded, covalently closed, circular DNA molecule.
- Plasmids are extrachromosomal DNA molecules found in many bacteria. Some are episomes—plasmids that are able to exist freely in the cytoplasm or can be integrated into the chromosome. Although plasmids are not required for survival in most conditions, they can encode traits that confer selective advantage in some environments. Many types of plasmids have been identified (**table 3.3**).

3.7 External Structures

- Many bacteria have hairlike appendages called fimbriae or pili. Fimbriae function primarily in attachment to surfaces, but type IV pili are involved in twitching motility. Sex pili participate in the transfer of DNA from one bacterium to another (**figure 3.42**).
- Many bacteria are motile, often by means of threadlike, locomotory organelles called flagella. Bacterial species differ in the number and distribution of their flagella (**figure 3.43**). Each bacterial flagellum is composed of a filament, hook, and basal body (**figure 3.44**).

3.8 Bacterial Motility and Chemotaxis

- Several types of bacterial motility have been observed: swimming by flagella, swarming by flagella, spirochete motility, twitching motility, and gliding motility.
- The bacterial flagellar filament is a rigid helix that rotates like a propeller to push the bacterium through water (**figures 3.46 and 3.47**). When bacteria swim, they usually alternate between two types of movement: a smooth swimming motion called a run and tumbling.
- Some bacterial species move as a group in a behavior called swarming. Swarming is mediated by flagella and occurs on moist surfaces.
- Spirochete motility is brought about by flagella that are wound around the cell and remain within the periplasmic space. When they rotate, the outer membrane of the spirochete is thought to rotate, thus moving the cell (**figure 3.49**).
- Twitching and gliding motility are similar in that both occur on moist surfaces and can involve type IV pili and the secretion of slime. Twitching motility is a jerky movement, whereas gliding motility is smooth.
- Motile cells can respond to gradients of attractants and repellents, a phenomenon known as chemotaxis. A peritrichously flagellated bacterium accomplishes movement toward an attractant by increasing the length of time it spends moving toward the attractant and shortening the time it spends tumbling (**figure 3.51**). Conversely, a bacterium increases its run time when it moves away from a repellent.

3.9 Bacterial Endospores

- Some bacteria survive adverse environmental conditions by forming endospores, dormant structures resistant to heat, desiccation, and many chemicals (**figure 3.52**).
- Both endospore formation and germination are complex processes made in response to certain environmental signals (**figures 3.54 and 3.55**).

Compare, Hypothesize, Invent

1. Propose a model for the assembly of a flagellum in a typical Gram-positive cell envelope.
2. The peptidoglycan of bacteria has been compared with the chain mail worn beneath a medieval knight's suit of armor. It provides both protection and flexibility. Describe other structures in biology that have an analogous function. How are they replaced or modified to accommodate the growth of the inhabitant?
3. Why might a microbe have more than one uptake system for certain substrates?
4. Design an experiment that illustrates the cell wall's role in protecting against lysis.
5. What would you expect to observe if you were able to "transplant" CreS into a rod-shaped bacterium such as *Bacillus subtilis*?
6. Develop a hypothesis to explain why gas vacuoles are bounded by proteins rather than a lipid bilayer membrane.
7. In 2009 it was reported that a member of the genus *Mycobacterium* was able to form endospores. This was greeted with surprise and skepticism because mycobacteria had always been thought to be non-endospore formers. Design a set of experiments that would determine if a bacterium produces true endospores. Explain your experimental design.

Archaeal Cell Structure

Cows and Buffaloes and Sheep, Oh My!

The next time you drive or walk through the countryside near your home, count the number of domesticated ruminants you see—dairy cows, beef cattle, sheep, and goats, among others. It is estimated that there are about 3 billion head worldwide. These animals are important because they are a substantial protein source. But they do something else that is noteworthy: each year they exhale about 200 million metric tons of methane, a potent greenhouse gas (GHG for short). The manure these and other domesticated animals produce is thought to release another 18 million metric tons of methane. Carbon dioxide is an important GHG and is considered to be a significant contributor to global warming. Methane and nitrous oxide are also GHGs. Carbon dioxide is the dominant GHG in the atmosphere. However, methane has about 20 times the heat-retaining capacity of carbon dioxide. Thus, although the contribution of methane by domesticated ruminants and their manure represents only about 5% of the total GHG emissions worldwide each year, the impact of these emissions is of concern. But don't blame the animals; they are not directly responsible for generating methane. Rather, it is a unique group of archaea—the methanogens—that make methane from hydrogen gas, carbon dioxide, and acetate. Furthermore, these substrates arise in the animals as their food is digested with the help of a complex community of microbes living in the rumen. For the animal, methane is a waste product; for the farmer or rancher, methane represents a loss in production (e.g., less milk produced or muscle made). As you might imagine, there is considerable interest in figuring out how to decrease methane production so that GHG emissions are lowered and the farmer or rancher can earn more from each animal.

Methanogens are only one physiological group in domain *Archaea*. Other archaea have attracted attention because of their ability to live in extreme environments. All are of interest because of their chimeric

Dairy cows such as this Holstein are one group of ruminant animals that contribute methane to Earth's atmosphere. The methane is produced by methanogens living in the rumen of the animal and is released when the animal breathes. Methane has about 20 times the heat-retaining capacity of carbon dioxide.

natures: they have some features that are similar to bacteria and some that are similar to eukaryotes. Their cell structure is like that of bacteria; that is, they look like the canonical prokaryotic cell. However, the molecules used to construct their cell structures are often unique or are similar to those found in eukaryotes. Furthermore, as we describe in chapters 15 and 20, their physiologies exhibit this dichotomy as well. In general, the processes and molecules used to conserve energy are like those of bacteria, whereas the processes and molecules used to replicate and express their genomes are like those of eukaryotes. In this chapter, we describe some of the molecular and structural aspects of archaeal cells that set them apart.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Summarize the structures observed in bacterial cells and their molecular makeup
- ✓ Describe the mechanisms used by bacteria to obtain nutrients

4.1 A Typical Archaeal Cell

After reading this section, you should be able to:

- Describe a typical archaeal cell

Recall that for many years, archaea and bacteria had been lumped together and referred to as prokaryotes. Today *Archaea* and *Bacteria* are recognized as distinct taxa. Archaeal taxonomy is currently in a state of flux, but two phyla are well established: *Crenarchaeota* and *Euryarchaeota*. The separation of bacteria and archaea into distinct taxa correlates with the observation that they each have unique and distinguishing characteristics. Some of these are summarized in **table 4.1**. Here we begin our discussion of archaeal cells by considering overall cell morphology and organization and then specific cell structures.

Table 4.1 Comparison of Bacterial and Archaeal Cells

| Property | Bacteria | Archaea |
|--------------------------|--|--|
| Plasma membrane lipids | Ester-linked phospholipids and hopanoids form a lipid bilayer; some have sterols | Glycerol diethers form lipid bilayers; glycerol tetraethers form lipid monolayers |
| Cell wall constituents | Peptidoglycan is present in nearly all; some lack cell walls | Very diverse but peptidoglycan is always absent: some consist of S-layer only, others combine S-layer with polysaccharides or proteins or both; some lack cell walls |
| Inclusions present | Yes, including gas vacuoles | Yes, including gas vacuoles |
| Ribosome size | 70S | 70S |
| Chromosome structure | Most are circular, double-stranded (ds) DNA; usually a single chromosome | All known are circular, dsDNA |
| Plasmids present | Yes; circular and linear dsDNA | Yes; circular dsDNA |
| External structures | Flagella, fimbriae (pili) common | Flagella, pili, and piluslike structures common |
| Capsules or slime layers | Common | Rare |

Shape, Arrangement, and Size

Archaeal cells, like bacterial cells, exhibit a variety of shapes. **Cocci** and **rods** are common (**figure 4.1a,b**). Both usually exist singly, but some cocci form clusters and some rods form chains. Curved rods, spiral shapes, and pleomorphic (many shaped) archaea have also been observed. To date, no spirochete-like and mycelial archaea have been discovered. However, some archaea exhibit unique shapes, such as the branched form of *Thermoproteus tenax* (**figure 4.1c**) and the flat, postage-stamp-shaped *Haloquadratum walsbyi*, an archaeon that lives in salt ponds and measures about 2 μm by 2 to 4 μm and only 0.25 μm thick (**figure 4.1d**). This shape has the advantage of greatly increasing the surface area-to-volume (S/V) ratio (*see figure 3.5*), which in turn increases efficiency of nutrient uptake, diffusion of molecules, and growth rate. **◀◀** A typical bacterial cell (*section 3.2*)

Archaeal cells also vary in size as much as in shape. Typical rods are 1 to 2 μm wide by 1.0 to 5.0 μm long; cocci are typically 1 to 3 μm in diameter. However, extremely small and extremely large archaea have been identified. Several free-living, acid-loving (acidophilic), mine-dwelling microbes measure a mere 0.2 to 0.4 μm in diameter. Also at the small end of the size continuum is the parasitic archaeon *Nanoarchaeum equitans* (0.4 μm in diameter). At the other extreme are two recently observed giant archaea that form long filaments up to 30 mm in length. For one archaeon, the filament is composed of numerous cells, each measuring 8 to 10 μm wide by 20 to 24 μm long. An interesting characteristic of this archaeon is that its filaments are coated with a bacterial biofilm (**figure 4.2**). The nature of this interaction is not known, but it is thought that the archaeon is the host and the bacteria are symbionts.

Cell Organization

Structures observed in members of both *Bacteria* and *Archaea* are summarized and their differences noted in table 4.1. The archaeal plasma membrane is composed of strikingly different lipids than those found in bacterial membranes; in fact, the unusual lipids were one of the first pieces of evidence to suggest that these microbes are phylogenetically distinct from bacteria. Most archaea have a cell wall, but their walls are considerably more diverse than bacterial walls. Notably, archaeal cell walls lack peptidoglycan. Capsules are not widespread among those archaea examined thus far. Within the archaeal cytoplasm, a nucleoid, ribosomes, and inclusions can be found. Finally, many archaea use flagella for locomotion.

In the remaining sections of this chapter, we describe the major structures observed in archaea in more detail, noting the aspects that distinguish them from the analogous bacterial structures. Understanding archaeal structures at the molecular level is an area of intense research because many archaea are found in extreme habitats. We note those structural adaptations that contribute to this lifestyle in the discussions. However, the topic of survival in extreme habitats is considered more thoroughly in chapter 7. **▶▶** Influences of environmental factors on growth (*section 7.3*)

Retrieve, Infer, Apply

1. Which cell shapes are observed in members of both *Bacteria* and *Archaea*? Which are unique to bacteria? Which to archaea?
2. *Archaea* was first defined as a distinct taxon by comparisons of ribosomal RNA sequences. Identify two other molecules that could be used to determine if a microbe having a typical prokaryotic architecture is a bacterium or an archaeon.

(a) *Methanobrevibacter smithii*—oval-to-short rod-shaped cells

(b) *Methanosarcina mazei*—a coccus that forms clusters

(c) *Thermoproteus tenax*—a branched archaeal cell

(d) *Haloquadratum walsbyi*—a square archaeon

Figure 4.2 A Giant Archaeon. *Candidatus Giganthauma karukerense* forms long filaments that are covered with a bacterial biofilm. The bacteria may be symbionts of the host archaeon.

4.2 Archaeal Cell Envelopes

After reading this section, you should be able to:

- Draw an archaeal cell envelope and identify the component layers
- Compare and contrast archaeal and bacterial cell envelopes in terms of their structure, molecular makeup, and functions
- Compare and contrast nutrient uptake mechanisms observed in bacteria and archaea

We define the **cell envelope** as the plasma membrane and any layers external to it. For bacteria, these extra layers include cell walls, S-layers, capsules, and slime layers. One of the most

distinctive features of archaeal cells is the nature of their cell envelopes. Their uniqueness begins with their plasma membranes. Recall from chapter 3 that the fluid mosaic model describes membranes as lipid bilayers within which proteins float (see figure 3.7). The model is based on studies of eukaryotic and bacterial membranes and is well established. Imagine the surprise of microbiologists when they found that some archaea have monolayer membranes that function like bilayers. This structural difference is due to the presence of unique lipids in archaeal plasma membranes. Archaeal cell envelopes also differ in terms of organization. For many archaea, an S-layer is the major, and sometimes only, component of the cell wall. Finally, capsules and slime layers are relatively rare among archaea and thus are not discussed.

Archaeal Plasma Membranes and Nutrient Uptake

Archaeal membranes are composed primarily of lipids that differ from bacterial and eukaryotic lipids in two ways. First, they con-

tain hydrocarbons derived from isoprene units—five-carbon, branched molecules (figure 4.3). Thus the hydrocarbons are branched as shown in figure 4.4. This affects the way the lipids pack together, which in turn affects the fluidity of the membrane and its permeability. This is especially important for extremophilic archaea for which membrane fluidity and permeability could be compromised by extreme conditions. Second, the hydrocarbons are attached to glycerol by ether links rather than ester links (figure 4.4a). Ether linkages are more resistant to chemical attack and heat than are ester links.

Figure 4.3 Isoprene. This five-carbon, branched molecule is the building block of archaeal lipids.

Figure 4.4 Comparison of Archaeal and Bacterial Membranes. (a) Archaeal membrane lipids are attached to glycerol by ether linkages instead of ester linkages, as found in bacteria and eukaryotes. The stereochemistry also differs. In archaeal lipids, the stereoisomer of glycerol is *sn*-glycerol-1-phosphate; in bacterial lipids, the stereoisomer is *sn*-glycerol-3-phosphate. Thus in archaeal lipids, the side chains are attached to carbons 2 and 3 of glycerol, and in bacterial lipids, the side chains are attached to carbons 1 and 2. (b) Examples of archaeal lipids are lipids 1, 2, and 3. Lipids 4, 5, and 6 are bacterial lipids. Note that some archaeal lipids can form monolayers (figure 4.5), whereas all bacterial lipids form bilayers.

Two major types of archaeal lipids have been identified: glycerol diethers and diglycerol tetraethers. **Glycerol diether lipids** are formed when two hydrocarbons are attached to glycerol (figure 4.4b, lipid 3). Usually, the hydrocarbon chains in glycerol diethers are 20 carbons in length. **Diglycerol tetraether lipids** are formed when two glycerol residues are linked by two long hydrocarbons that are 40 carbons in length (figure 4.4b, lipids 1 and 2). Tetraethers are more rigid lipids than diethers. Cells can adjust the overall length of the tetraethers and increase their rigidity by cyclizing the chains to form pentacyclic rings (figure 4.4b, lipid 2). Phosphorus-, sulfur-, and sugar-containing groups can be attached to the glycerol moieties in the diethers and tetraethers, just like the phospholipids observed in bacterial and eukaryotic membranes.

Despite the significant differences in membrane lipids, the basic design of archaeal membranes is similar to that of bacterial and eukaryotic membranes: there are two hydrophilic surfaces and a hydrophobic core. When C_{20} diethers are used, a typical bilayer membrane is formed (figure 4.5a). When the membrane is constructed of C_{40} tetraethers, a monolayer membrane with much more rigidity is formed (figure 4.5b). The addition of pentacyclic rings further increases this rigidity. As might be expected from their need for stability, the membranes of extreme thermophiles such as *Thermoplasma* and *Sulfolobus*, which grow best at temperatures over 85°C , are almost completely tetraether monolayers. Archaea that live in moderately hot environments have membranes containing some regions with monolayers and some with bilayers. ►► *Phylum Crenarchaeota* (section 20.2)

As we discuss in chapter 3, organisms have several options for obtaining the nutrients they need from their environment. However, microbes often find themselves in nutrient-poor environments and therefore must be able to accumulate nutrients in their

cytoplasm at concentrations higher than the external milieu. Thus, although passive and facilitated diffusion have been observed in archaea, they primarily use active transport for nutrient uptake. Both primary (e.g., ABC transport) and secondary active transport systems have been identified in archaeal cells, often by searching an archaeon's genome for the genes encoding components of these systems (i.e., genomic analysis). These systems tend to be similar to those seen in bacteria. Of note is the observation that group translocation systems such as the phosphoenolpyruvate:sugar phosphotransferase system (PTS) have so far not been identified in archaea by any experimental approach. ►► *Uptake of nutrients* (section 3.3); ►► *Microbial genomics* (chapter 18)

Archaeal Cell Walls

Before they were distinguished as a unique domain of life, archaeal species were characterized as being either Gram positive or Gram negative based on their response to Gram staining. Thus, like all cells (even eukaryotic cells), they will stain either purple or pink when Gram stained. However, their staining reaction does not correlate reliably with a particular cell wall structure as it does for bacteria. Archaeal cell walls exhibit considerable variety in terms of their chemical makeup. Furthermore, their cell walls lack peptidoglycan.

The most common type of archaeal cell wall is an **S-layer** composed of either glycoprotein or protein (figure 4.6a). The layer may be as thick as 20 to 40 nm. Some methanogens (*Methanobacterium* and *Methanococcus*), salt-loving archaea (*Halobacterium*),

(a) Bilayer of C_{20} diethers

Figure 4.5 Examples of Archaeal Plasma Membranes.

and extreme thermophiles (*Sulfolobus*, *Thermoproteus*, and *Pyrodicticum*) have S-layer cell walls.

Other archaea have additional layers of material outside the S-layer. For instance, *Methanospirillum* has a protein sheath external to the S-layer (figure 4.6b). Another methanogen, *Methanosarcina*, has a polysaccharide layer covering the S-layer (figure 4.6c). This material, called methanochondroitin, is similar to the chondroitin sulfate of animal connective tissue.

In some archaea, the S-layer is the outermost layer and is separated from the plasma membrane by a peptidoglycan-like molecule called pseudomurein (figure 4.6d). Pseudomurein differs from peptidoglycan in that it has L-amino acids instead of D-amino acids in its cross-links, *N*-acetylalosaminuronic acid instead of *N*-acetylmuramic acid, and $\beta(1\rightarrow3)$ glycosidic bonds instead of $\beta(1\rightarrow4)$ glycosidic bonds (figure 4.7). These differences mean that lysozyme, penicillin, and other chemicals that affect bacterial cell wall structure and synthesis have no effect on archaeal cell walls.

Cell walls and osmotic protection (section 3.4)

The last type of archaeal cell wall consists of a single, thick homogeneous layer resembling that in Gram-positive bacteria (figure 4.6e). These archaea lack an S-layer and often stain Gram positive. Their wall chemistry varies from species to species but usually consists of complex polysaccharides such as pseudomurein.

Some archaea lack any layer resembling a cell wall. For instance, members of the acidophilic genera *Ferroplasma* and *Thermoplasma* have envelopes consisting only of a plasma membrane covered by a layer of slime. The slime, which is referred to as a glycocalyx, may provide some of the protection needed for these

Figure 4.7 Pseudomurein. The amino acids and amino groups in parentheses are not always present. Ac represents the acetyl group.

MICRO INQUIRY How is pseudomurein similar to peptidoglycan? How does it differ?

Figure 4.8 Cell Envelope of the Wall-less Archaeon *Ignicoccus hospitalis*.

Cy is cytoplasm, PM is plasma membrane, IMC is intermembrane compartment, and OM is outermost membrane. TEM, Bar = 200 nm.

archaea to survive in their acidic habitats. The most unique wall-less archaeon is *Ignicoccus hospitalis*. Its envelope consists only of the plasma membrane and an outermost membrane, with an intermembrane compartment between them (figure 4.6f and figure 4.8). The outermost membrane contains protein complexes that form pores, much like bacterial porin proteins create pores in the outer membrane of typical Gram-negative bacteria.

Retrieve, Infer, Apply

1. Identify three features that distinguish archaeal plasma membranes from those of bacteria.
2. Both bacteria and archaea can have S-layers. How does their use as components of the cell envelope differ?

4.3 Archaeal Cytoplasm

After reading this section, you should be able to:

- Compare and contrast the cytoplasm of bacterial and archaeal cells

Overall, the cytoplasm of archaeal cells is very similar to that of bacteria. Within it can be found inclusions—polyhydroxyalkonates, polyphosphate granules, glycogen granules, and gas vacuoles (figure 4.9); ribosomes; a nucleoid; and, in some cases, plasmids. Cytoskeletal proteins have also been identified, including FtsZ (tubulin homologue), MreB (actin homologue), and crenactin, an actin homologue unique to certain members of the phylum *Crenarchaeota*. In those archaea having FtsZ, the protein participates in cell division, as it does in bacteria. Evidence suggests that the actin homologues MreB and crenactin are involved in conferring a rod shape. Some structures found in the cytoplasm of archaeal cells have distinctive molecular makeup. In this section, we focus on those structures. ►► *Phylum Crenarchaeota* (section 20.2)

Ribosomes

Like bacterial cells, the **ribosomes** of archaeal cells are 70S in size and are constructed of a 50S and a 30S subunit. However, their shape is somewhat different and their component molecules are

Figure 4.9 Gas Vesicles. TEM of gas vesicles of *Halobacterium salinarum* (~ ×150,000).

not the same. Both have **ribosomal RNA (rRNA)** molecules of similar size: 16S in the small subunit, and 23S and 5S in the large subunit. However, as we discuss in chapter 1, the differences in nucleotide sequences of these molecules were the initial basis for establishing the taxon *Archaea*. Furthermore, at least one archaeon has an additional rRNA, a 5.8S rRNA, in the large subunit. This is of interest because the large subunit of eukaryotic ribosomes contains both 5S and 5.8S rRNA molecules.

The protein composition of bacterial and archaeal ribosomes also differs. Archaeal ribosomes have more proteins: about 68 rather than about 55. Archaeal ribosomal proteins can be sorted into three groups based on their similarity to proteins found in bacterial and eukaryotic ribosomes: (1) those observed in all three domains of life, (2) those unique to archaea, (3) those observed in both archaea and eukaryotes. There are only a few ribosomal proteins unique to archaea; the rest are about evenly divided between the other two groups. Importantly, all the ribosomal proteins present in both archaeal and bacterial ribosomes are also seen in eukaryotic ribosomes. Thus there are no ribosomal proteins that might be referred to as prokaryotic (i.e., present only in the ribosomes of archaea and bacteria). The difference in bacterial and archaeal ribosomes correlates with the fact that archaeal ribosomes are impervious to antibiotics that bind and inhibit bacterial ribosomes.

Nucleoid

The **nucleoid** provides another example of the difference between archaea and bacteria. This irregularly shaped region in the cytoplasm contains the cell's **chromosome** and numerous proteins. The chromosomes of all known archaea are circular, double-stranded **deoxyribonucleic acid (DNA)**. Evidence exists that some archaea are polyploid; that is, they have multiple copies of their chromosomes throughout their life cycles. Archaeal chromosomes, like bacterial chromosomes, are longer than the length of the cell and must be compacted to fit in the cell. In bacteria, proteins such as HU are thought to be important in compacting the chromosome. An HU homologue is also found in

some archaea. In many members of the phylum *Crenarchaeota*, a protein called Alba is also important for compacting chromosomes. Of particular interest is the observation that many members of the phylum *Euryarchaeota* have histones associated with their chromosomes. These **histones** form **nucleosomes** that are similar to the nucleosomes observed in eukaryotes (see figure 5.11). It is hypothesized that in thermophilic archaea, histones help prevent denaturation of the chromosomes. Like bacteria and eukaryotes, archaea also employ condensins to further compact their chromosomes so that they segregate properly during cell division. ►► *Nucleus* (section 5.5)

Retrieve, Infer, Apply

1. Thus far, homologues of intermediate filaments have not been identified in archaea. Is it likely that they will be identified eventually? Explain your answer.
2. Archaea are often described as hybrid organisms having some features that are similar to bacteria and some that are similar to eukaryotes. Based on what you have just read in this section, provide two examples that illustrate the similarity of archaea to bacteria; list two examples of their similarity to eukaryotes.

4.4 External Structures

After reading this section, you should be able to:

- Describe cannulae and hami
- Compare and contrast bacterial and archaeal pili
- Compare and contrast bacterial and archaeal flagella in terms of their structure and function

Like bacteria, many archaea have structures that extend beyond the cell envelope. Some will be familiar: pili and flagella. However, some are unique to archaea. These external structures and their functions are discussed in this section.

Pili, Cannulae, and Hami

Many archaea have **pili**, but relatively little is known about their structural proteins. Some archaeal pili are composed of pilin proteins that are homologues of bacterial type IV pili proteins. However, the pilus formed from these proteins is unique in several ways, including the presence of a central lumen. Central lumens are observed in bacterial flagella but not in bacterial type IV pili. The function of archaeal pili has not been thoroughly investigated. However, some have been shown to attach archaeal cells to surfaces. ►► *Bacterial pili and fimbriae* (section 3.7)

Two structures appear to be unique to archaea: cannulae and hami. **Cannulae** are hollow, tubelike structures observed on the surface of thermophilic archaea belonging to the genus *Pyrodicticum* (figure 4.10). Members of this genus also have flagella, but in electron micrographs the cannulae are distinguishable by their larger diameter. The function of cannulae is unknown, but it is known that daughter cells arising from a single round of cell

Figure 4.10 Cannulae. Cannulae are tubular structures thicker than flagella. They have only been observed on *Pyrodictium* spp. They connect daughter cells, ultimately forming a dense network of cells. SEM, bar = 1 μ m.

division remain connected to each other by cannulae. After many rounds of cell division, a network of cells is formed. **Hami** are of particular interest because of their shape (figure 4.11). They look like tiny grappling hooks, which suggests they might function to attach cells to surfaces. Indeed, archaeal cells that produce hami are members of biofilm communities generally consisting of a hami-producing archaeon and a bacterium.

Archaeal Flagella and Motility

Archaeal **flagella** have not been as thoroughly studied as bacterial flagella. They are superficially similar to their bacterial counterparts, but important differences have been identified. Archaeal flagella are thinner than bacterial flagella (10 to 13 nm rather

(a) Hami radiating from cell

(b) "Grappling hooks" at distal ends of hami

Figure 4.11 Hami. (a) A coccus-shaped cell is in the center of the electron micrograph and about 100 hami are radiating out from the platinum-shadowed cell. TEM, bar = 500 nm (b) At the ends of the hami are grappling hooklike structures that are thought to allow cells to adhere to surfaces, including other cells. TEM, bar = 50 nm.

than 20 nm) and are composed of more than one type of flagellin subunit (figure 4.12). The flagellum is not hollow. Archaeal hooks are difficult to distinguish from the filament; they also tend to be longer than bacterial hooks. A basal body has not been identified, but some preparations of archaeal flagella have a knoblike structure at the end embedded in the cell.

One interesting feature of the characterized flagellar proteins is that they are similar to the proteins in bacterial type IV pili. Thus far, no homologues of bacterial flagellar proteins have been identified in archaeal genomes. Like type IV pili, it is thought that the filament of the archaeal flagellum increases in length as flagellin subunits are added at the base of the filament rather than the tip. As we noted in our discussion of archaeal pili, some archaea construct pili from proteins similar to bacterial type IV pilins. The use of similar proteins to make two structures having distinct functions has raised many questions. It has been suggested that the machinery used to assemble archaeal flagella differs from that used to assemble pili but that some components may be shared.

◀ Bacterial flagella (section 3.7)

Despite their similarity to bacterial type IV pili, archaeal flagella work in a manner similar to bacterial flagella: rotation propels the cell. However, there are some important differences. First, evidence suggests that flagellar rotation is powered by ATP hydrolysis rather than by proton motive force. Second, when the direction of rotation switches, it causes the cell to move in either the forward or reverse direction, just as is seen for some bacteria having polar flagella. Thus far, alternation between runs and tumbles has not been observed.

Figure 4.12 Archaeal Flagellum. The different shades of blue in the filament illustrate that the filament is composed of more than one type of flagellin. Clear images of the basal body have not been obtained, although some electron micrographs show a knob at the cell end of the flagellum, as illustrated here.

Halobacterium salinarum flagellar movement is the best studied. In this archaeon, clockwise rotation of the flagella pushes the cell forward, and counterclockwise rotation pulls the cell (i.e., the flagella are in front of the cell as it moves). *H. salinarum* exhibits both chemotaxis and phototaxis. Phototaxis is used to position the archaeon properly to absorb light when carrying out rhodopsin-based phototrophy. Surprisingly, considering the difference in flagellar architecture, the machinery controlling chemotaxis and phototaxis in *H. salinarum* is homologous to that found in bacterial systems. ►► *Phototrophy (section 11.11)*

Retrieve, Infer, Apply

- At least some archaeal pili are similar to bacterial type IV pili. However, the archaeal pili are unique in terms of their structure. What is that distinctive feature?
- What observations about cannulae and hami suggest that they allow archaeal cells to adhere to surfaces, including other cells?
- List three aspects of archaeal flagella and flagellar motility that are similar to bacterial flagella and flagellar motility.

4.5 Comparison of Bacteria and Archaea

After reading this section, you should be able to:

- Compare and contrast bacterial and archaeal cells in terms of the structures observed and their chemical makeup

Although members of *Bacteria* and *Archaea* share a common cell architecture, this chapter has clearly outlined the significant differences between the two taxa. Here we review those differences.

The cell envelopes of bacteria and archaea are one of the distinctive features. Bacterial membranes contain lipids built by attaching fatty acids to glycerol by ester linkages. Archaeal membranes link isoprenoid hydrocarbons to glycerol by ether bonds. In some archaea, the membranes are monolayers rather than bilayers. Nearly all bacterial cell walls contain peptidoglycan. This molecule is unique to bacteria. Archaeal cell walls are much more varied than those of bacteria; many are composed solely of S-layers.

The ribosomes of bacteria and archaea are the same size but differ at the molecular level. The rRNA molecules are similar size, but the nucleotide sequences are distinguishable. Furthermore, the ribosomes of at least one archaeon have an additional rRNA that is not observed in bacterial ribosomes. A few ribosomal proteins are unique to archaea. However, the rest either have homologues in eukaryotic ribosomes or have homologues in both bacterial and eukaryotic ribosomes.

Most bacteria and archaea have chromosomes composed of double-stranded, circular DNA. These molecules are compacted using similar mechanisms. In addition, some archaea have histones that form nucleosomes similar to those observed in eukaryotic chromosomes.

Clearly, in terms of cell structure, the placement of archaea and bacteria into two separate domains of life is warranted. As you will see in subsequent chapters, archaea also differ from bacteria in their metabolic capabilities and gene expression. Considerably more is known about archaea now than a decade ago. As microbiologists have learned more, there have been many surprises. However, many questions about archaea remain unanswered. As more of these interesting microbes are isolated and studied, many of these questions will be answered and even more questions generated; expect more surprises.

Key Concepts

4.1 A Typical Archaeal Cell

- Members of *Bacteria* and *Archaea* share a common cell architecture. However, they have characteristics that define them as distinct taxa. **Table 4.1** summarizes some of the differences.
- Rods and cocci are the most common archaeal shapes. Archaea also can be curved rods, spirals, branched, square, and pleomorphic (**figures 4.1**).
- Most archaea are similar in size to bacteria. Archaea that are extremely small or are extremely large have also been identified (**figure 4.2**).

4.2 Archaeal Cell Envelopes

- The cell envelope consists of the plasma membrane and all external coverings, including cell walls and other layers. Archaeal cell envelopes usually consist of only the plasma membrane and the cell wall.
- Archaeal membranes are composed of glycerol diether and diglycerol tetraether lipids (**figure 4.4**). Membranes composed of glycerol diether are lipid bilayers. Membranes

composed of diglycerol tetraethers are lipid monolayers (**figure 4.5**). The overall structure of a monolayer membrane is similar to that of the bilayer membrane in that the membrane has a hydrophobic core and its surfaces are hydrophilic.

- Archaea typically use primary and secondary active transport systems to obtain nutrients from their environment. Thus far, group translocation systems such as the phosphoenolpyruvate:sugar phosphotransferase system have not been identified in any archaea.
- Archaeal cell walls do not contain peptidoglycan, and they exhibit great diversity in their makeup. The most common type of cell wall is one consisting of an S-layer only (**figure 4.6**).

4.3 Archaeal Cytoplasm

- Cytoskeletal proteins have been identified in archaeal cells. They include FtsZ (tubulin homologue), MreB (actin homologue), and crenactin (an unique archaeal actin homologue).

- Numerous inclusions are observed in archaeal cells, including gas vesicles (figures 4.9).
- Bacterial and archaeal ribosomes are 70S in size but differ slightly in their morphology. They also differ in terms of their protein content, with many archaeal ribosomal proteins being more similar to those in eukaryotic ribosomes than to those in bacterial ribosomes.
- The genetic material of archaeal cells is located in the nucleoid, which is not enclosed by a membrane. All known archaeal chromosomes consist of a double-stranded, covalently closed, circular DNA molecule. In many archaea, the nucleoid contains a single chromosome. However, some archaea are polyploid, having more than one copy of their chromosome. Like eukaryotes, some archaea use histone proteins to organize their chromosomes.

4.4 External Structures

- Many archaea have pili. Some archaeal pili are similar to bacterial type IV pili.

- Cannulae (figure 4.10) and hami (figure 4.11) are external structures that are unique to archaea. Their function is not known, but it is likely that they help cells attach to surfaces, including other cells.
- Many archaea are motile by means of flagella (figure 4.12). Archaeal flagella are structurally related to bacterial type IV pili. They are rigid helices that rotate, and the direction of rotation determines if the cell moves forward or backward. Rotation is powered by ATP hydrolysis.
- Motile archaea exhibit chemotaxis. Some are also phototactic. The archaeal taxis machinery is similar to that of bacteria.

4.5 Comparison of Bacteria and Archaea

- One major difference between bacterial and archaeal cells is that they have distinctive cell envelopes.
- There are also important differences between bacterial and archaeal ribosomes, chromosomes, flagella, and pili.

Compare, Hypothesize, Invent

1. Archaea with cell walls consisting of a thick, homogeneous layer of complex polysaccharides often retain crystal violet dye when stained using the Gram-staining procedure. Suggest a reason for this staining reaction.
2. Isoprene serves as a building block not only for the hydrocarbons observed in archaeal membranes but also for sterols, carotenoids, retinal, and quinones. Use any resources necessary to identify the function of these other isoprene-based molecules and to determine their distribution in nature. What does the use of isoprene to make this diverse array of molecules suggest about the nature of the last universal common ancestor (LUCA)?
3. As we note in section 4.3, archaeal ribosomal proteins can be divided into three classes: (1) those with homologues in all three domains of life, (2) those unique to archaea, and (3) those with homologues in eukaryotic ribosomes. Predict what class of archaeal ribosomal proteins would refute the argument made by some microbiologists that the term *prokaryote* should be abandoned.
4. Archaea exhibit a wide variety of cell shapes, including some that are unique. Suggest why this diversity exists and what advantages the unique shapes might confer.
5. In the chapter opening case study, we focus on the production of methane by archaea living in the rumens of domesticated ruminant animals. However, there are many other sources of methane besides livestock. These include wild ruminants, the anoxic soils of rice paddies, and deforestation. There is considerable interest in more precisely measuring the output of methane by all these sources, yet current methods have many drawbacks. Some are laborious; some have a high degree of variability; others can only be used in highly controlled environments. In 2011 a group of scientists reported their attempts to correlate methane production with the amount of archaeol in the feces of cattle. They also determined archaeol levels resulting from different feeding regimens. Archaeol is a glycerol diether that can be measured by chemical procedures such as gas chromatography. What assumption did the scientists make when they chose to measure archaeol? Why did they choose to measure a glycerol diether rather than a diglycerol tetraether in their study? Suggest one other application of this method to better understand methane release into the atmosphere.

Eukaryotic Cell Structure

Red Means Dead

Anyone driving down a highway in the Rocky Mountains of Canada and the United States will observe an astonishing sight: large stands of rust-colored, dead pine trees in once verdant mountain forests. In British Columbia alone, over 40 million acres of trees have been killed. In 2008, about 4 million acres of trees were estimated killed in the northern Rocky Mountain states.

Two culprits working together have caused this destruction: the mountain pine beetle and its symbiont, the blue stain fungus *Grosmannia clavigera*. How they kill is an interesting example of a mutualistic relationship—one in which both benefit. The fungus is helped by the beetle, which carries the fungus on its mouth parts and transports it from one tree to another. The beetle is helped by the fungus, which protects the beetle from the tree's defense mechanisms and nourishes the beetle's young.

The killing process begins when the beetle chews through the bark of a pine tree to reach underlying tissues. The tree fights back by producing a resin toxic to the beetle. However, the fungus is able to degrade the toxic resin and use it as a carbon and energy source. Thus, with the fungus' help, the beetle is able to continue its attack, ultimately laying its eggs in the tree and carrying the fungus deeper into the tree. The fungus, now deep inside the tree, produces masses of filaments that help feed the beetle's progeny. These filaments are lethal as they literally clog the tree's circulatory system. Nutrients and water can no longer flow through the tree, and it dries up as it starves to death.

Much of this text is devoted to a discussion of bacteria and archaea. But as just demonstrated, eukaryotic microbes also deserve our attention. They are prominent members of ecosystems, important model organisms, and exceptionally useful in industrial microbiology. A number are also major human pathogens.

Eukaryotic microbes can be divided into two major groups: protists and fungi. Protists are very diverse. Some use organic molecules as energy

A Rocky Mountain forest ravaged by the mountain pine beetle and a fungus.

sources just as animals do; others are photosynthetic like plants. Many protist lineages have been identified in *Eukarya*. Currently, protists cannot be grouped together in a single monophyletic taxon—one that includes all descendants of the most recent common ancestor. Thus the term protist is a common name for these microbes rather than a valid taxon. Fungi, on the other hand, all share a common evolutionary history, so they are placed in one taxon (*Fungi*).

The division of eukaryotes into appropriate taxa is currently being debated, as is their evolution. The taxonomy and evolution of eukaryotes are discussed more completely in chapters 25 and 26. In this chapter, we introduce eukaryotic cell structures and their functions. As we do so, comparisons are made to plants and animals. Thus it is important that you review what you already know about them.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ List the three domains of life (section 1.1)
- ✓ Describe the application of small subunit (SSU) rRNA analysis to the establishment of the three domain classification system proposed by Carl Woese (section 1.2)
- ✓ Identify the following structures or regions of a plant or animal cell and describe their functions: cell wall, plasma membrane, cytoplasm, mitochondria, chloroplasts, and ribosomes
- ✓ Identify the major cell structures observed in bacterial and archaeal cells, and describe the function and molecular makeup of each (chapters 3 and 4)

5.1 A Typical Eukaryotic Cell

After reading this section, you should be able to:

- Compare and contrast eukaryotic, bacterial, and archaeal cells in terms of their use of membranes, size, morphological diversity, and organelles

(a) *Paramecium* sp.

(b) Diatom frustules

(c) *Penicillium* sp.(d) *Stentor* sp.(e) *Gonium* sp.(f) *Polysiphonia* sp.

Figure 5.1 Some Eukaryotic Microorganisms. (a) *Paramecium* sp., a protist; interference-contrast microscopy ($\times 115$). (b) Mixed diatom frustules. (c) *Penicillium* sp., the mold's hyphae and conidia. (d) *Stentor* sp., a ciliated protist in its extended, actively feeding form; phase-contrast microscopy ($\times 100$). (e) *Gonium* sp., a freshwater, colonial alga ($\times 40$). (f) *Polysiphonia* sp., a filamentous, red alga (photosynthetic protist).

Before we begin our discussion of the numerous structures and organelles observed in eukaryotic cells, it is wise to begin with an overview. Here we make broad generalizations about eukaryotic cells. As we proceed in this chapter, we will give examples of deviations from the common features.

Shape and Size

One hallmark of eukaryotic cells is their morphological diversity. This is especially true for eukaryotic microbes, which are found in numerous habitats and have evolved morphological adaptations accordingly. Some of the diverse shapes of eukaryotic microbes are shown in **figure 5.1**.

In general, eukaryotic cells are larger than bacterial and archaeal cells. This is true for eukaryotic microbes as well (see *figure 2.20*). However, just as some bacteria and archaea are very large, even larger than some of the largest protists (see *figure 3.4*), so too are there some protists smaller than many bacteria and

archaea. These small eukaryotic microbes include *Ostreococcus tauri*, the smallest free-living alga known. Many other picoeukaryotes have been discovered in marine environments, as many as 10^3 to 10^4 per milliliter.

Cell Organization

Eukaryotic cells are distinctive because of their use of membranes (**figures 5.2** and **5.3**; compare these figures with *figure 3.6*). They have membrane-delimited nuclei, and membranes play a prominent part in the structure of many other organelles. **Organelles** are intracellular structures that perform specific functions in cells analogous to the functions of organs in the body of a multicellular organism. The partitioning of the eukaryotic cell interior by membranes makes possible the placement of different cellular functions in separate compartments so that they can more easily take place simultaneously under independent control and proper coordination. Large membrane

Figure 5.2 Eukaryotic Cell Ultrastructure. An electron cryotomogram of the yeast *Schizosaccharomyces pombe*. This image is the first high-resolution, three-dimensional reconstruction of a complete eukaryotic cell.

surfaces make possible greater respiratory and photosynthetic activity because these processes are located exclusively in membranes. The intracytoplasmic membrane complex also serves as a transport system to move materials between different cell locations. Thus abundant membrane systems probably are necessary in eukaryotic cells because of their large volume and the need for adequate regulation, metabolic activity, and transport.

Figures 5.2 and 5.3 illustrate most of the organelles discussed in this chapter. **Table 5.1** briefly summarizes the functions of the major organelles observed in most eukaryotes, including plants and animals. Our detailed discussion of eukaryotic cell structure begins with eukaryotic cell envelopes. We then proceed to the cytoplasm, organelles within the cytoplasm, and finally to external structures.

Retrieve, Infer, Apply

1. What is an organelle? How are organelles analogous to organs of a multicellular organism?
2. Why is the compartmentation of the cell interior advantageous to eukaryotic cells?

Figure 5.3 The Structure of Two Representative Eukaryotic Microbes.

MICRO INQUIRY In addition to separating each organelle from the rest of the cytoplasm, what other functions do internal membranes serve?

5.2 Eukaryotic Cell Envelopes

After reading this section, you should be able to:

- Identify the types of eukaryotic microbes that have cell walls and distinguish them from plant cell walls
- Compare and contrast the cell envelopes of members of *Bacteria*, *Archaea*, and *Eukarya* in terms of their component layers, molecular makeup, and function

The cell envelope consists of the plasma membrane and all coverings external to it. Eukaryotic microorganisms differ greatly from bacterial and archaeal cells in the structures they have external to the plasma membrane. Many eukaryotic microbes lack a cell wall. When cell walls are present, they are chemically distinctive.

The plasma membrane of eukaryotes is a lipid bilayer composed of a high proportion of sphingolipids and sterols (e.g., cholesterol and ergosterol) in addition to the phospholipids observed in bacterial membranes (**figure 5.4**). In both lipids, the fatty acids are attached to glycerol with ester links. The large amounts of sphingolipids and sterols contribute to the strength of the plasma membrane; they are able to pack together very closely, more so than phospholipids can. This explains, in part, why so many eukaryotic microbes are able to resist osmotic pressure and other mechanical stresses even though they lack cell walls.

Table 5.1 Functions of Eukaryotic Organelles

| | |
|------------------------|--|
| Plasma membrane | Mechanical cell boundary; selectively permeable barrier with transport systems; mediates cell-cell interactions and adhesion to surfaces; secretion; signal transduction |
| Cytoplasm | Composed of cytosol (liquid portion) and organelles; location of many metabolic processes |
| Cytoskeleton | Composed of actin filaments, intermediate filaments, and microtubules; provides cell structure and movements |
| Endoplasmic reticulum | Transport of materials; lipid synthesis |
| Ribosomes | Protein synthesis |
| Golgi apparatus | Packaging and secretion of materials for various purposes; lysosome formation |
| Lysosomes | Intracellular digestion |
| Mitochondria | Energy production through use of the tricarboxylic acid cycle, electron transport, oxidative phosphorylation, and other pathways |
| Chloroplasts | Photosynthesis—trapping light energy and forming carbohydrate from CO ₂ and water |
| Nucleus | Repository for genetic information |
| Nucleolus | Ribosomal RNA synthesis; ribosome construction |
| Cell wall and pellicle | Strengthen and give shape to the cell |
| Cilia and flagella | Cell movement |
| Vacuole | Temporary storage and transport; digestion (food vacuoles); water balance (contractile vacuole) |

The distribution of lipids in the plasma membrane is asymmetric. Lipids in the outer leaflet differ from those of the inner leaflet. Although most lipids in each leaflet mix freely with each other, there are microdomains that differ in lipid and protein composition. These microdomains are sometimes referred to as lipid rafts. They have been implicated in a variety of cellular

processes (e.g., signal transduction, assembly and release of virus particles, and endocytosis). **▶▶ Viral multiplication** (section 6.3)

As with the plasma membranes of bacterial and archaeal cells, eukaryotic cells must be able to move materials across their membranes. Facilitated diffusion plays a more prominent role in eukaryotic cells than it does in bacterial and archaeal cells (see figure 3.10). Eukaryotes also use passive diffusion and active transport. In addition, eukaryotes have another option for bringing materials into cells: endocytosis. We focus on this unique process in section 5.4.

The chemical composition of the cell walls of eukaryotic microbes varies considerably. Those of photosynthetic protists (commonly called algae) usually have a layered appearance and contain large quantities of polysaccharides such as cellulose and pectin. In addition, inorganic substances such as silica (in diatoms) or calcium carbonate may be present. Fungal cell walls normally are rigid. Their exact composition varies with the organism; usually cellulose, chitin, or glucan (a glucose polymer different from cellulose) is present. Despite their nature, the rigid materials in eukaryotic cell walls are chemically simpler than bacterial peptidoglycan. **◀◀ Bacterial cell walls** (section 3.4)

Figure 5.4 Examples of Eukaryotic Membrane Lipids. (a) Phosphatidylcholine, a phospholipid. (b) Sphingomyelin, a sphingolipid. (c) Cholesterol, a sterol.

5.3 Cytoplasm of Eukaryotes

After reading this section, you should be able to:

- Describe the functions of the cytoplasm
- Identify the three filaments that make up the cytoskeleton of eukaryotic cells and describe their functions

The **cytoplasm** is one of the most important and complex parts of a eukaryotic cell. It consists of a liquid component, the cytosol, in which many organelles are located. It is the location of many important biochemical processes, and several physical changes (e.g., viscosity changes and cytoplasmic streaming) are due to cytoplasmic activity. Because so many different kinds of organelles are observed in the eukaryotic cytoplasm, we address them separately in sections 5.4–5.6. Here we focus on the cytoskeleton, which helps organize the contents of the cytoplasm.

The **cytoskeleton** is a vast, dynamic network composed of three types of interconnected filaments: actin filaments (also called microfilaments), intermediate filaments, and microtubules (figure 5.5). Motor proteins (myosin, kinesin, and dynein) are often associated with actin filaments and

microtubules. These cellular motors track along the cytoskeletal filaments, helping to move cell structures from one location to another.

Actin filaments are minute protein filaments, 4 to 7 nm in diameter, that are organized to form a variety of structures depending on the cell type (figure 5.6). They are composed of an actin protein that is similar to the actin contractile protein of muscle tissue. Actin filaments are involved in amoeboid movement, endocytosis, cytokinesis, and the movement of some structures within the cell. Interestingly, some bacterial pathogens use the actin proteins of their eukaryotic hosts to move rapidly through the host cell and to propel themselves into new host cells (see figure 35.9).

Intermediate filaments are heterogeneous elements of the cytoskeleton that play structural roles. They are about 10 nm in diameter and are assembled from a group of proteins that can be divided into several classes (e.g., keratin and vimentin). Intermediate filaments having different functions are assembled from one or more of these classes of proteins. The role of intermediate filaments in eukaryotic microorganisms is unclear. Thus far, they have been identified and studied only in animals: some intermediate filaments form the nuclear lamina, a structure that provides support for the nuclear envelope (p. 101); some help position organelles within the cell; and others help link cells together to form tissues.

Microtubules are shaped like thin cylinders about 25 nm in diameter. They are constructed of two spherical protein subunits— α -tubulin and β -tubulin. The

Figure 5.5 The Eukaryotic Cytoplasm and Cytoskeleton. The cytoplasm of eukaryotic cells contains many important organelles. The cytoskeleton helps form a framework within which the organelles lie. The cytoskeleton is composed of three elements: actin filaments, microtubules, and intermediate filaments.

MICRO INQUIRY Which cytoskeletal filament is made of the proteins α - and β -tubulin?

Figure 5.6 The Actin Cytoskeleton of the Yeast *Saccharomyces cerevisiae*. Cells from different stages in the yeast cell cycle were stained with the fluorescent dye rhodamine phalloidin. Three kinds of structures made from actin filaments can be observed: actin patches, actin rings, and actin cables. The actin structures appear white in this micrograph.

two proteins are the same molecular weight and differ only slightly in terms of their amino acid sequence and tertiary structure. Each tubulin is approximately 4 to 5 nm in diameter. These subunits are assembled in a helical arrangement to form a cylinder with an average of 13 subunits in one turn (figure 5.5).

Microtubules have several important functions. They form the spindle apparatus that separates chromosomes during mitosis and meiosis. They form tracks along which numerous types of organelles and vesicles are moved about the cell, and they are found in cilia and flagella, two organelles that confer motility (p. 104). Microtubules also are found in cell structures requiring support such as long, slender, rigid pseudopodia (called axopodia) observed in some protists (figure 5.7).

5.4 Organelles of the Secretory and Endocytic Pathways

After reading this section, you should be able to:

- Differentiate the two types of endoplasmic reticulum in terms of structure and function
- Outline the pathway of molecules through the secretory pathway, noting the structures involved and their role in the process
- List the endocytic pathways observed in mammalian cells, noting the structures involved and their role in the process, and noting those pathways that have been observed in eukaryotic microbes

The cytoplasm of eukaryotic cells is permeated with an intricate complex of membranous organelles and vesicles that move materials into the cell from the outside (endocytic pathway) and from the inside of the cell out, as well as from location to location within the cell (secretory pathway). In this section, some of these organelles are described. This is followed by a summary of how the organelles function in the secretory and endocytic pathways.

Endoplasmic Reticulum

The **endoplasmic reticulum (ER)** (figure 5.3) is an irregular network of branching and fusing membranous tubules, around 40 to 70 nm in diameter, and many flattened sacs called cisternae (s., cisterna). The nature of the ER varies with the functional and physiological status of the cell. In cells synthesizing a great deal of protein to be secreted, a large part of the ER is studded on its outer surface with ribosomes and is called **rough endoplasmic reticulum (RER)**. Other cells, such as those producing large quantities of lipids, have ER that lacks ribosomes. This is **smooth endoplasmic reticulum (SER)**.

The endoplasmic reticulum has many important functions. Not only does it transport proteins, lipids, and other materials through the cell, it is also involved in the synthesis of many of the materials it transports. Lipids and proteins are synthesized by ER-associated enzymes and ribosomes. Polypeptide chains synthesized on RER-bound ribosomes may be inserted either into the ER membrane or into its lumen for transport elsewhere. The ER is also a major site of cell membrane synthesis.

Figure 5.8 Golgi Apparatus. Golgi apparatus of the protist *Euglena gracilis*. Cisternal stacks are shown in the electron micrograph ($\times 165,000$) in (a) and diagrammatically in (b). Each cisterna is 15 to 20 nm thick and separated from other cisternae by 20 to 30 nm.

Golgi Apparatus

The **Golgi apparatus** is composed of flattened, saclike cisternae (**figure 5.8**). A complex network of tubules and vesicles is located at the edges of the cisternae. In many eukaryotes, the cisternae are stacked on each other, forming a structure called a dictyosome. There are usually around four to eight cisternae in a stack. In many cells, multiple stacks are linked to form a Golgi ribbon. Most eukaryotic microbes have just a single stack of cisternae, and in some, the cisternae are not in stacks (e.g., the yeast *Saccharomyces cerevisiae*).

A stack of cisternae has two faces that are quite different from one another. The sacs on the cis or forming face are closest to the ER and often associated with it. The sacs on the trans or maturing face are farthest from the ER. The two faces of the Golgi differ in thickness, enzyme content, and degree of vesicle formation.

The Golgi apparatus packages materials and prepares them for secretion, the exact nature of its role varying with the organism. For instance, the surface scales of some flagellated photosynthetic and radiolarian protists are constructed within the Golgi apparatus and then transported to the surface in vesicles. The Golgi often participates in the development of cell membranes and the packaging of cell products. The growth of some fungal hyphae occurs when Golgi vesicles contribute their contents to the wall at the hyphal tip. ▶▶ *The Protists (chapter 25)*

Lysosomes

Lysosomes are found in animal cells. They are roughly spherical, are enclosed in a single membrane, and average about 500 nm in diameter but range from 50 nm to several μm in size. They are involved in intracellular digestion and contain the enzymes needed to digest all types of macromolecules. These enzymes, called hydrolases, catalyze the hydrolysis of molecules and function best under slightly acidic conditions (usually around pH 3.5

to 5.0). Lysosomes maintain an acidic environment by pumping protons into their interior. 🌀 *Lysosomes*

Lysosome-like organelles are found in fungal and protist cells, where they are usually called vacuoles, phagocytic vacuoles, or food vacuoles. They function in intracellular digestion, but many have other functions, including storage of calcium ions, phosphate, and amino acids. These organelles are components of the endocytic pathways observed in protists and fungi, just as lysosomes are part of the endocytic pathways observed in animal cells.

Secretory Pathway

The **secretory pathway** is used to move materials to various sites within the cell, as well as to either the plasma membrane or the cell exterior. The process is complex and not fully understood. The movement of proteins is of particular importance and is our focus.

Proteins destined for the plasma membrane, structures of the endocytic pathway (p. 99), or secretion are synthesized by ribosomes attached to the rough endoplasmic reticulum (RER). These proteins have sequences of amino acids that target them to the lumen of the RER through which they move until released in small vesicles that bud from the ER. As the proteins pass through the ER, they are often modified by the addition of sugars—a process known as glycosylation.

Vesicles released from the ER travel to the cis face of the Golgi apparatus (the side closest to the ER; **figure 5.8**). One popular model of the secretory pathway posits that these vesicles fuse to form the cis face of the Golgi. How this occurs is still unresolved. As the proteins proceed from the cis to the trans side of the Golgi (the side farthest from the ER), they are further modified. Some of these modifications target the proteins for their final location.

Transport vesicles are released from the trans face of the Golgi and deliver their contents to various locations in the cell.

Two types of vesicles transport materials to the plasma membrane. One type constitutively delivers proteins in an unregulated manner, releasing them to the outside of the cell as the transport vesicle fuses with the plasma membrane. Other vesicles, called secretory vesicles, are found only in multicellular eukaryotes, where they are observed in secretory cells such as mast cells and other cells of the immune system. Secretory vesicles store the proteins to be released until the cell receives an appropriate signal. Once received, the secretory vesicles move to the plasma membrane, fuse with it, and release their contents to the cell exterior.

▶▶ *Cells, tissues, and organs of the immune system (section 33.4)*

One important feature of the secretory pathway is its quality-assurance mechanism. Proteins that fail to fold or have misfolded are not transported to their intended destination. Instead they are released into the cytosol, where they are targeted for destruction by the attachment of several small ubiquitin polypeptides, as detailed in **figure 5.9**. The ubiquitin-tagged proteins are degraded by a huge, cylindrical complex called a **26S proteasome**. The protein is broken down to smaller peptides using energy supplied by adenosine triphosphate (ATP) when the terminal phosphate is removed. As the protein is broken down, ubiquitins are released. In

animal cells, the proteasome is involved in producing peptides for antigen presentation during immunological responses, as described in chapter 34. ▶▶ *ATP (section 10.2)*

Endocytic Pathway

Endocytosis is observed in all eukaryotic cells. It is used to bring materials into the cell from the outside. During endocytosis, a cell takes up solutes (pinocytosis) or particles (phagocytosis) by enclosing them in vesicles pinched off from the plasma membrane. In most cases, these materials are delivered to a lysosome, where they are digested. Endocytosis occurs regularly in all cells as a mechanism for recycling molecules in the membrane. In addition, some cells have specialized **endocytic pathways** that allow them to concentrate materials outside the cell before bringing them in. Others use endocytic pathways as a feeding mechanism. Many viruses and other intracellular pathogens enter their host cells via the cell's endocytic pathways.

Mammalian cells have several types of endocytic pathways (**figure 5.10**). **Phagocytosis** involves the use of protrusions from the cell surface to surround and engulf particulates. The endocytic vesicles formed by phagocytosis are called **phagosomes**. **Clathrin-dependent endocytosis** begins with coated pits, which are specialized membrane regions coated on the cytoplasmic side with the protein clathrin. The endocytic vesicles formed when these regions invaginate are called coated vesicles. Clathrin-dependent endocytosis is used to internalize hormones, growth factors, iron, and cholesterol. **Caveolin-dependent endocytosis** involves caveolae ("little caves"), tiny, flask-shaped invaginations of the plasma membrane (about 50 to 80 nm in diameter) that are enriched in cholesterol and the membrane protein caveolin. The vesicles formed when caveolae pinch off are called caveolin-coated vesicles. Caveolin-dependent endocytosis has been implicated in signal transduction, transport of small molecules such as folic acid, as well as transport of macromolecules. Evidence exists that toxins such as cholera toxin enter their target cells via caveolae. Caveolae also are used by many viruses, bacteria, and protozoa to enter host cells.

Endocytosis is often triggered by the binding of a molecule called a **ligand** to a **receptor** located in the cell membrane. This is referred to as **receptor-mediated endocytosis**. The nature of ligands varies (e.g., hormones or molecules on the surface of a virus). Sometimes receptors are concentrated in certain areas of the membrane, and receptor-mediated endocytosis serves to concentrate the ligand before it is endocytosed.

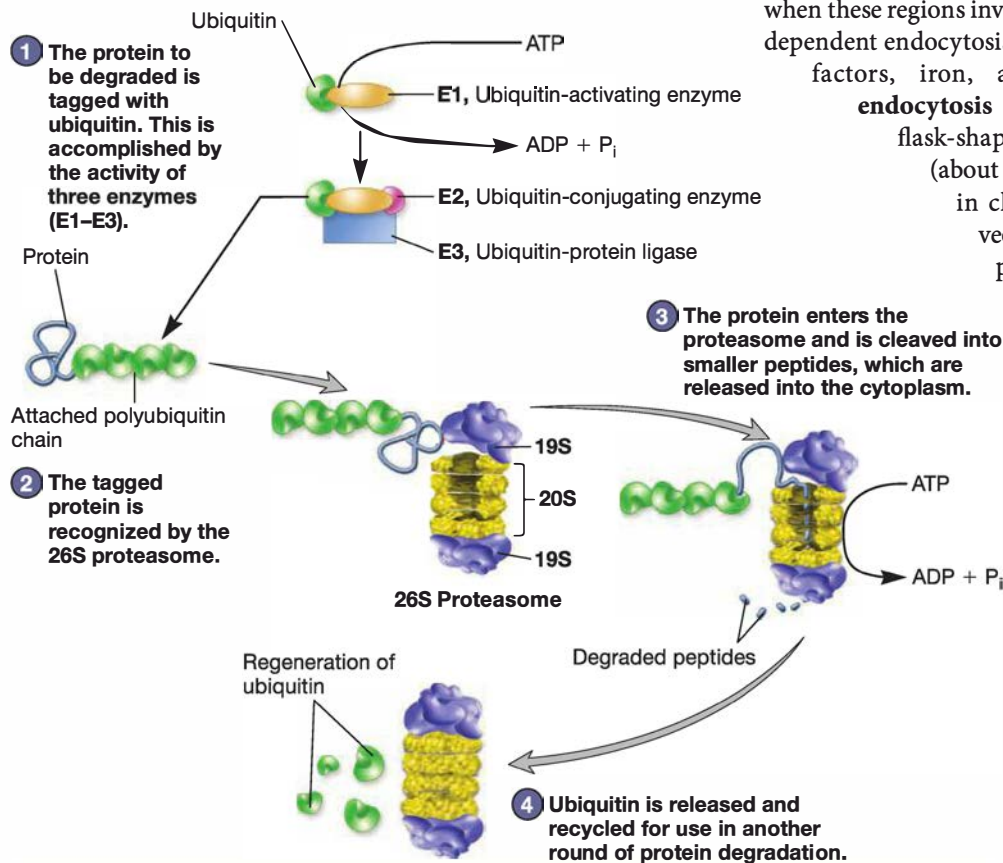

Figure 5.9 Proteasome Degradation of Proteins.

MICRO INQUIRY Why must proteins be unfolded when they enter the proteasome?

Clathrin-coated vesicles and some caveolin-coated vesicles deliver their contents to small organelles containing hydrolytic enzymes. These organelles are called early endosomes (figure 5.10). Early endosomes mature into late endosomes, which fuse with lysosomes. The development of early endosomes into late endosomes is not well understood. It is thought that maturation involves the selective retrieval of membrane proteins. Phagosomes and some caveolin-coated vesicles take a different route to lysosomes. Phagosomes fuse directly with lysosomes (figure 5.10) to form a phagolysosome. The caveolin-coated vesicles deliver their contents to an organelle termed a caveosome. The caveosome then fuses with an early endosome.

Endocytosis in eukaryotic microbes has not been studied as extensively as it has in mammals. It is known that some eukaryotic microbes carry out phagocytosis and probably macropinocytosis (figure 5.10). Pathways similar to clathrin-dependent endocytosis have been observed in fungi. These pathways have been best characterized in the yeast *Saccharomyces cerevisiae*.

Although some aspects of the endocytic process differ between this yeast and mammals, considerable similarity has been discovered, especially in terms of the mechanisms used to sort materials among early endosomes, late endosomes, lysosomes, and the plasma membrane.

Lysosomes are involved in another process that is increasingly attracting the attention of scientists: autophagy. Several types of autophagy have been identified. Perhaps the best studied is **macroautophagy**. Macroautophagy is used by mammalian cells and some eukaryotic microbes to selectively digest and recycle cytoplasmic components (including organelles such as mitochondria). This is a normal process that helps maintain cellular homeostasis. It is also sometimes used to destroy pathogens that have entered a host cell by endocytosis.

During macroautophagy, materials to be digested are surrounded by a double membrane to form a structure called an **autophagosome**. Evidence exists that the outer membrane of mitochondria, the endoplasmic reticulum, and the plasma membrane provide the lipids used to form the autophagosome, depending on the material being digested. Ultimately the autophagosome fuses with a lysosome.

No matter the route taken, digestion occurs once the lysosome is formed. As the contents of the lysosome are digested, small products of digestion leave the lysosome and are used as nutrients or for other purposes. The resulting lysosome containing undigested material is sometimes called a **residual body**. In some cases, the residual body can release its contents to the cell exterior by a process called lysosome secretion.

Figure 5.10 Some Endocytic Pathways Observed in Mammalian Cells. Materials ingested by endocytic processes are delivered to lysosomes. The pathway to lysosomes differs, depending on the type of endocytosis. In addition, cell components are recycled when autophagosomes deliver them to lysosomes for digestion. This process is called autophagy.

5.5 Organelles Involved in Genetic Control of the Cell

After reading this section, you should be able to:

- Describe the structure of the nucleus, chromosomes, nucleolus, and eukaryotic ribosomes
- Compare and contrast the chromosomes and ribosomes of bacterial, archaeal, and eukaryotic cells

DNA is the molecule that houses the genetic blueprint of the cell. Eukaryotic cells differ dramatically from bacterial and archaeal cells in the way DNA is stored and used. In this section, the organelles involved with these important cellular functions are introduced.

Nucleus

The nucleus is by far the most visually prominent organelle in eukaryotic cells. It was discovered early in the study of cell structure and was shown by Robert Brown in 1831 to be a constant feature of eukaryotic cells. The **nucleus** is the repository for the cell's genetic information.

Nuclei are membrane-delimited spherical bodies about 5 to 7 μm in diameter (figures 5.2 and 5.3). They contain more than one chromosome; the exact number depends on the organism, cell type, and stage in the life cycle. Each eukaryotic **chromosome** is composed of chromatin. **Chromatin** is a complex of DNA and proteins, including histones. Histones are small basic proteins rich in the amino acids lysine, arginine, or both. There are five types of histones in most eukaryotic cells: H1, H2A, H2B, H3, and H4. Eight histone molecules form an ellipsoid about 11 nm long and 6.5 to 7 nm in diameter around which the DNA wraps to form a "beads-on-a-string" formation (figure 5.11). Each bead is called a **nucleosome**.

Chromosomes are very dynamic and vary in terms of their degree of compaction. When the cell is not dividing, there is less compaction. The highest degree of compaction occurs during cell division. Compaction is brought about in part by

Figure 5.11 Nucleosomes. DNA is wrapped around an ellipsoid composed of eight histone proteins (two each of H2A, H2B, H3, and H4). In most eukaryotes, the histone H1 associates with the nucleosome.

histones and other proteins, including condensins. Recall that condensins are also used by bacterial and archaeal cells to compact their chromosomes during cell division. Tethering of one region of the chromosome to another and tethering of the chromosome to nuclear structures also contribute to chromosome folding and compaction.

The nucleus is surrounded by the **nuclear envelope** (figure 5.3), a complex structure consisting of inner and outer membranes separated by a perinuclear space. The nuclear envelope is continuous with the ER at several points, and its outer membrane is covered with ribosomes. A network of intermediate filaments, called the nuclear lamina, is observed in animal cells. It lies against the inner surface of the nuclear envelope and supports it. Many nuclear pores penetrate the envelope, and each pore is formed by about 30 proteins; each pore plus the associated proteins is called a **nuclear pore complex** (figure 5.12). Pores are about 70 nm in diameter and collectively occupy about 10 to 25% of the nuclear surface. The nuclear pore complexes serve as transport routes between the nucleus and surrounding cytoplasm. Small molecules move through the nuclear pore complex unaided. However, large molecules are transported through the nuclear pore complex. Some nuclear pore complex proteins are involved in these transport processes.

Often the most noticeable structure within the nucleus is the **nucleolus** (figure 5.13). A nucleus may contain from one to many nucleoli. Although the nucleolus is not membrane-enclosed, it is a complex organelle with separate granular and fibrillar regions. It is present in nondividing cells but frequently disappears during mitosis. After mitosis, the nucleolus reforms around the nucleolar organizer, a particular part of a specific chromosome.

The nucleolus plays a major role in ribosome synthesis. The DNA of the nucleolar organizer directs the production of ribosomal RNA (rRNA). This RNA is synthesized in a single long piece that is cut to form the final rRNA molecules. The processed rRNAs combine with ribosomal proteins (which have been synthesized in the cytoplasm) to form partially completed ribosomal subunits. The granules seen in the nucleolus are probably these subunits. Immature ribosomal subunits then leave the nucleus, presumably by way of the nuclear pore complexes, and mature in the cytoplasm.

Eukaryotic Ribosomes

Eukaryotic ribosomes (i.e., those not found in mitochondria and chloroplasts) are larger than bacterial and archaeal 70S ribosomes. Each ribosome is a dimer of a 60S and a 40S subunit. The 60S subunit is composed of three rRNA molecules (5S, 28S, and 5.8S rRNAs) and about 50 proteins. The 40S subunit

is composed of an 18S rRNA and about 30 proteins. Each ribosome is about 22 nm in diameter and has a sedimentation coefficient of 80S and a molecular weight of 4 million (**figure 5.14**). Eukaryotic ribosomes are either associated with the endoplasmic reticulum or free in the cytoplasm. When bound to the endoplasmic reticulum to form rough ER, they are attached through their 60S subunits.

Both free and ER-bound ribosomes synthesize proteins. Proteins made on the ribosomes of the RER are often secreted or are inserted into the ER membrane as integral membrane proteins. Free ribosomes are the sites of synthesis for nonsecretory and nonmembrane proteins. Some proteins synthesized by free ribosomes are inserted into organelles such as the nucleus, mitochondrion, and chloroplast. As we discuss in chapters 13 and 15, proteins called molecular chaperones aid the proper folding of proteins after synthesis. They also assist the transport of proteins into eukaryotic organelles such as mitochondria.

Figure 5.13 The Nucleolus. The nucleolus is a prominent feature of the nucleus, as seen in this electron micrograph of an interphase nucleus. The nucleolus functions in rRNA synthesis and the assembly of ribosomal subunits.

5.6 Organelles Involved in Energy Conservation

After reading this section, you should be able to:

- Draw a mitochondrion and identify its component parts
- Compare and contrast mitochondria and hydrogenosomes in terms of their structure and the chemical processes they carry out
- Draw a chloroplast and identify its component parts

Three important energy-conserving organelles have been identified in eukaryotes: mitochondria, hydrogenosomes, and chloroplasts. They are of scientific interest not only for this role but also because of their evolutionary history. All are thought to be derived from bacterial cells that invaded or were ingested by early ancestors of eukaryotic cells (see figure 19.11). ►► *Evolutionary processes and the concept of a microbial species* (section 19.5)

Mitochondria

Found in most eukaryotic cells, **mitochondria** (s., **mitochondrion**) frequently are called the “powerhouses” of the cell (figure 5.15). Metabolic processes such as the tricarboxylic acid cycle and the generation of ATP, the major energy currency of all life forms, take place here. When viewed with a transmission electron microscope, many mitochondria are cylindrical structures and measure approximately 0.3 to 1.0 μm by 5 to 10 μm . (In other words, they are about the same size as bacterial cells.) Some cells possess 1,000 or more mitochondria; others (some yeasts, unicellular algae, and trypanosome protists) have a single, giant, tubular mitochondrion twisted

into a continuous network permeating the cytoplasm. ►► *Tricarboxylic acid cycle* (section 11.5); *Electron transport and oxidative phosphorylation* (section 11.6)

The mitochondrion is bounded by two membranes: an outer mitochondrial membrane separated from an inner mitochondrial membrane by a 6 to 8 nm intermembrane space (figure 5.15). The outer mitochondrial membrane contains porins and thus is similar to the outer membrane of Gram-negative bacteria. The inner membrane has infoldings called **cristae** (s., **crista**), which greatly increase its surface area. The shape of cristae differs in mitochondria from various species. Platelike (laminar) cristae, cristae shaped like disks, tubular cristae, and cristae in the shape of vesicles have all been observed. The inner membrane encloses the mitochondrial matrix, a dense material containing ribosomes, DNA, and often large calcium phosphate granules. In many organisms, mitochondrial DNA is a closed circle, like most bacterial DNA. However, in some protists, mitochondrial DNA is linear.

Each mitochondrial compartment has a characteristic chemical and enzymatic composition. For example, the outer and inner mitochondrial membranes possess different lipids. Enzymes and electron carriers involved in electron transport and oxidative phosphorylation (the formation of ATP during respiration) are located only in the inner membrane. Enzymes of the tricarboxylic acid cycle and those involved with the catabolism (breaking down) of fatty acids are located in the matrix.

►► *Lipid catabolism* (section 11.9)

The mitochondrion uses its DNA and ribosomes to synthesize some of its own proteins. In fact, mutations in mitochondrial DNA often lead to serious diseases in humans. However, most mitochondrial proteins are manufactured under the direction of

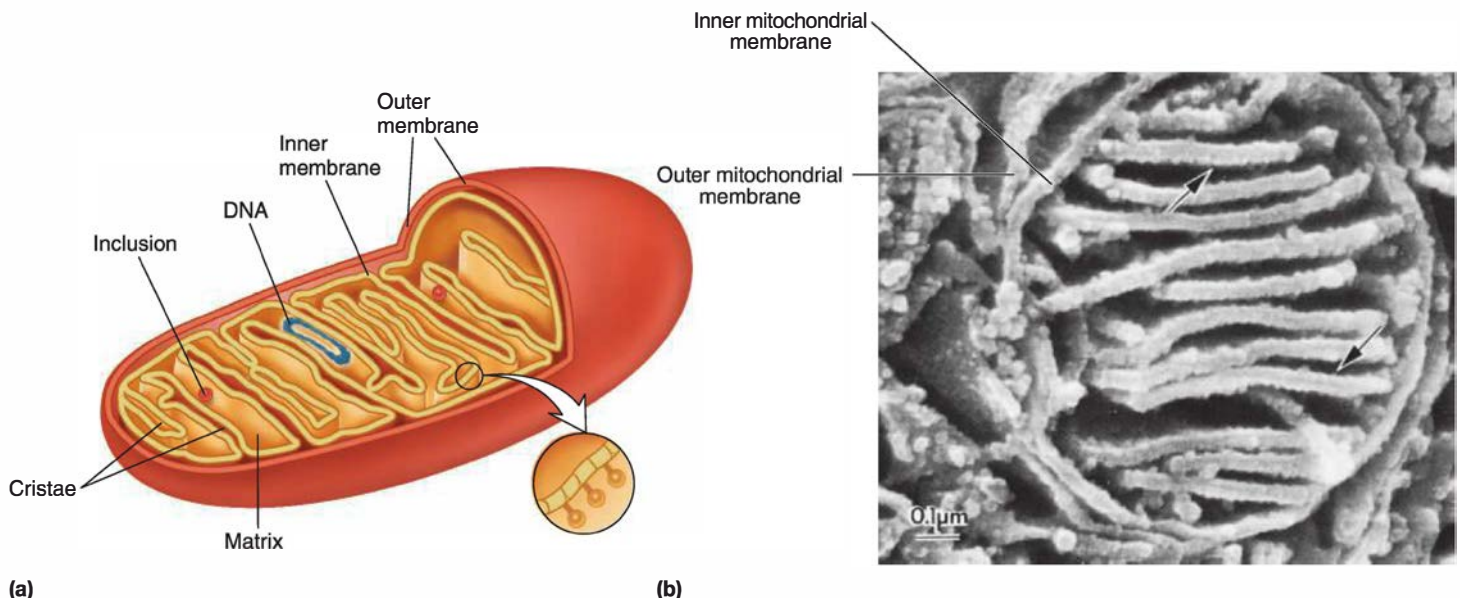

Figure 5.15 Mitochondrial Structure. (a) A diagram of mitochondrial structure. The insert shows the ATP-synthesizing enzyme ATP synthase lining the inner surface of the cristae. (b) Scanning electron micrograph ($\times 70,000$) of a freeze-fractured mitochondrion showing the cristae (arrows). The outer and inner mitochondrial membranes also are evident.

the nucleus and must be transported into the mitochondrion. Mitochondria reproduce by binary fission, a reproductive process used by many bacteria. ►► *Bacterial cell cycle (section 7.2); Protein localization and secretion in eukaryotes (section 15.4)*

Hydrogenosomes

Hydrogenosomes are small organelles involved in energy-conservation processes in some anaerobic protists (**figure 5.16**). Like mitochondria, hydrogenosomes are bound by a double membrane. However, they often lack cristae and usually lack DNA. They also differ from mitochondria in terms of the method used to generate ATP. Within hydrogenosomes, pyruvate is catabolized by a fermentative process rather than respiration, and CO_2 , H_2 , and acetate are formed. In some hydrogenosome-bearing protists, these metabolic products are consumed by symbiotic bacteria and archaea living within the protist. The symbiotic archaea include methanogens that consume the CO_2 and H_2 and generate methane (CH_4). ►► *Fermentation (section 11.8); Mutualism (section 32.1)*

Chloroplasts

Plastids are cytoplasmic organelles of photosynthetic protists and plants. They often possess pigments such as chlorophylls and carotenoids, and are the sites of synthesis and storage of food reserves. The most important type of plastid is the chloroplast. **Chloroplasts** contain chlorophyll and use light energy to convert CO_2 and water to carbohydrates and O_2 ; that is, they are the site of photosynthesis. Two major types of chloroplasts have been identified: those that evolved from a primary endosymbiotic event and those that evolved from a secondary (or tertiary) event (**Microbial Diversity & Ecology 5.1**). The chloroplasts of plants and some photosynthetic protists are primary plastids and are the focus of this discussion.

Chloroplasts are quite variable in size and shape, but they share many structural features. Most are oval with dimensions of 2 to 4 μm by 5 to 10 μm , but some photosynthetic protists possess one huge chloroplast that fills much of the cell. Like mitochondria, chloroplasts are encompassed by two membranes (**figure 5.17**). A matrix called the stroma is enclosed by the inner membrane. The stroma contains DNA, ribosomes, lipid droplets, starch granules, and a complex internal membrane system whose most prominent components are flattened, membrane delimited sacs called **thylakoids**.

Figure 5.16 The Metabolic Activities of Hydrogenosomes.

Clusters of two or more thylakoids are dispersed within the stroma of most algal chloroplasts (**figure 5.17b**). In some photosynthetic protists, several disklike thylakoids are stacked on each other like coins to form grana (s., granum).

Photosynthetic reactions are separated structurally in the chloroplast just as electron transport and the tricarboxylic acid cycle are in the mitochondrion. The trapping of light energy to generate ATP, NADPH, and O_2 is referred to as the light reactions. These reactions are located in the thylakoid membranes, where chlorophyll and electron transport components are also found. The ATP and NADPH formed by the light reactions are used to form carbohydrates from CO_2 and water in the dark reactions. The dark reactions take place in the stroma. ►► *Phototrophy (section 11.11)*

5.7 External Structures

After reading this section, you should be able to:

- Describe the structure of eukaryotic flagella and cilia
- Compare and contrast bacterial, archaeal, and eukaryotic flagella
- List the types of motility observed in eukaryotic microbes

Cilia (s., **cilium**) and **flagella** (s., **flagellum**) are the most prominent external structures observed on eukaryotic cells; they are associated with motility. Although both are whiplike and beat to move the microorganism along, they differ from one another in two ways. First, cilia are typically only 5 to 20 μm in length, whereas flagella are 100 to 200 μm long. Second, their patterns of movement are usually distinctive (**figure 5.18**). Flagella move in an undulating fashion and generate planar or helical waves originating at either the base or the tip. If the wave moves from base to tip, the cell is pushed along; a beat traveling from the tip toward the base pulls the cell through the water. Some flagella have lateral hairs called flimmer filaments (thicker, stiffer hairs are called mastigonemes). These filaments change flagellar action so that a wave moving down the

MICRO INQUIRY In what regions of the chloroplast do the light reactions occur? The dark reactions?

filament toward the tip pulls the cell along instead of pushing it. Such flagella often are called tinsel flagella, whereas naked flagella are referred to as whiplash flagella (**figure 5.19**). Cilia, on the other hand, normally have a beat with two distinctive phases. In the effective stroke, the cilium moves through the surrounding fluid like an oar, thereby propelling the organism. The cilium next bends along its length while it is pulled forward during the recovery stroke in preparation for another effective stroke (**figure 5.18**).

Figure 5.18 Patterns of Flagellar and Ciliary Movement. Flagellar and ciliary movement often takes the form of waves. Flagella (left illustration) move either from the base of the flagellum to its tip or in the opposite direction. The motion of these waves propels the organism along. The beat of a cilium (right illustration) may be divided into two phases. In the effective stroke, the cilium remains fairly stiff as it swings through the water. This is followed by a recovery stroke in which the cilium bends and returns to its initial position. The black arrows indicate the direction of water movement in these examples.

Microbial Diversity & Ecology

5.1 There Was an Old Woman Who Swallowed a Fly

The children's song "There Was an Old Woman Who Swallowed a Fly" describes the unusual eating habits of an old woman. Her story began when she ate a fly but continued as she ate a series of other animals, all in an attempt to get rid of the fly. The evolutionary history of chloroplasts also appears to involve a series of meals. Molecular studies of the chloroplasts of a wide variety of photosynthetic protists have revealed that some chloroplasts arose when a phagocytic ancestor of a eukaryotic cell engulfed the ancestor of a cyanobacterium (**box figure**). This evolutionary event eventually gave rise to plants and the photosynthetic protists commonly called green algae and red algae. These organisms are now classified together in the supergroup *Archaeplastida* (see chapter 25). The chloroplasts that evolved from this endosymbiosis are the typical chloroplasts that biology students are familiar with. These primary plastids have two

membranes. Subsequently, a phagocytic plastid-free eukaryote ingested an archaeplastid; in particular, a red alga. The ingested archaeplastid evolved into a chloroplast surrounded by three membranes. These chloroplasts are known as secondary plastids and are found in photosynthetic protists in the supergroup *Stramenopila*. They include diatoms and brown algae. The final meal in the series was eaten by some dinoflagellates. These interesting protists can be either chemorganotrophic or phototrophic. It appears that some photosynthetic dinoflagellates ingested a protist containing secondary plastids. The ingested protist evolved into a tertiary plastid surrounded by four membranes.

Figure 5.20 Coordination of Ciliary Activity. A scanning electron micrograph of *Paramecium* showing cilia ($\times 1,500$). The ciliary beat is coordinated and moves in waves across the protist's surface.

A ciliated microorganism actually coordinates the beats so that some of its cilia are in the recovery phase while others are carrying out their effective stroke (**figure 5.20**). This coordination allows the organism to move smoothly through the water.

Despite their differences, cilia and flagella are very similar in ultrastructure. They are membrane-bound cylinders about $0.2\ \mu\text{m}$ in diameter. Located in the matrix of the organelle is the axoneme, which usually consists of nine microtubule doublets arranged in a circle around two central microtubules (**figure 5.21**). This is called the $9 + 2$ pattern of microtubules. Each doublet has pairs of arms projecting from submicrotubule A toward a neighboring doublet. A radial spoke extends from submicrotubule A toward the internal pair of microtubules with their central sheath. These microtubules are similar to those found in the cytoplasm.

A basal body lies in the cytoplasm at the base of each cilium or flagellum. It is a short cylinder with nine microtubule triplets around its periphery (a $9 + 0$ pattern) and is separated from the rest of the organelle by a basal plate. The basal body directs the construction of these organelles. Cilia and flagella appear to grow through the addition of preformed microtubule subunits at their tips.

Cilia and flagella bend because adjacent microtubule doublets slide along one another while maintaining their individual lengths. The doublet arms, about $15\ \text{nm}$ long, are made of the protein dynein (**figure 5.21**). Dynein arms interact with the B submicrotubules of adjacent doublets to cause the sliding. The radial spokes also participate in this sliding motion. ATP powers the movement of cilia and flagella.

Cilia and flagella beat at a rate of about 10 to 40 strokes or waves per second and propel microorganisms rapidly. The flagellate protist *Monas stigmatica* swims at a rate of $260\ \mu\text{m}/\text{second}$ (approximately 40 cell lengths per second); the euglenoid flagellate *Euglena gracilis* travels at around $170\ \mu\text{m}$ or 3 cell lengths per second. The ciliate protist *Paramecium caudatum* swims about

Retrieve, Infer, Apply

1. Prepare and label a diagram showing the detailed structure of a cilium or flagellum.
2. How do cilia and flagella move, and what is dynein's role in the process? Contrast the ways in which flagella and cilia propel eukaryotic microorganisms through water.
3. How do the structure and mechanism of action of bacterial, archaeal, and eukaryotic flagella differ?

5.8 Comparison of Bacterial, Archaeal, and Eukaryotic Cells

After reading this section, you should be able to:

- Create a Venn diagram or concept map that clearly distinguishes bacterial, archaeal, and eukaryotic cells in terms of their genome organization, organelles, cell envelopes, ribosome size and component molecules, and cytoskeleton
- Determine the type of microbe when given a description of a newly discovered microbe

A comparison of the bacterial and eukaryotic cells in **figure 5.22** demonstrates that there are many fundamental differences between these cells. These differences are also observed between archaeal and eukaryotic cells, because archaea are similar to bacteria at the gross structural level. Eukaryotic cells have a

membrane-enclosed nucleus. In contrast, bacterial and archaeal cells lack a true, membrane-delimited nucleus. Most bacteria and archaea are smaller than eukaryotic cells, often about the size of eukaryotic mitochondria and chloroplasts.

Many other major distinctions between these groups exist. It is clear from **table 5.2** that bacterial and archaeal cells are much simpler structurally. In particular, an extensive and diverse collection of membrane-delimited organelles is missing. Furthermore, bacterial and archaeal cells are functionally simpler in several ways. They lack mitosis and meiosis, and have a simpler genetic organization. Many complex eukaryotic processes are absent in bacteria and archaea: endocytosis, intracellular digestion, directed cytoplasmic streaming, and ameboid movement are just a few.

Despite the many significant differences, all cells are remarkably similar on the biochemical level, as we discuss in succeeding chapters. With a few exceptions, the genetic code is the same in all, as is the way in which the genetic information in DNA is expressed. The principles underlying metabolic processes and many important metabolic pathways are identical. Thus beneath the profound structural and functional differences between bacterial, archaeal, and eukaryotic cells, there is an even more fundamental unity: a molecular unity that is basic to all known life processes.

(b) The eukaryotic alga *Chlamydomonas reinhardtii*. Note the large chloroplast with its pyrenoid body ($\times 30,000$).

Table 5.2 Comparison of Bacterial, Archaeal, and Eukaryotic Cells

| Property | Bacteria | Archaea | Eukaryotes |
|--|---|--|---|
| Organization of Genetic Material | | | |
| True membrane-bound nucleus | No | No | Yes |
| DNA complexed with histones | No | Some | Yes |
| Chromosomes | Usually one circular chromosome | One circular chromosome | More than one; chromosomes are linear |
| Plasmids | Very common | Very common | Rare |
| Introns in genes | Rare | Rare | Yes |
| Nucleolus | No | No | Yes |
| Mitochondria, Chloroplasts, Endoplasmic Reticulum, Golgi, and Lysosomes Observed | No | No | Yes |
| Plasma Membrane Lipids | Ester-linked phospholipids and hopanoids; some have sterols | Glycerol diethers and diglycerol tetraethers | Ester-linked phospholipids and sterols |
| Flagella | Submicroscopic in size; filament composed of single type of flagellin | Submicroscopic in size; filament composed of multiple different flagellins | Microscopic in size; membrane bound; usually 20 microtubules in 9 + 2 pattern |
| Peptidoglycan in Cell Walls | Yes | No | No |
| Ribosome Size and Structure | 70S; 3 rRNAs; ~55 ribosomal proteins | 70S; most have 3 rRNAs; ~68 ribosomal proteins | 80S; 4 rRNAs and ~80 ribosomal proteins |
| Cytoskeleton | Rudimentary | Rudimentary | Yes |
| Gas Vesicles | Yes | Yes | No |

Key Concepts

5.1 A Typical Eukaryotic Cell

- Eukaryotic cells are generally larger than bacterial and archaeal cells, and they exhibit considerably more morphological diversity.
- The eukaryotic cell has a true, membrane-delimited nucleus and many membranous organelles (**table 5.1; figures 5.2 and 5.3**).
- The membranous organelles compartmentalize the cytoplasm of the cell. This allows the cell to carry out a variety of biochemical reactions simultaneously. It also provides more surface area for membrane-associated activities such as respiration.

5.2 Eukaryotic Cell Envelopes

- Eukaryotic membranes are similar in structure and function to bacterial membranes. The two differ in terms of their lipid composition.

- Eukaryotic membranes contain microdomains that are enriched for certain lipids and proteins, and participate in a variety of cellular processes.
- When a cell wall is present, it is constructed from polysaccharides (e.g., cellulose) that are chemically simpler than peptidoglycan, the molecule found in bacterial cell walls.

5.3 Cytoplasm of Eukaryotes

- The cytoplasm consists of a cytosol in which are found the organelles and cytoskeleton.
- The cytoskeleton is organized from actin filaments, intermediate filaments, and microtubules. These cytoskeletal elements are partly responsible for cell structure, endocytosis, movement of cell structures, and motility (**figure 5.5**).

- Actin filaments and microtubules have been observed in eukaryotic microbes. Actin filaments are composed of actin proteins; microtubules are composed of α -tubulin and β -tubulin.
- Intermediate filaments are assembled from a heterogeneous family of proteins. They are found in animal cells but have not been identified or studied in eukaryotic microbes.

5.4 Organelles of the Secretory and Endocytic Pathways

- The cytoplasm is permeated with a complex of membranous organelles and vesicles. Some are involved in the synthesis and secretion of materials (secretory pathway). Some are involved in the uptake of materials from the extracellular milieu (endocytic pathway).
- The endoplasmic reticulum (ER) is an irregular network of tubules and flattened sacs (cisternae). Rough ER has ribosomes attached to it and is active in protein synthesis. Smooth ER lacks ribosomes.
- The ER donates some materials to the Golgi apparatus, an organelle usually composed of one or more stacks of cisternae (figure 5.8). The Golgi prepares and packages cell products for secretion.
- The Golgi apparatus buds off vesicles that deliver hydrolytic enzymes and other proteins to lysosomes and lysosome-like organelles. Lysosomes contain digestive enzymes and aid in intracellular digestion of extracellular materials delivered to them by endocytosis and macroautophagy.
- Mammalian cells use several kinds of endocytosis (figure 5.10). These include phagocytosis, clathrin-dependent endocytosis, and caveolin-dependent endocytosis. Some macromolecules are bound to receptors prior to endocytosis in a process called receptor-mediated endocytosis.
- Endocytic pathways in eukaryotic microbes are not as well studied as are mammalian pathways. However, similar mechanisms are employed.

5.5 Organelles Involved in Genetic Control of the Cell

- The nucleus is a large organelle containing the cell's chromosomes. It is surrounded by a double-membrane

envelope perforated by pores through which materials can move (figure 5.12).

- The nucleolus lies within the nucleus and participates in the synthesis of ribosomal RNA and ribosomal subunits (figure 5.13).
- Eukaryotic ribosomes are found either free in the cytoplasm or bound to the ER. They are 80S in size (figure 5.14).

5.6 Organelles Involved in Energy Conservation

- Mitochondria are organelles bounded by two membranes, with the inner membrane folded into cristae (figure 5.15). They are responsible for energy conservation by cell respiration, which involves the tricarboxylic acid cycle, electron transport, and oxidative phosphorylation.
- Hydrogenosomes have a double membrane and carry out metabolic processes that generate hydrogen gas (figure 5.16).
- Chloroplasts are pigment-containing organelles that serve as the site of photosynthesis (figure 5.17). The trapping of light energy takes place in the thylakoid membranes of the chloroplast, whereas CO₂ fixation occurs in the stroma.

5.7 External Structures

- Many eukaryotic cells are motile because of cilia and flagella, membrane-enclosed organelles with nine microtubule doublets surrounding two central microtubules (figure 5.21).
- Cilia and flagella exhibit a whiplike motion. This occurs when the microtubule doublets slide along each other, causing the cilium or flagellum to bend.

5.8 Comparison of Bacterial, Archaeal, and Eukaryotic Cells

- Bacterial and archaeal cells are similar in appearance but differ at the molecular levels. A major difference between these cells and eukaryotic cells is that eukaryotic cells contain a nucleus and numerous membranous structures.
- Despite the fact that eukaryotic, bacterial, and archaeal cells differ structurally in many ways (table 5.2), they are quite similar biochemically.

Compare, Hypothesize, Invent

1. Discuss the statement: "The most obvious difference between eukaryotic, bacterial, and archaeal cells is in their use of membranes." Specifically, compare the roles of the bacterial and archaeal plasma membrane with those of the organelle membranes in eukaryotes.
2. Bacterial and archaeal cell size is limited by the rate at which nutrients diffuse from one place in the cell to another. Are eukaryotic cells similarly limited? Why or why not?
3. In addition to their role in packaging chromosomes, histones are involved in the regulation of transcription. How might this be the case?
4. Compare the mechanisms by which most eukaryotic cells can acquire nutrients with that of bacteria and archaea. What are the implications in terms of survival in different habitats and competition between eukaryotic microbes such as protists and bacteria and archaea?
5. In recent years, there have been advances in understanding longevity through research on three model organisms: mice, nematode worms, and the yeast *Saccharomyces cerevisiae*. It is clear that caloric restriction is linked to increased life span in multicellular organisms (mice and worms). This phenomenon can be studied at the molecular level in yeast, where loss of the protein Sch9p increases the yeast life span by increasing the rate of mitochondrial activity. In this way, caloric restriction is mimicked. List the pros and cons of the use of eukaryotic microorganisms as models for complex physiological and genetic questions that are relevant to higher organisms, including humans. What is the most significant advantage and the most unfortunate disadvantage?

Read the original paper: Lovoie, L., and Whiteway, M. 2008. Increased respiration in the *sch9Δ* mutant is required for increasing chronological life span but not replicative life span. *Euk. Cell* 7:1127.

Viruses and Other Acellular Infectious Agents

Mustard, Catsup, and Viruses?

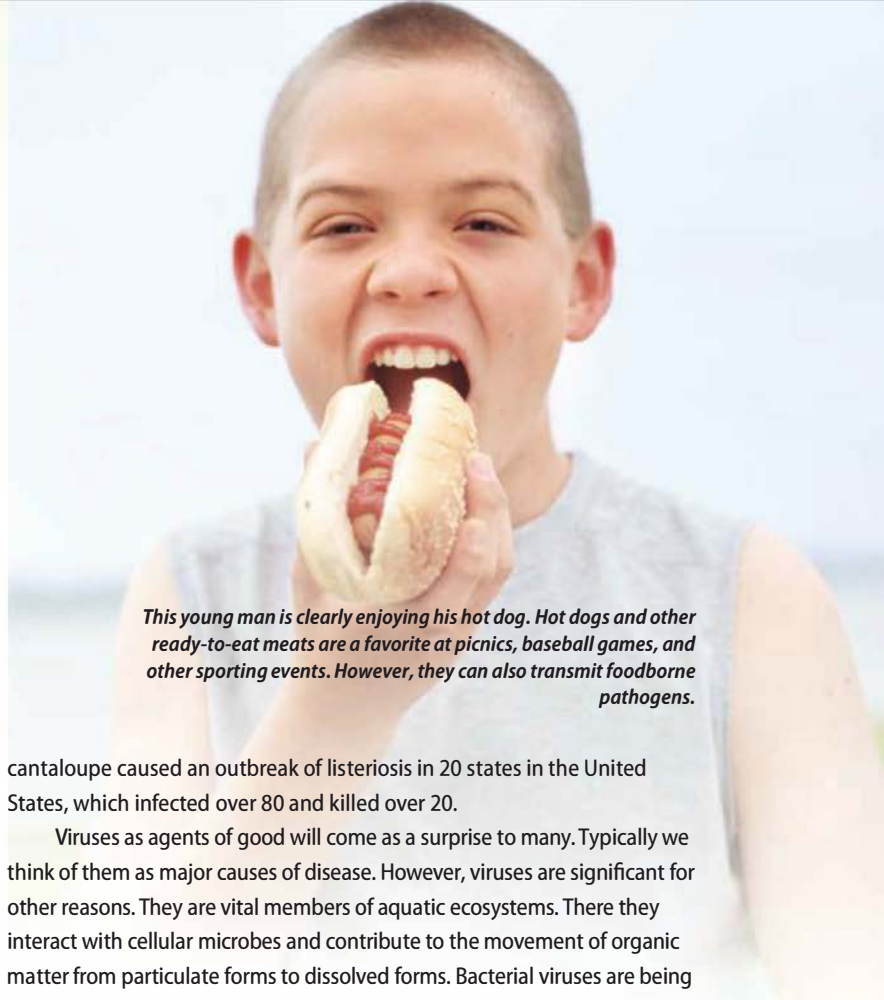

During the summer of 2010, over 21 million hot dogs were sold to fans attending games at major league baseball parks in the United States. Hot dogs and lunch meats are popular at outings such as baseball games and in lunches carried to work or school. Yet each year in the United States, approximately 1,600 people are sickened by a bacterium that can contaminate the meat and, even worse, survive and grow when the meat is properly refrigerated.

The disease culprit is *Listeria monocytogenes*, a Gram-positive rod found in soil and many other environmental sites. It is not only cold tolerant but salt and acid tolerant as well. Although it is in the minor leagues when compared to some of the big hitters of foodborne disease (e.g., *Salmonella enterica*), it is of concern for two reasons: who it kills and how many it kills. *L. monocytogenes* targets the young and old, pregnant women, and immunocompromised individuals; about 15% of those infected die.

Its effect on pregnant women is particularly heartbreaking. The woman usually only suffers mild, flulike symptoms; however, these innocuous symptoms belie the fact that the child she carries is in serious danger. Her pregnancy often ends in miscarriage or stillbirth. Newborns infected with the bacterium are likely to develop meningitis. Many will die as a result. Those who survive often have neurological disorders.

Currently, pregnant women are counseled against eating ready-to-eat foods unless they have been cooked prior to consumption. However, *L. monocytogenes* is known to contaminate many foods other than hot dogs and these can't always be heated. In 2006 the U.S. Food and Drug Administration (FDA) approved a new approach to prevent listeriosis: spraying viruses that attack and destroy the bacterium on ready-to-eat cold cuts and luncheon meats. In other words, the viruses are a food additive! The method is safe because the viruses only attack *L. monocytogenes*, not human cells.

Since approval, the use of viruses to control the transmission of listeriosis by other foods has been studied. Unfortunately, those studies did not include foods such as fresh fruit. In 2011 *L. monocytogenes*-contaminated

This young man is clearly enjoying his hot dog. Hot dogs and other ready-to-eat meats are a favorite at picnics, baseball games, and other sporting events. However, they can also transmit foodborne pathogens.

cantaloupe caused an outbreak of listeriosis in 20 states in the United States, which infected over 80 and killed over 20.

Viruses as agents of good will come as a surprise to many. Typically we think of them as major causes of disease. However, viruses are significant for other reasons. They are vital members of aquatic ecosystems. There they interact with cellular microbes and contribute to the movement of organic matter from particulate forms to dissolved forms. Bacterial viruses are being used in some European countries to treat infections caused by bacteria. Finally, they are important model organisms. In this chapter, we introduce viruses and other acellular infectious agents. ►► *Aquatic viruses (section 30.2); Biological control of microorganisms (section 8.7)*

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Define the term acellular
- ✓ Compare and contrast in general terms viruses, viroids, satellites, and prions (section 1.1)

6.1 Viruses

After reading this section, you should be able to:

- Define the terms virology, bacteriophages, and phages
- List organisms that are hosts to viruses

The discipline of **virology** studies **viruses**, a unique group of infectious agents whose distinctiveness resides in their simple, acellular organization and pattern of multiplication. Despite this simplicity, viruses are major causes of disease. For instance, many human diseases are caused by viruses, and more are discovered every year, as demonstrated by the appearance of SARS in 2003, new avian influenza viruses over the past 5 to 6 years, and the H1N1 (swine) influenza virus in 2009. However, their simplicity also has made them attractive model organisms. They served as models for understanding DNA replication, RNA synthesis, and protein synthesis. Therefore the study of viruses has contributed significantly to the discipline of molecular biology. In fact, the

field of genetic engineering is based in large part on the use of viruses and viral enzymes such as the retroviral enzyme reverse transcriptase. ►► *Recombinant DNA technology (chapter 17)*

Viruses can exist either extracellularly or intracellularly. When extracellular, they are inactive (with one known interesting exception: **Microbial Diversity & Ecology 6.1**) because they possess few, if any, enzymes and cannot reproduce outside of living cells. When intracellular, viruses exist primarily as replicating nucleic acids that induce the host to synthesize viral components from which progeny virions are assembled and eventually released.

Viruses can infect all cell types. Numerous viruses infect bacteria. They are called **bacteriophages**, or **phages** for short. Fewer archaeal viruses have been identified. Most known viruses infect eukaryotic organisms, including plants, animals, protists, and fungi. Viruses have been classified into numerous families based primarily on genome structure, life cycle, morphology, and genetic relatedness. These families have been designated by the International Committee for the Taxonomy of Viruses (ICTV), the agency responsible for standardizing the classification of viruses. ►► *Virus taxonomy and phylogeny (section 27.1)*

In this chapter, we introduce the structure and multiplication strategies of viruses. Their taxonomic diversity is presented in chapter 27, and their ecological relevance is discussed in chapter 30.

6.2 Virion Structure

After reading this section, you should be able to:

- State the size range of virions
- Identify the parts of a virion and describe their function
- Distinguish enveloped viruses from nonenveloped viruses
- Describe the types of capsid symmetry

A complete virus particle is called a **virion**. Virion morphology has been intensely studied over the past decades because of the importance of viruses and the realization that virion structure is simple enough to be understood in detail. Progress has come from the use of several different techniques: electron microscopy, X-ray diffraction, biochemical analysis, and immunology. Although our knowledge is incomplete due to the large number of different viruses, we can discuss the general nature of virion structure.

General Structural Properties

Virions range in size from about 10 to 400 nm in diameter (**figure 6.1**). The smallest are a little larger than ribosomes, whereas mimiviruses, the largest viruses known, have virions

Figure 6.1 The Size and Virion Morphology of Selected Viruses. The virions are drawn to scale.

MICRO INQUIRY Which capsids are icosahedral? Which are helical? Which have complex symmetry?

Microbial Diversity & Ecology

6.1 Host-Independent Growth of an Archaeal Virus

Viruses cannot multiply without first infecting a host cell, and when outside a host cell, they have been thought to be inert. Thus they are often described as “entities” rather than organisms. So it was quite a surprise when an archaeal virus was discovered that develops long tails only when outside its host (**box figure**). This archaeal virus was found in acidic hot springs (pH 1.5, 85–93°C) in Italy, where it infects the hyperthermophilic archaeon *Acidianus convivator*. When the virus infects its host, lemon-shaped virions are assembled. Following host lysis, two “tails” begin to form at either end of the virion. These projections continue to assemble until they reach a length at least that of the capsid. Curiously, tails are only produced if virions are incubated at high temperature. The virus is called ATV for *Acidianus* two-tailed virus.

To learn more about the structure of the tails, the ATV genome was sequenced. ATV is a double-stranded DNA virus that encodes only nine structural proteins. The tail protein is 800 amino acids long and is homologous to eukaryotic intermediate filament proteins. Both intermediate filaments and purified ATV tail proteins assemble into filamentous structures without additional energy or cofactors. ◀◀ *Cytoplasm of eukaryotes* (section 5.3)

It is suspected that the development of tails only at high temperatures may be a survival strategy for the virus when host cell density is low. ATV induces lysis rather than lysogeny in its archaeal host. Most other viruses that infect archaea living in acidic hot springs have evolved lysogeny as a means to survive these harsh conditions. Why this virus has evolved lysis and tail development is unknown, but it suggests that viruses may be more complicated than simple “entities.”

Acidianus Two-Tailed Virus, ATV. Negative contrast electron micrograph of ATV virions at successive steps of extracellular tail development. Scale bar = 200 nm.

Source: Häring, M.; Vestergaard, G.; Rachel, R.; Chen, L.; Garret, R. A.; and Prangishvili, D. 2005. Independent virus development outside a host. *Nature* 436:1101–02.

larger than some of the smallest bacteria and can be seen in the light microscope. However, most virus particles must be viewed with electron microscopes. ◀◀ *Electron microscopy* (section 2.4)

The simplest virions are constructed of a **nucleocapsid** (**figure 6.2a**). The nucleocapsid is composed of a nucleic acid, either DNA or RNA, and a protein coat called the **capsid**. The viral nucleic acid is surrounded by the capsid, which protects the viral genome and aids in its transfer between host cells. Among the proteins encoded by the viral genome are the capsid proteins, which are called **protomers**. Capsids self-assemble by a process that is not fully understood. Some viruses use noncapsid proteins as scaffolding upon which the capsids are assembled.

Probably the most important advantage of this design strategy is that the viral genome is used with maximum efficiency. For

(a) Nonenveloped virus

(b) Enveloped virus

Figure 6.2 Generalized Structure of Virions. (a) The simplest virion is that of a nonenveloped virus (nucleocapsid), consisting of a capsid assembled around its nucleic acid. (b) Virions of enveloped viruses are composed of a nucleocapsid surrounded by a membrane called an envelope. The envelope usually has viral proteins called spikes inserted into it.

Figure 6.3 Tobacco Mosaic Virus (TMV) Virions. (a) An electron micrograph of the negatively stained helical capsid ($\times 400,000$). The virions are usually 15 to 18 nm in diameter and 300 nm long. (b) Illustration of a TMV nucleocapsid. Note that it is composed of a helical array of protomers with the RNA spiraling on the inside. (c) A model of a TMV virion.

example, the *tobacco mosaic virus* (TMV) capsid is constructed using a single type of protomer (figure 6.3). Recall that the building blocks of proteins are amino acids and that each amino acid is encoded by three nucleotides, the building blocks of nucleic acids. The TMV protomer is 158 amino acids in length. Therefore only about 474 nucleotides are required to code for the coat protein. The TMV genome consists of 6,400 nucleotides. Thus only a small fraction of the genome is used to code for the capsid. Suppose, however, that the TMV capsid were composed of six different protomers, all about 150 amino acids in length. If this were the case, about 2,900 of the 6,400 nucleotides in the TMV genome would be required just for capsid construction, and much less genetic material would be available for other purposes.

The various morphological types of virions primarily result from the combination of a particular type of capsid symmetry with the presence or absence of an envelope—a lipid layer external to the nucleocapsid. There are three types of capsid symmetry: helical, icosahedral, and complex. Viruses with virions having an envelope are called **enveloped viruses**, whereas those lacking an envelope are called **nonenveloped** or **naked viruses** (figure 6.2).

Helical Capsids

Helical capsids are shaped like hollow tubes with protein walls. Tobacco mosaic virus is a well-studied example of helical capsid structure (figure 6.3). The self-assembly of TMV protomers into a helical arrangement produces a rigid tube. The capsid

encloses an RNA genome, which is wound in a spiral and lies within a groove formed by the protein subunits. Not all helical capsids are as rigid as the TMV capsid. The genomes of influenza viruses are enclosed in thin, flexible helical capsids that are folded within an envelope (figure 6.4). ►► *Tobacco mosaic virus* (section 27.6)

The size of a helical capsid is influenced by both its protomers and the nucleic acid enclosed within the capsid. The diameter of the capsid is a function of the size, shape, and interactions of the protomers. The nucleic acid appears to determine its length because a helical capsid does not extend much beyond the end of the viral genome.

Icosahedral Capsids

An icosahedron is a regular polyhedron with 20 equilateral triangular faces and 12 vertices (figure 6.1f,g). **Icosahedral capsids** are the most efficient way to enclose a space. They are constructed from ring- or knob-shaped units called **capsomers**, each usually made of five or six protomers (figure 6.5). Pentamers (pentons) have five protomers; hexamers (hexons) possess six. Pentamers are usually at the vertices of the icosahedron, whereas hexamers generally form its edges and triangular faces. The virions of some RNA viruses have pentamers and hexamers constructed with only one type of subunit. Other virions have pentamers and hexamers composed of different proteins. Although many icosahedral capsids contain both pentamers and hexamers, some have only pentamers.

Figure 6.4 Influenza Virus Virions: An Enveloped Virus with Helical Nucleocapsids. (a) Schematic view. Influenza viruses have segmented genomes consisting of seven to eight different RNA molecules. Each is coated by capsid proteins to create seven to eight flexible nucleocapsids. The envelope has spikes that project 10 nm from the surface at 7 to 8 nm intervals. (b) Because the nucleocapsids are flexible, the virions are pleomorphic. Electron micrograph ($\times 350,000$).

Figure 6.5 The Icosahedral Capsid of Adenovirus. (a) Electron micrograph of adenovirus virions, 252 capsomers ($\times 171,000$). (b) Computer-simulated model of an adenovirus virion.

MICRO INQUIRY Are the capsomers at the vertices of an adenovirus virion pentamers or hexamers? What is the difference between a pentamer and hexamer?

Capsids of Complex Symmetry

Most viruses have either icosahedral or helical capsids, but some viruses do not fit into either category. Poxviruses and large bacteriophages are two important examples.

Poxvirus virions are among the largest of the animal viruses (about 400 by 240 by 200 nm in size) and can be seen with a light microscope. They possess an exceptionally complex internal structure with an ovoid- to brick-shaped exterior. **Figure 6.6**

shows the virion morphology of a vaccinia virus. Its double-stranded DNA genome is associated with proteins and contained in the core, a central structure shaped like a biconcave disk and surrounded by a membrane. Two lateral bodies lie between the core and the virion's outer envelope.

Some large bacteriophages have virions that are even more elaborate than those of poxviruses. The virions of T2, T4, and T6 phages (T-even phages) that infect *Escherichia coli* are said to have **binal symmetry** because they have a head that resembles an icosahedron and a tail that is helical. The icosahedral head is elongated by one or two rows of hexamers in the middle and contains the DNA genome (**figure 6.7**). The tail is composed of a collar joining it to the head, a central hollow tube, a sheath surrounding the tube, and a complex baseplate. In T-even phages, the baseplate is hexagonal and has a pin and a jointed tail fiber at each corner. **▶▶ Bacteriophage T4 (section 27.2)**

Considerable variation in structure exists among the large bacteriophages, even those infecting a single host. In contrast with the T-even phages, many other phages that infect *E. coli* have true icosahedral heads. T1, T5, and lambda phages have sheathless tails that lack a baseplate and terminate in rudimentary tail fibers. Coliphages T3 and T7 have short tails without tail fibers. **▶▶ Bacteriophage lambda (section 27.2)**

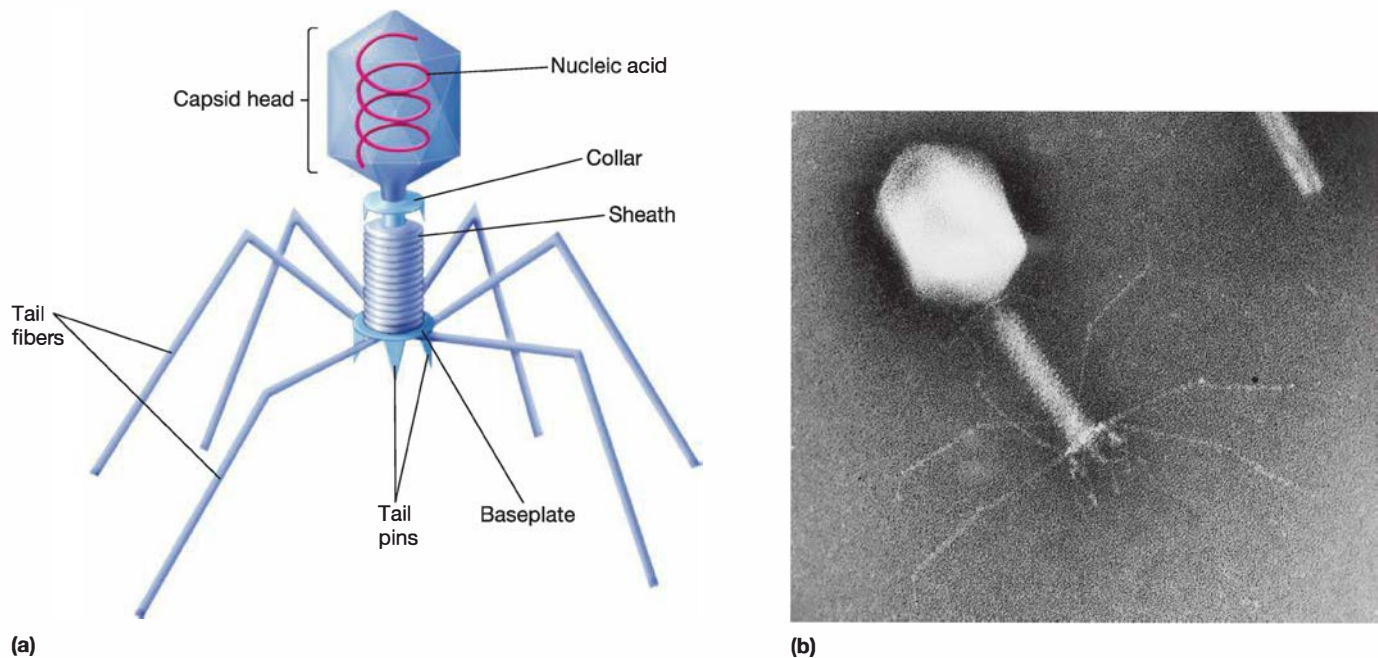

Figure 6.7 T4 Phage of *E. coli*. (a) The structure of T4 bacteriophage virion. (b) Micrograph showing the virion before injection of its DNA.

MICRO INQUIRY Why is T4 said to have binal symmetry?

Viral Envelopes and Enzymes

The nucleocapsids of many animal viruses, some plant viruses, and at least one bacterial virus are surrounded by an outer membranous layer called an **envelope** (figure 6.8). Animal virus envelopes usually arise from the plasma or nuclear membranes of the host cell. Envelope lipids and carbohydrates are therefore acquired from the host. In contrast, envelope proteins are coded for by viral genes and may even project from the envelope surface as **spikes**, which are also called **peplomers**

(figure 6.8). In many cases, spikes are involved in virion attachment to the host cell surface. Because spikes differ among viruses, they also can be used to identify some viruses. Many enveloped viruses have virions with a somewhat variable shape and are called **pleomorphic**. However, the envelopes of viruses such as the bullet-shaped rabies viruses are firmly attached to the underlying nucleocapsid and endow the virion with a constant, characteristic shape (figure 6.8a).

(a) Rabies virus

(b) Herpesvirus

Figure 6.8 Examples of Enveloped Viruses. (a) Negatively stained virion of a rabies virus. (b) Herpesvirus virion. Images are artificially colored.

Influenza virus (figure 6.4) is a well-studied enveloped virus with two types of spikes. Some spikes consist of the enzyme **neuraminidase**, which functions in the release of mature virions from the host cell. Other spikes are **hemagglutinin** proteins, so named because they bind virions to red blood cells and cause the cells to clump together—a process called hemagglutination. Influenza virus's hemagglutinins participate in virion attachment to host cells. Most of its envelope proteins are glycoproteins—proteins that have carbohydrate attached to them. A nonglycosylated protein, the M (matrix) protein, is found on the inner surface of the envelope and helps stabilize it.

In addition to enzymes associated with the envelope or capsid (e.g., influenza neuraminidase), some viruses have enzymes within their capsids. Such enzymes are usually involved in nucleic acid replication. For example, influenza virus virions have an RNA genome and carry an enzyme that synthesizes RNA using an RNA template. Thus although viruses lack true metabolism and cannot reproduce independently of living cells, their virions may carry one or more enzymes essential to the completion of their life cycles.

Viral Genomes

One clear distinction between cellular organisms and viruses is the nature of their genomes. Cellular genomes are always double-stranded (ds) DNA. Viruses, on the other hand, employ all four possible nucleic acid types: dsDNA, single-stranded (ss) DNA, ssRNA, and dsRNA. All four types are used by animal viruses. Most plant viruses have ssRNA genomes, and most bacterial viruses have dsDNA. The size of viral genomes also varies greatly. Very small genomes are around 4,000 nucleotides—just large enough to code for three or four proteins. Some viruses save additional space by using overlapping genes. At the other extreme are the genomes of

mimiviruses, which infect protists. They are about 1.2×10^6 nucleotides long, rivaling some bacteria and archaea in coding capacity. ►► *Bacterial gene structure (section 13.4); What is a virus? (Microbial Diversity & Ecology 27.1)*

Most DNA viruses use dsDNA as their genetic material. However, some have ssDNA genomes (e.g., ϕ X174 and M13). In both cases, the genomes may be either linear or circular. Some DNA genomes can switch from one form to the other. For instance, the *E. coli* phage lambda has a linear genome in its capsid, but it becomes circular once it enters the host cell.

►► *Bacteriophages ϕ X174 and fd (section 27.3)*

Relatively few RNA viruses have dsRNA genomes. More common are viruses with ssRNA genomes. Polio, tobacco mosaic, SARS, rabies, mumps, measles, influenza, human immunodeficiency, and brome mosaic viruses are all ssRNA viruses.

Many RNA viruses have **segmented genomes**—genomes that consist of more than one piece (segment) of RNA. In many cases, each segment codes for one protein and there may be as many as 10 to 12 segments (figure 6.4). Usually all segments are enclosed in the same capsid; however, this is not always the case. For example, the genome of brome mosaic virus, a virus that infects certain grasses, is composed of three segments distributed among three different virions.

Retrieve, Infer, Apply

1. How are viruses similar to cellular organisms? In what fundamental way do they differ?
2. What is the difference between a nucleocapsid and a capsid?
3. Compare the structure of an icosahedral capsid with that of a helical capsid. How do pentamers and hexamers associate to form a complete icosahedron? Which virus would have a longer helical capsid: a virus with a 7200 bp DNA genome or one with an 11,000 base RNA genome?

4. What is an envelope? What are spikes (peplomers)? Why do some enveloped viruses have pleomorphic virions? Give two functions spikes might serve in the viral life cycle and the proteins that the influenza virus uses in these processes.
5. All four nucleic acid forms can serve as viral genomes. Describe each. What is a segmented RNA genome?
6. The RNA genomes of some RNA viruses resemble the messenger RNA (mRNA) of their eukaryotic hosts. What advantage would an RNA virus gain by having this type of genome?

6.3 Viral Multiplication

After reading this section, you should be able to:

- Describe the five steps common to the life cycles of all viruses
- Discuss the role of receptors, capsid proteins, and envelope proteins in the life cycles of viruses
- Describe the two most common methods for virion release from a host cell

Differences in virion structure have important implications for the mechanism a virus uses to multiply within its host cell. Indeed, even among viruses with similar structures, each can exhibit unique life cycles. Despite these differences, a general pattern of viral life cycles can be discerned. Because viruses need a host cell in which to multiply, the first step in the life cycle of a virus is attachment (often called adsorption) to a host (**figure 6.9**). This is followed by entry of either the nucleocapsid or the viral nucleic acid into the host. If the nucleocapsid enters, uncoating of the genome usually occurs before the life cycle continues. Once inside the host cell, the synthesis stage begins. During this stage, viral genes are expressed. That is, the virus's genes are transcribed and translated. This allows the virus to take control of the host cell, forcing it to manufacture viral genomes and viral proteins. This is followed by the assembly stage, during which new nucleocapsids are constructed by self-assembly of coat proteins with the nucleic acids. Finally, during the release step, mature virions escape the host.

Attachment (Adsorption)

All viruses, with the exception of plant viruses, must associate with a potential host cell long enough to gain entry into the cell. Attachment to the host is accomplished by specific interactions between molecules on the surface of the virion (ligands) and molecules on the surface of the host cell called **receptors**. For instance, some bacteriophages use cell wall lipopolysaccharides and proteins as receptors, while others use teichoic acids, flagella, or pili. Binding of an animal virus particle to its receptor often causes conformational changes in virion proteins that facilitate interaction with secondary receptors, entry into the host, and uncoating.

Variation in receptors used by viruses for attachment is at least partly responsible for host preferences. Bacteriophages not only

Figure 6.9 Generalized Illustration of Virus Multiplication. The life cycle of a virus that infects a eukaryotic cell is shown. Figure 6.15 illustrates the generalized life cycle of bacterial and archaeal viruses. Virions are not drawn to scale.

infect a particular species but often infect only certain strains within a given species. Receptor specificity also accounts for the observation that animal viruses infect specific animals and, in some cases, only particular tissues within that host. However, if the receptor recognized by a virus is present in numerous animals, then the virus will infect more than one animal species. Such is the case with rabies viruses.

Viruses have evolved such that they use host receptors that are always present on the cell surface of the host cell and are important for normal host cell function. Because the cell surface proteins are vital for cellular function, mutations that change them significantly are not tolerated, and this ensures that the virus can infect the host. In some cases, two or more host cell receptors are involved in attachment. For instance, human immunodeficiency virus (HIV) particles bind to two different proteins on human cells (e.g., CD4 and CCR5). Both of these host molecules normally bind chemokines—signaling molecules used by the immune system.

►► Cytokines (section 33.3)

The distribution of the host cell receptors to which animal viruses attach also varies at the cellular level. Eukaryotic cell membranes have microdomains often called lipid rafts that are thought to be involved in both virion entrance and assembly. For example, the receptors for enveloped viruses such as HIV and Ebola are concentrated in lipid rafts. Distribution at the tissue level plays a crucial role in determining the **tropism** of the virus and the outcome of infection. For example, poliovirus receptors are found only in the human nasopharynx, gut, and anterior horn cells of the spinal cord. Therefore polioviruses infect these tissues, causing disease that ranges in severity from milder forms such as gastrointestinal disease to more serious paralytic disease. In contrast, measles virus receptors are present in most tissues and disease is disseminated throughout the body, resulting in the widespread rash characteristic of measles. ◀◀ *Eukaryotic cell envelopes (section 5.2);*

►► Human diseases caused by viruses and prions (chapter 38)

Plant viruses are a notable exception to attachment based on receptor binding as no receptors have been identified for plant viruses. Rather, damage of host cells is required for the virus particles to access and enter the host. This is often achieved by plant-eating insects that carry virions from one plant to another. The virions are deposited in plant tissues as the insect devours the plant. Interestingly, evidence suggests that some viruses alter their plant hosts to promote the activity of the insects and thereby foster transmission to new plants.

Entry into the Host

After attachment to the host cell, the virus's genome or the entire nucleocapsid enters the cytoplasm. Many bacteriophages inject their nucleic acid into the cytoplasm of their host, leaving the capsid outside and attached to the cell. In contrast to phages, the nucleocapsid of many viruses of eukaryotes enters the cytoplasm with the genome still enclosed. Once inside the cytoplasm, some shed their capsid proteins in a process called uncoating, whereas others remain encapsidated. Because penetration and uncoating are often coupled, we consider them together.

The mechanisms of penetration and uncoating vary with the type of virus, and for many animal viruses, detailed mechanisms of penetration are unclear. However, it appears that one of three different modes of entry is usually employed: fusion of the viral envelope with the host cell membrane, entry by endocytosis, and injection of viral nucleic acid into the cytoplasm of the host cell, leaving the capsid outside (**figure 6.10**).

◉ Entry of Animal Viruses into Host Cells

Fusion of viral envelopes with the host cell plasma membrane often involves viral envelope glycoproteins that interact with proteins in the plasma membrane of the host cell (**figure 6.10a**). This interaction sets into motion events that allow the nucleocapsid to enter. For example, after attachment of paramyxovirus virions (single-stranded RNA viruses such as measles virus), membrane lipids rearrange, the adjacent halves of the contacting membranes merge, and a proteinaceous fusion pore forms. The nucleocapsid then enters the host cell cytoplasm, where a viral enzyme carried within the nucleocapsid begins synthesizing viral mRNA while it is still within the capsid.

Virions of nonenveloped viruses and some enveloped viruses enter cells by endocytosis. They may be engulfed by receptor-mediated endocytosis (**figure 6.10b**). The resulting endocytic vesicles are filled with virions and fuse with endosomes; depending on the virus, escape of the nucleocapsid or its genome may occur either before or after fusion. Endosomal enzymes can aid in virion uncoating, and low pH often triggers the uncoating process. In at least some instances, the viral envelope fuses with the endosomal membrane, and the nucleocapsid is released into the cytoplasm (the capsid proteins may have been partially removed by endosomal enzymes). Once in the cytoplasm, the viral nucleic acid may be released from the capsid upon completion of uncoating or may function while still attached to capsid components. Nonenveloped animal viruses cannot employ the membrane fusion mechanism for release from the endosome (**figure 6.10c**). In this case, it is thought that the low pH of the endosome causes a conformational change in the capsid. The altered capsid contacts the vesicle membrane and either releases the viral nucleic acid into the cytoplasm or ruptures the membrane to release the intact nucleocapsid. ◀◀ *Organelles of the secretory and endocytic pathways (section 5.4)*

Synthesis Stage

This stage of the viral life cycle differs dramatically among viruses because the genome of a virus dictates the events that occur. For dsDNA viruses, the synthesis stage can be very similar to the typical flow of information in cells. That is, the genetic information is stored in DNA and replicated by enzymes called DNA polymerases, recoded as mRNA (transcription), and decoded during protein synthesis (translation). Because of this similarity, some dsDNA viruses have the luxury of depending solely on their host cells' biosynthetic machinery to replicate their genomes and synthesize their proteins.

The same is not true for RNA viruses. Cellular organisms (except for plants) lack the enzymes needed to replicate RNA or to

(a) Entry of enveloped virus by fusing with plasma membrane

(b) Entry of enveloped virus by endocytosis

(c) Entry of nonenveloped virus by endocytosis

Figure 6.10 Animal Virus Entry. Examples of animal virus attachment and entry into host cells. Enveloped viruses can (a) enter after fusion of the envelope with the plasma membrane or (b) escape from an endosome after endocytosis. (c) Nonenveloped viruses may be taken up by endocytosis and then insert their nucleic acid into the cytoplasm through the vesicle membrane. It also is possible that they insert the nucleic acid directly through the plasma membrane.

MICRO INQUIRY Which of these mechanisms involves the production of a vesicle within the host cell? Which involves the interaction between viral proteins and host cell membrane proteins?

synthesize mRNA from an RNA genome. Therefore RNA viruses must carry in their nucleocapsids the enzymes needed to complete the synthesis stage, or they must be synthesized during the infection process. This process is discussed in more detail in chapter 27.

Regardless of genome structure, synthesis of viral proteins is tightly regulated. Some proteins are synthesized early in the infection and are called early proteins; other proteins are synthesized later and are called late proteins. The genes that encode these proteins are called early and late genes, respectively. Many early proteins are involved in taking over the host cell. Late proteins usually include capsid proteins and other proteins involved in self-assembly and release.

Assembly

Several kinds of late proteins are involved in the assembly of mature virions. Some are nucleocapsid proteins, some are not incorporated into the nucleocapsid but participate in its assembly, and still other late proteins are involved in virion release. In addition, proteins and other factors synthesized by the host may be involved in assembling mature virions.

The assembly process can be quite complex with multiple subassembly lines functioning independently and converging in later steps to complete nucleocapsid construction. As shown in **figure 6.11**, the baseplate, tail fibers, and head

Figure 6.11 The Assembly of T4 Virions. Note the subassembly lines for the baseplate, tail tube and sheath, tail fibers, and head.

Figure 6.12 Paracrystalline Clusters. A crystalline array of adenovirus virions within the cell nucleus (×35,000).

components of bacteriophage T4 are assembled separately. Once the baseplate is finished, the tail tube is built on it and the sheath is assembled around the tube. The phage prohead (procapsid) is constructed with the aid of scaffolding proteins that are degraded or removed after assembly is completed. DNA is incorporated into the prohead by a complex of proteins sometimes called the “packasome.” The packasome consists of a protein called the portal protein, which is located at the base of the prohead, and a set of proteins called the terminase complex, which moves DNA into the prohead. The movement of DNA consumes energy in the form of ATP, which is supplied by the metabolic activity of the host bacterium. After the head is completed, it spontaneously combines with the tail assembly.

While bacteriophages are assembled in the host cytoplasm, the site of morphogenesis varies with plant and animal viruses. Most are assembled in the cytoplasm, and some are assembled in the nucleus. For many viruses, so-called “virus factories” are generated. These are large paracrystalline clusters of either complete nucleocapsids or procapsids (**figure 6.12**).

Virion Release

Many viruses, especially nonenveloped viruses, lyse their host cells at the end of the intracellular phase. This process involves the activity of viral proteins. For instance, the lysis of *E. coli* by T4 requires two specific proteins (**figure 6.13**). One is lysozyme, an enzyme that attacks peptidoglycan in the host’s cell wall. The other, called holin, creates holes in *E. coli*’s plasma membrane, enabling T4 lysozyme to move from the cytoplasm to the peptidoglycan.

Another common release mechanism is budding. This is frequently observed for enveloped viruses; in fact, envelope formation and virion release are usually concurrent processes. When virions are released by budding, the host cell may survive and continue releasing virions for some time. All envelopes of animal viruses are derived from host cell membranes

Figure 6.13 Release of T4 Virions by Lysis of the Host Cell. The host cell has been lysed (upper right portion of the cell) and virions have been released into the surroundings. Progeny virions also can be seen in the cytoplasm. In addition, empty capsids of the infecting virus particles coat the outside of the cell (×36,500).

MICRO INQUIRY Why do the empty capsids remain attached to the cell after the viral genome enters the host cell?

by a multistep process. First, virus-encoded proteins are incorporated into the membrane. Then the nucleocapsid is simultaneously released and the envelope formed by membrane budding (figure 6.14). In several virus families, a matrix (M) protein attaches to the plasma membrane and aids in budding.

Most envelopes arise from the plasma membrane. The endoplasmic reticulum, Golgi apparatus, and other internal membranes also can be used to form envelopes. **Mechanism for Releasing Enveloped Virions**

Interestingly, some viruses are not released from their host cell into the surrounding environment. Rather, their virions move from one host cell directly to another host cell. For example, vaccinia viruses elicit the formation of long actin tails that propel nucleocapsids through the plasma membrane, directly into an adjacent cell. In this way, the virus avoids detection by the host immune system. The genomes of plant viruses also move directly from cell to cell through small connections called plasmodesmata that link adjacent cells. This spread of the viral genome typically involves virus-encoded movement proteins. **Cytoplasm of eukaryotes (section 5.3)**

Retrieve, Infer, Apply

1. Explain why the receptors that viruses have evolved to use are host surface proteins that serve very important, and sometimes essential, functions for the host cell?
2. What probably plays the most important role in determining the tissue and host specificity of viruses? Give some specific examples.
3. How do you think the complexity of the viral assembly process correlates with viral genome size?
4. In general, DNA viruses can be much more dependent on their host cells than can RNA viruses. Why is this so?
5. Consider the origin of viral envelopes and suggest why enveloped viruses that infect plants and bacteria are rare.

6.4 Types of Viral Infections

After reading this section, you should be able to:

- Compare and contrast the major steps of the life cycles of virulent phages and temperate phages
- List examples of lysogenic conversion
- Differentiate among the types of viral infections of eukaryotic cells
- Summarize the current understanding of how oncoviruses cause cancer

So far, our discussion has focused on viral structures and modes of multiplication with little mention of the cost to host cells. The dependence of viruses on their host cells has many consequences—as anyone who has ever had a cold or the flu well understands. Next we discuss the interaction between virus and host cell.

Infections of Bacterial and Archaeal Cells: Lysis and Lysogeny

Bacteriophages can be either virulent or temperate. A **virulent phage** is one that has only one option: to begin multiplying immediately upon entering its bacterial host, followed by release from the host by lysis. T4 is an example of a virulent phage. **Temperate phages** have two options: upon entry into the host, they can multiply like virulent phages and lyse the host cell, or they can remain within the host without destroying it (figure 6.15).

Bacteriophage lambda is an example of this type of phage. The life cycles of both T4 and lambda are described in more detail in chapter 27. *Steps in the Replication of T4 Phage in E. coli; Lambda Phage Replication Cycle*

The relationship between a temperate phage and its host is called **lysogeny**. The form of the virus that remains within its host is called a **prophage**. A prophage is simply the viral nucleic acid either integrated into the bacterial chromosome or free in the cytoplasm. The infected bacteria are called **lysogens** or **lysogenic bacteria**. Lysogenic bacteria reproduce and in most other ways appear to be perfectly normal. However, they have two distinct characteristics. The first is that they cannot be reinfectd by the same virus; that is, they have immunity to superinfection. The second is that as they reproduce, the prophage is replicated and inherited by progeny cells. This can continue for many generations until conditions arise that cause the prophage to initiate synthesis of phage proteins and to assemble new virions, a process called **induction**. Induction is commonly caused by changes in growth conditions or ultraviolet irradiation of the host cell. As a result of induction, the **lysogenic cycle** ends and the **lytic cycle** commences; the host cell lyses and progeny phage particles are released.

Another important outcome of lysogeny is **lysogenic conversion**. This occurs when a temperate phage changes the phenotype of its host. Lysogenic conversion often involves alteration in surface characteristics of the host. For example, when a member of the genus *Salmonella* is infected by epsilon phage, the phage changes the activities of several enzymes involved in

Figure 6.15 **Lytic and Lysogenic Cycles of Temperate Phages.** Temperate phages have two phases to their life cycles. The lysogenic cycle allows the genome of the virus to be replicated passively as the host cell's genome is replicated. Certain environmental factors such as UV light can cause a switch from the lysogenic cycle to the lytic cycle. In the lytic cycle, new virus particles are made and released when the host cell lyses. Virulent phages are limited to just the lytic cycle.

MICRO INQUIRY Why is a lysogen considered a new or different strain of a given bacterial species?

construction of the carbohydrate component of the bacterium's lipopolysaccharide. This eliminates the receptor for epsilon phage, so the bacterium becomes immune to infection by another epsilon phage. Many other lysogenic conversions give the host pathogenic properties. This is the case when *Corynebacterium diphtheriae*, the cause of diphtheria, is infected with phage β . The phage genome encodes diphtheria toxin, which is responsible for the disease. Thus only those strains of *C. diphtheriae* that are infected by the phage (i.e., lysogens) cause disease. ►► *Diphtheria* (section 39.1)

Clearly the infection of a bacterium by a temperate phage has significant impact on the host, but why would viruses evolve this alternate life cycle? Two advantages of lysogeny have been recognized. The first is that lysogeny allows the viral nucleic acid to be maintained within a dormant host. Bacteria often become dormant due to nutrient deprivation, and while in this state, they do not synthesize nucleic acids or proteins. In such situations, a prophage would survive but most virulent bacteriophages would not be replicated, as they require active cellular biosynthetic machinery. Furthermore, their genome would be degraded as the host cell entered dormancy. The second advantage arises when there are many more phages in an environment than there are host cells, a situation virologists refer to as a high multiplicity of infection (MOI). In these conditions, lysogeny enables the survival of infected host cells within a population that has few uninfected cells. When MOI is high, a virulent phage would rapidly destroy the available host cells in its environment. However, a prophage will be replicated as the host cell reproduces.

Archaeal viruses can also be virulent or temperate. Most archaeal viruses discovered thus far are temperate or establish chronic infections. Unfortunately, little is known about the mechanisms they use to regulate their life cycles. ►► *Archaeal viruses* (section 27.2)

Retrieve, Infer, Apply

1. Define the terms lysogeny, temperate phage, lysogen, prophage, immunity, and induction.
2. What advantages might a phage gain by being capable of lysogeny?
3. Describe lysogenic conversion and its significance.

Infections of Eukaryotic Cells

Viruses can harm their eukaryotic host cells in many ways. An infection that results in cell death is a cytotoxic infection. As with bacterial and archaeal viruses, this can occur by lysis of the host (figure 6.16a). Infection does not always result in the lysis of host cells. Some viruses (e.g., herpesviruses) can establish persistent infections lasting many years (figure 6.16b,c). Eukaryotic viruses can cause microscopic or macroscopic degenerative changes or abnormalities in host cells and in tissues that are distinct from lysis. These are called **cytopathic effects** (CPEs). Viruses use a variety of mechanisms to cause cytopathic and cytotoxic effects. Many of these are noted in chapter 38. One mechanism of particular note is that some viruses cause the host cell to be transformed into a malignant cell (figure 6.16d). This is discussed next.

Viruses and Cancer

Cancer is one of the most serious medical problems in developed nations, and it is the focus of an immense amount of research. A tumor is a growth or lump of tissue resulting from **neoplasia**—unregulated abnormal new cell growth and reproduction. Tumor cells have aberrant shapes and altered plasma membranes that may contain distinctive molecules (tumor antigens). Their unregulated proliferation and loss of differentiation result in invasive growth that forms unorganized cell masses. This reversion to a more primitive or less differentiated state is called **anaplasia**.

Two major types of tumor growth patterns exist. If the tumor cells remain in place to form a compact mass, the tumor is benign. In contrast, cells from malignant or cancerous tumors actively spread throughout the body in a process known as metastasis. Some cancers are not solid but cell suspensions. For example, leukemias are composed of undifferentiated malignant white blood cells that circulate throughout the body. Indeed, dozens of kinds of cancers arise from a variety of cell types and afflict all kinds of organisms.

As one might expect from the wide diversity of cancers, cancer has many causes, only a few of which are directly related to viruses. Carcinogenesis is a complex, multistep process that involves the mutation of multiple genes. Genes involved in carcinogenesis are called **oncogenes**. Some oncogenes are introduced into a cell by viruses; others arise from normal genes within the cell called **proto-oncogenes**. Proto-oncogenes are cellular genes required for normal growth, but when mutated or overexpressed, they become oncogenes. Many oncogenes are involved in the regulation of cell growth and signal transduction; for example, some code for growth factors that regulate cell reproduction. Proto-oncogenes can be transformed into oncogenes by spontaneous mutation or through the activity of a mutation-causing agent, called a mutagen. ►► *Mutations* (section 16.1)

Viruses are associated with cancers in animals, including humans. In some human cancers, the virus has been established as the cause of the cancer (table 6.1). In others, causality has not been established. For these cancers, the virus often functions as a cofactor. Most human viruses associated with cancer have dsDNA genomes.

Viruses known to cause cancer are called **oncoviruses**. Most known human dsDNA oncoviruses trigger cancerous transformation of cells by a similar mechanism. They encode proteins that bind to and thereby inactivate host proteins known as **tumor suppressor proteins**. Tumor-suppressor proteins regulate cell cycling or monitor or repair DNA damage. Two tumor suppressors known to be targets of human oncovirus proteins are called Rb and p53. Rb has multiple functions in the nucleus, all of which are critical to normal cell cycling. When Rb molecules are rendered inactive by an oncoviral protein, cells undergo uncontrolled reproduction and are said to be hyperproliferative. The protein p53 is often referred to as “the guardian of the genome.” This is because p53 normally initiates either cell cycle arrest or

Figure 6.16 Types of Viral Infections and Their Effects on Animal Cells.

(a) Lytic infections of host cells can lead to disease states in animal hosts called acute infections. There are two types of persistent infections: (b) latent infections and (c) chronic infections. (d) Some infections of animal cells cause the cell to be transformed into a malignant cell, which can cause cancer in the animal host.

programmed cell death in response to DNA damage. However, when p53 is inactivated by the binding of an oncoviral protein, it cannot do so and genetic damage persists. From the point of view of the virus, hyperproliferation and the lack of programmed cell death are beneficial. For the cell, however, it can be catastrophic. Cells can rapidly accumulate the additional mutations needed to become cancerous. **Tumor Suppressor Genes**

Some oncogenic viruses are retroviruses, which are viruses related to HIV. They exert their oncogenic powers in a different manner. Some carry oncogenes captured from host cells many,

many generations ago. For example, the retrovirus HTLV-1 transforms a group of immune system cells called T cells by producing a regulatory protein that sometimes activates genes involved in cell division and stimulates viral multiplication. The second transformation mechanism used by retroviruses involves the integration of the viral genome into the host chromosome such that strong, viral regulatory elements are near a cellular proto-oncogene. These elements cause the nearby proto-oncogene to be transcribed at a high level, causing the gene to be considered an oncogene.

Table 6.1 Some Viruses Associated with Human Cancers

| Virus | Genome Type | Cancer |
|--|--------------------------|--|
| Human herpesvirus 8 (HHV8) | Double-stranded (ds) DNA | Several, including Kaposi's sarcoma |
| Epstein-Barr virus (EBV) | dsDNA | Several, including Burkitt's lymphoma and nasopharyngeal carcinoma |
| Hepatitis B virus | dsDNA | Hepatocellular carcinoma |
| Hepatitis C virus | Single-stranded (ss) RNA | Liver cancer |
| Human papillomaviruses (HPV) strains 6, 11, 16, and 18 | dsDNA | Cervical cancer |
| Human T-cell lymphotropic virus1 (HTLV-1) | ssRNA (retrovirus) | T-cell leukemia |

Retrieve, Infer, Apply

1. What is a cytocidal infection? What is a cytopathic effect?
2. Define the following terms: tumor, neoplasia, anaplasia, metastasis, and oncogene.
3. Distinguish the mechanism by which dsDNA viruses cause cancer from that of retroviruses. Why do you think there is an environmental component to many kinds of cancer?

6.5 Cultivation and Enumeration of Viruses

After reading this section, you should be able to:

- List the types of approaches used to cultivate viruses, noting which types of viruses are cultivated by each method
- Describe three direct counting methods and two indirect counting methods used to enumerate viruses
- Outline the events that lead to the formation of a plaque in a lawn of bacterial cells
- Distinguish lethal dose from infectious dose

Because they are unable to reproduce outside of living cells, viruses cannot be cultured in the same way as cellular microorganisms. It is relatively simple to culture lytic bacterial and archaeal viruses as long as the host cell is easily grown in culture. Cells and virus particles are simply mixed together in a broth culture. Over time, more and more cells are infected and lysed, releasing virions into the broth. Culturing temperate viruses requires an additional step of inducing the lytic phase of their life cycles. Animal viruses are often cultivated by inoculating suitable host animals or embryonated eggs—fertilized chicken eggs incubated about 6 to 8 days after laying. Animal viruses also are grown in tissue (cell) culture on monolayers of animal cells. If the virus causes its host cell to lyse, plaques often are formed (**figure 6.17**). Viruses that cause cytopathic effects are also grown and detected in tissue culture.

Figure 6.17 Viral Plaques.

Plant viruses are cultivated in a variety of ways. Plant tissue cultures, cultures of separated cells, or cultures of protoplasts (cells lacking cell walls) may be used. Viruses also can be grown in whole plants, usually after the leaves are mechanically inoculated by rubbing them with a mixture of virus particles and an abrasive. When the cell walls are broken by the abrasive, the virions directly contact the plasma membrane and infect the exposed host cells. Some plant viruses can be transmitted only if a diseased part is grafted onto a healthy plant. A localized necrotic lesion often develops in infected plants due to the rapid death of cells in the infected area (**figure 6.18**). Even when lesions do not occur, the infected plant may show symptoms such as changes in pigmentation or leaf shape.

It is often necessary to determine the number of virions in a preparation of viruses or an environmental sample. One direct approach is to count virions with the electron microscope. However, this is a time-consuming process that requires a high concentration of virus particles. Another direct counting method uses epifluorescence microscopy. This approach is often used to enumerate virus particles in aquatic habitats. The procedure stains the virions with fluorescent dyes prior to microscopic examination. Finally, sometimes rather than counting virions, the nucleic acid of a virus can be quantified by quantitative-polymerase chain reaction (qPCR). This is possible because PCR amplifies specific nucleic

Figure 6.18 Necrotic Lesions on Plant Leaves. Tobacco mosaic virus infection of an orchid showing leaf color changes.

acids in a mixture of nucleic acids. ►► *Aquatic viruses* (section 30.2); *Polymerase chain reaction* (section 17.2)

An indirect method of counting animal viruses is the **hemagglutination assay**. Many animal virus particles bind to the surface of red blood cells (see figure 36.11). If the ratio of virions to cells is large enough, virions will join the red blood cells together; that is, they agglutinate, forming a network that settles out of suspension. In practice, red blood cells are mixed with diluted samples of the virus particles, and each mixture is examined. The hemagglutination titer is the highest dilution of the virus preparation (or the reciprocal of the dilution) that still causes hemagglutination. ►► *Agglutination* (section 36.4)

Other indirect assays determine virion numbers based on their infectivity, and many of these are based on the same techniques used for virus cultivation. For example, in the **plaque assay**, several dilutions of a sample containing virus particles are plated with appropriate host cells. When the multiplicity of infection (p. 125) is very low, each plaque in a layer of host cells is assumed to have arisen from the multiplication of a single virion (figure 6.19). Therefore a count of the plaques produced at a particular dilution can be used to calculate the **plaque-forming units (PFU)** in the original sample. The number of PFU does not equal the total number of virions because not all virions may be infective.

Figure 6.19 Formation of Phage Plaques. When phage particles and host bacterial cells are mixed at an appropriate ratio, only a portion of the cells are initially infected. When this mixture is plated, the infected cells will be separated from each other. The infected cells eventually lyse, releasing progeny phage particles. They infect nearby cells, which eventually lyse, releasing more phage particles. This continues and ultimately gives rise to a clear area within a lawn of bacteria. The clear area is a plaque.

MICRO INQUIRY What would happen to a plate with individual plaques if it were returned to an incubator so that the viral infection could continue?

Furthermore, even though there are far fewer virus particles than host cells, it is still possible for more than one virion to infect the same cell (figure 6.13). However, the number of PFU is proportional to the number of virus particles: a preparation with twice as many virions will have twice the plaque-forming units.

Figure 6.20 Determination of LD₅₀. The LD₅₀ is indicated by the dashed line.

The same approach employed in the plaque assay may be used with embryos and plants. Chicken embryos and plant leaves can be inoculated with a diluted preparation of virus particles. The number of pocks on embryonic membranes or necrotic lesions on leaves is used to calculate the concentration of infectious units.

When biological effects are not readily quantified by plaque and hemagglutination assays, the amount of virions required to cause disease or death can be determined. Organisms or cell cultures are inoculated with serial dilutions of a preparation of virus particles. The **lethal dose (LD₅₀)** is the dilution that contains a concentration (dose) of virions large enough to destroy 50% of the host cells or organisms. In a similar sense, the **infectious dose (ID₅₀)** is the dose that causes 50% of the host organisms to become infected (figure 6.20).

Retrieve, Infer, Apply

1. Discuss the ways that viruses can be cultivated. Define the terms plaque, cytopathic effect, and necrotic lesion.
2. Given that viruses must be cultivated to make vaccines against viral diseases, discuss the advantages and disadvantages that might occur with each approach (embryonated egg versus cell culture) to growing animal viruses.

6.6 Viroids and Satellites

After reading this section, you should be able to:

- Describe the structure of a viroid and discuss the practical importance of viroids
- Distinguish satellite viruses from satellite nucleic acids

Although viruses are exceedingly simple, even simpler infectious agents exist. **Viroids** are infectious agents that consist only of RNA. They cause over 20 different plant diseases, including potato spindle-tuber disease, exocortis disease of citrus trees,

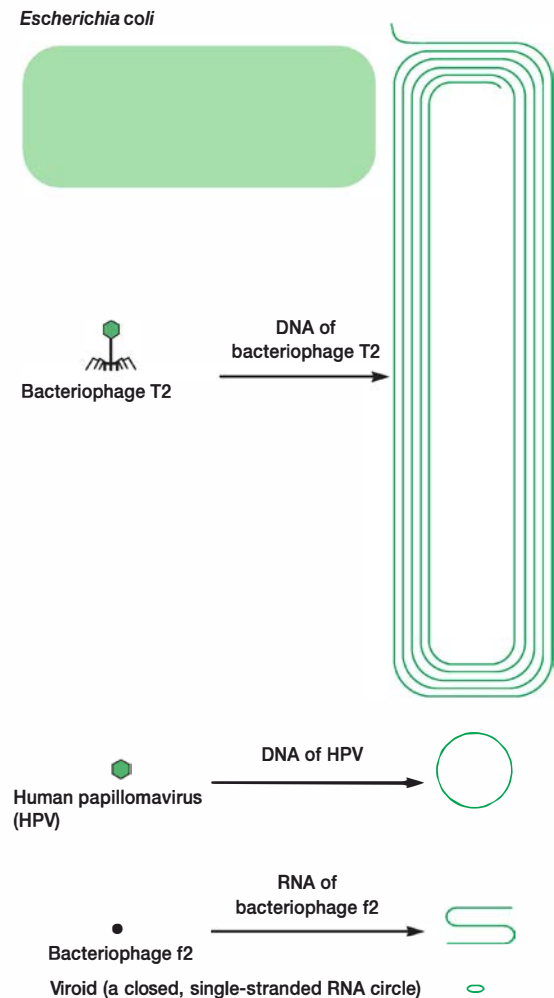

Figure 6.21 Viroids, Viruses, and Bacteria. A comparison of *E. coli*, several viruses, and the potato spindle-tuber viroid with respect to size and the amount of nucleic acid possessed. (All dimensions are enlarged approximately $\times 40,000$.)

and chrysanthemum stunt disease. Viroids are covalently closed, circular ssRNAs, about 250 to 370 nucleotides long (figure 6.21). The circular RNA exists as a rodlike shape due to intrastrand base pairing, which forms double-stranded regions with single-stranded loops (figure 6.22). Some viroids are found in the nucleolus of infected host cells, where between 200 and 10,000 copies

Figure 6.22 Viroid Structure. This schematic diagram shows the general organization of a viroid. The closed single-stranded RNA circle has extensive intrastrand base pairing and interspersed unpaired loops. Viroids have five domains. Most changes in viroid pathogenicity arise from variations in the P and T_L domains.

may be present. Others are located within chloroplasts. The RNA of viroids does not encode any gene products, so they cannot replicate themselves. Rather, evidence exists that a viroid is replicated by a host cell enzyme called a DNA-dependent RNA polymerase. This enzyme normally functions in the host to synthesize RNA using DNA as the template during transcription. However, when infected by a viroid, the host polymerase evidently uses the viroid RNA as a template for RNA synthesis, rather than its own DNA. The host polymerase synthesizes a complementary RNA molecule, which then serves as the template for synthesis of new viroid RNAs.

A plant may be infected with a viroid without showing symptoms; that is, it may have a latent infection. However, the same viroid in another host species may cause severe disease. The pathogenicity of viroids is not well understood, but it is known that particular regions of the RNA are required; studies have shown that removing these regions blocks the development of disease (figure 6.22). Some data suggest that viroids cause disease by triggering a eukaryotic response called **RNA silencing**, which normally functions to protect against infection by dsRNA viruses. During RNA silencing, the cell detects the presence of dsRNA and selectively degrades it. Viroids may usurp this response by hybridizing to specific host mRNA molecules to which they have a complementary nucleotide sequence. Formation of the viroid-host hybrid dsRNA molecule is thought to elicit RNA silencing. This results in destruction of the host mRNA and therefore silencing of the host gene. Failure to express a required host gene leads to disease in the host plant.

Satellites are similar to viroids in that they also consist only of a nucleic acid (either DNA or RNA). They differ from viroids in that they may encode one or more gene products and need a helper virus to replicate and infect host cells. There is no homology between the genome of the satellite and its helper virus. Satellites are further divided into three types: satellite viruses, satellite RNAs, and satellite DNAs. Satellite viruses encode their own capsid proteins, whereas satellite RNAs and DNAs do not. Most satellites use plant viruses as their helper viruses.

6.7 Prions

After reading this section, you should be able to:

- Describe prion structure and how prions are thought to replicate
- List characteristics common to all animal diseases caused by prions
- Name at least two human diseases caused by prions
- Describe the mechanisms by which a prion protein might first appear in a brain cell

Prions (for *proteinaceous infectious particle*) cause a variety of neurodegenerative diseases in humans and other animals, including scrapie in sheep, bovine spongiform encephalopathy (BSE or “mad cow disease”) and the human diseases kuru, fatal familial insomnia, Creutzfeldt-Jakob disease (CJD), and

Gerstmann-Sträussler-Scheinker syndrome (GSS). All result in progressive degeneration of the brain and eventual death. At present, no effective treatment exists.

The best-studied prion is the scrapie prion. Researchers have shown that scrapie is caused by an abnormal form of a cellular protein. The abnormal form is called PrP^{Sc} (for scrapie-associated prion protein), and the normal cellular form is called PrP^{C} . Evidence supports a model in which entry of PrP^{Sc} into the brain of an animal causes the PrP^{C} protein to change from its normal conformation to the abnormal form (figure 6.23). The newly

Figure 6.23 One Proposed Model for Prion Replication. The normal and prion proteins differ in their tertiary structures.

produced PrP^{Sc} molecules then convert more PrP^{C} molecules into the abnormal PrP^{Sc} form. How the PrP^{Sc} causes this conformational change is unclear. However, the best-supported model is that the PrP^{Sc} directly interacts with PrP^{C} , causing the change. It is noteworthy that mice lacking the PrP gene cannot be infected with PrP^{Sc} .

Although evidence is strong that PrP^{Sc} causes PrP^{C} to fold abnormally, how this triggers neuron loss is poorly understood. Some possible mechanisms include changes in plasma membrane structure of infected cells. It is known that PrP^{C} is anchored to the plasma membrane. Its conversion to PrP^{Sc} and subsequent aggregation may interfere with membrane functions. There is also evidence that both forms of PrP must be present in the cell for neuron death. It may be that an interaction

between the two inhibits normal PrP^{C} . As yet, the function of PrP^{C} is unknown. However, evidence points to it having a protective role that prevents a cell from killing itself by a process called apoptosis (programmed cell death).

Retrieve, Infer, Apply

1. What are viroids and why are they of great interest?
2. How does a viroid differ from a virus?
3. What is a prion? In what way does a prion differ fundamentally from viruses and viroids?
4. Prions are difficult to detect in host tissues. Why do you think this is so? Why do you think we have not been able to develop effective treatments for prion-caused diseases?

Key Concepts

6.1 Viruses

- Virology is the study of viruses and other acellular infectious agents.
- Viruses cannot reproduce independently of living cells.

6.2 Virion Structure

- All virions have a nucleocapsid composed of a nucleic acid, either DNA or RNA, held within a protein capsid made of one or more types of protein subunits called protomers (**figure 6.2**).
- Helical capsids resemble hollow protein tubes and may be either rigid or flexible (**figures 6.3 and 6.4**).
- Icosahedral capsids are usually constructed from two types of capsomers: pentamers (pentons) at the vertices and hexamers (hexons) on the edges and faces of the icosahedron (**figure 6.5**).
- Complex virions (e.g., poxviruses and large phages) have complicated morphology not characterized by icosahedral and helical capsid symmetry (**figure 6.6**). Virions of large phages often have binal symmetry: their heads are icosahedral and their tails are helical (**figure 6.7**).
- Some viruses have a membranous envelope surrounding their nucleocapsid. The envelope lipids usually come from the host cell; in contrast, many envelope proteins are viral and may project from the envelope surface as spikes or peplomers (**figure 6.8**).
- Viral nucleic acids can be either single stranded (ss) or double stranded (ds), DNA or RNA. Most DNA viruses have dsDNA genomes that may be linear or closed circles. RNA viruses usually have ssRNA. Some RNA genomes are segmented.
- Although viruses lack true metabolism, some contain a few enzymes necessary for their multiplication.

6.3 Viral Multiplication

- Viral life cycles can be divided into five steps: (1) attachment to host; (2) entry into host; (3) synthesis of viral nucleic acids and proteins; (4) self-assembly of nucleocapsids; and (5) release from host (**figures 6.9–6.11 and 6.13–6.15**).
- The synthesis stage of a virus's life cycle depends on the nature of its genome. DNA viruses may use enzymes that are similar to host enzymes. In some cases, they rely solely on their hosts for synthesis of their nucleic acids and proteins.
- RNA viruses must either encode the enzymes they need to make mRNA and replicate their genomes or carry these enzymes in their capsids.

6.4 Types of Viral Infections

- Virulent bacteriophages and archaeal viruses lyse their host. In addition to host cell lysis, temperate bacterial and archaeal viruses can enter the lysogenic cycle in which they remain dormant in the host cell. This is often accomplished by integrating the viral genome into that of the host (**figure 6.15**).
- Viruses that infect eukaryotic cells can cause either host cell lysis or a more insidious cellular death; such viruses cause cytotoxic infection. One relatively rare outcome of animal virus infection is the transformation of normal host cells into malignant or cancerous cells (**figure 6.16**).

6.5 Cultivation and Enumeration of Viruses

- Viruses are cultivated using tissue cultures, embryonated eggs, bacterial cultures, and other living hosts.
- Phages produce plaques in bacterial lawns. Sites of animal viral infection may be characterized by cytopathic

effects such as pocks and plaques. Plant viruses can cause localized necrotic lesions in plant tissues (**figures 6.17–6.19**).

- Virions can be counted directly with the transmission electron microscope or indirectly by hemagglutination and plaque assays.
- Infectivity assays can be used to estimate virion numbers in terms of plaque-forming units, lethal dose (LD₅₀), or infectious dose (ID₅₀) (**figure 6.20**).

6.6 Viroids and Satellites

- Viroids are infectious agents of plants that consist only of circular ssRNA molecules (**figures 6.21 and 6.22**). They do not encode any proteins.
- Satellites are subviral infectious agents that may encode some proteins but require a helper virus for replication.

Satellite viruses encode their own capsid proteins, whereas satellite RNAs and satellite DNAs do not.

6.7 Prions

- Prions are small proteinaceous agents associated with at least six degenerative nervous system disorders: scrapie, bovine spongiform encephalopathy, kuru, fatal familial insomnia, Gerstmann-Sträussler-Scheinker syndrome, and Creutzfeldt-Jakob disease.
- Most evidence supports the hypothesis that prion proteins exist in two forms: the infectious, abnormally folded form and a normal cellular form. The interaction between the abnormal form and the cellular form converts the cellular form into the abnormal form (**figure 6.23**).

Compare, Hypothesize, Invent

1. Many classification schemes are used to identify bacteria. These start with Gram staining, progress to morphology and arrangement characteristics, and include a battery of metabolic tests. Build an analogous scheme that could be used to identify viruses. You might start by considering the host, or you might start with viruses found in a particular environment, such as a marine filtrate.
2. The origin and evolution of viruses is controversial. Discuss whether you think viruses evolved before the first cell or whether they have coevolved and are perhaps still coevolving with their hosts.
3. Consider the separate stages of an animal virus life cycle. Assemble a short list of structures and processes that are unique to the virus and would make good drug targets for an antiviral agent. Explain your rationale for each choice.
4. Chronic wasting disease (CWD) is a neurodegenerative disease of cervid animals (e.g., deer, elk, moose) caused by prions. Unlike other prion diseases, CWD is readily transmitted from one animal to another in a herd. How this

occurs is not understood. However, evidence suggests the mode of transmission is by animal excreta: saliva, urine, and feces. In this mechanism, a healthy animal would be exposed to the prion present in excreta from a diseased animal. Since many cervids congregate, the prion would easily spread from one animal to another. One problem facing scientists studying CWD is measuring the amount of infectious prions in excreta and determining their source (i.e., whether they are produced solely in nervous system tissue or in organs of excretion). Why is CWD of concern to fish and wildlife biologists and game managers in states where CWD is prevalent (e.g., Colorado, Wyoming, Wisconsin)? Why would the presence of CWD prions in tissues other than those of the central nervous system be important to know? (Hint: Learn about the variant Creutzfeldt-Jakob epidemic that occurred in the 1990s.)

Microbial Growth

Metal or Plastic?

Each day in grocery stores, as their bill is tallied and their groceries readied for bagging, customers are asked, “Paper or plastic?” People who are about to pierce their tongues face a similar question: “Metal or plastic?” The desire is to have a tongue stud with “flash,” which is thought to brighten the person’s smile. However, there is more at stake than flash: recent studies suggest that pathogenic bacteria are more likely to accumulate on the surfaces of metal tongue studs (stainless steel and titanium) than on other materials (polypropylene, a plastic, and polytetrafluoroethylene, better known as Teflon). Even more worrisome is the observation that these bacteria are forming biofilms.

What are biofilms and why should they be of concern to those wanting a tongue piercing? Biofilms are complex, slime-encased communities of microorganisms growing on surfaces such as rocks in a stream, the hulls of ships, medical devices, and your teeth. The microbes in biofilms are different than those swimming freely in their environment. They are more resistant to antimicrobial agents, including antibiotics, than are their planktonic brethren. Furthermore, they can escape the slime and travel to other sites: another rock, a different tooth, a heart valve.

Biofilm formation is just one aspect of microbial growth that is of concern to microbiologists. Even when microbes are not growing in a biofilm, they can create problems. Thus there are many situations in which it is important to inhibit their growth—in hospital rooms, kitchen counters, food-handling facilities, to name a few. In other situations, microbiologists want to promote microbial growth—from a clinical specimen so that a diagnosis can be made, in brewing vats at a brewery, or a fermentation vessel at a pharmaceutical plant.

To control the growth of microbes, it is imperative that microbiologists be able to understand how they reproduce, determine the environmental conditions that promote or hinder their growth, and measure the growth of microbial populations. This requires that

Body piercings, such as those sported by this young woman, are popular among teens and young adults.

microbiologists not only study the growth of microbes in natural settings but in the laboratory as well. Microbial growth in both settings is the focus of this chapter.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Describe the functions of eukaryotic cytoskeletal proteins (section 5.3)
- ✓ Define and list examples of essential nutrients, and describe how they are used by cells
- ✓ Distinguish macroelements (macronutrients) from micronutrients (trace elements), list examples of each, and describe how they are used (section 3.3)
- ✓ Provide examples of growth factors needed by some microorganisms (section 3.3)

7.1 Reproductive Strategies

After reading this section, you should be able to:

- Describe binary fission as observed in bacteria and archaea
- Compare the three reproductive strategies used by bacteria and contrast these with binary fission

Eukaryotic microbes differ dramatically from bacteria and archaea in their reproductive strategies. Many eukaryotic microbes exhibit both asexual reproduction, involving mitosis, and sexual reproduction, involving meiosis to produce gametes or gametelike cells. Furthermore, eukaryotic microbes often alternate between haploid and diploid stages in their life cycles. Some eukaryotic life cycles are described in chapters 25 and 26. Here our focus is on the types of cell division observed in bacterial and archaeal cells.

Unlike eukaryotes, most bacterial and archaeal cells are haploid. Most reproduce by **binary fission** (figure 7.1). Binary fission is a relatively simple type of cell division: the cell elongates as new material is synthesized, replicates its chromosome,

(a) A young cell at early phase of cycle

(b) A parent cell prepares for division by enlarging its cell wall, cell membrane, and overall volume. DNA replication then starts.

(c) The septum begins to grow inward as the chromosomes move toward opposite ends of the cell. Other cytoplasmic components are distributed to the two developing cells.

(d) The septum is synthesized completely through the cell center, creating two separate cell chambers.

(e) At this point, the daughter cells are divided. Some species separate completely as shown here, while others remain attached, forming chains, doublets, or other cellular arrangements.

Figure 7.1 Binary Fission.

MICRO INQUIRY In addition to chromosomes, what other cytoplasmic contents must be equally distributed between daughter cells?

and separates the newly formed DNA molecules so there is one chromosome in each half of the cell. Finally, a septum (cross wall) is formed at midcell, dividing the parent cell into two progeny cells, each having its own chromosome and a complement of other cellular constituents.

Several other reproductive strategies have been identified in bacteria (**figure 7.2**). Some bacteria that have stalks called prostheca (e.g., *Hyphomonas*) reproduce by forming a bud at the end of their prostheca. Certain cyanobacteria undergo multiple fission. The progeny cells, called baeocytes, are held within the cell wall of the parent cell until they are released. Other bacteria, such as members of the genus *Streptomyces*, form multinucleoid filaments that eventually divide to form uninucleoid spores. These spores are readily dispersed, much like the dispersal spores formed by filamentous fungi. ►► *Fungal reproduction (section 26.1)*

Despite the diversity of bacterial reproductive strategies, they share certain features. In all cases, the genome of the cell must be replicated and segregated to form distinct nucleoids. At some point during reproduction, each nucleoid and its surrounding cytoplasm becomes enclosed within its own plasma membrane. These processes are the major steps of the cell cycle. In section 7.2, we examine the bacterial cell cycle in more detail.

7.2 Bacterial Cell Cycle

After reading this section, you should be able to:

- Summarize the two major events in a typical bacterial cell cycle
- State the functions of cytoskeletal proteins during cell division and in determining cell shape

The **cell cycle** is the complete sequence of events extending from the formation of a new cell through the next division. It is of intrinsic interest as a fundamental biological process. However, understanding the cell cycle has practical importance as well. For instance, the synthesis of peptidoglycan during the cell cycle is the target of numerous antibiotics used to treat bacterial infections. ►► *Inhibitors of cell wall synthesis (section 9.4)*

The cell cycles of several bacteria—*Escherichia coli*, *Bacillus subtilis*, and the aquatic bacterium *Caulobacter crescentus*—have been examined extensively, and our understanding of the bacterial cell cycle is based largely on these studies. Two pathways function during the bacterial cell cycle: one pathway replicates and partitions the DNA into the progeny cells, and the other carries out cytokinesis—formation of the septum and

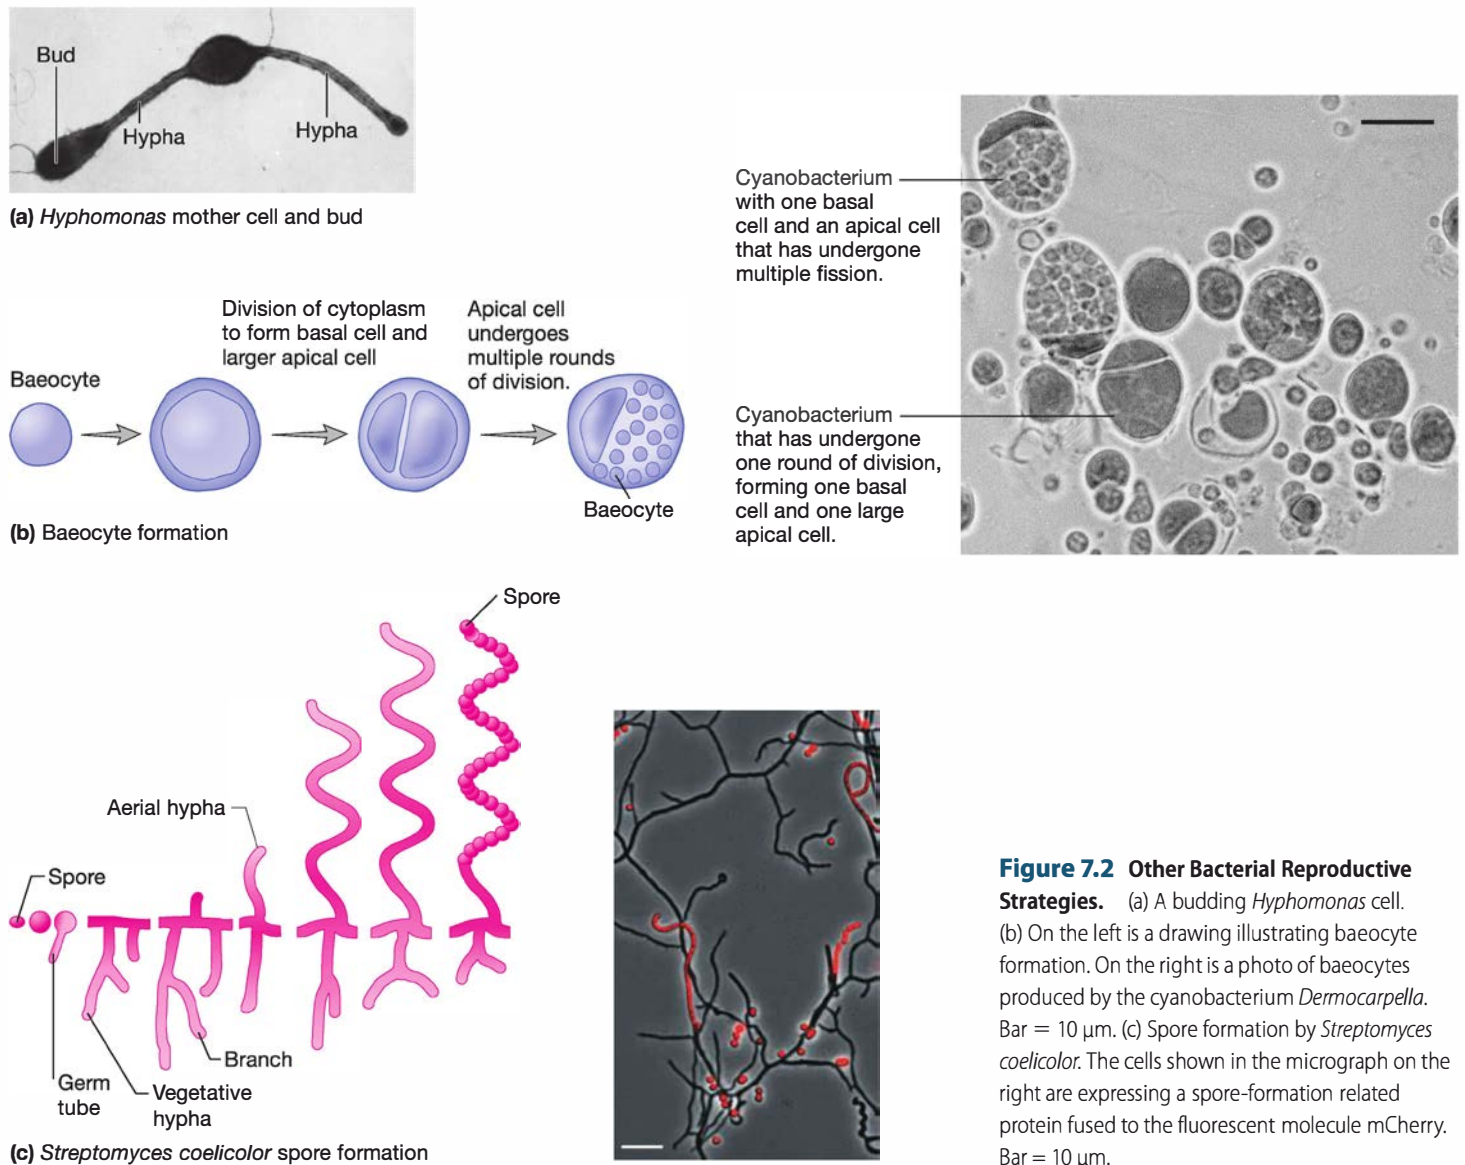

Figure 7.2 Other Bacterial Reproductive Strategies. (a) A budding *Hyphomonas* cell. (b) On the left is a drawing illustrating baeocyte formation. On the right is a photo of baeocytes produced by the cyanobacterium *Dermocarpella*. Bar = 10 μm . (c) Spore formation by *Streptomyces coelicolor*. The cells shown in the micrograph on the right are expressing a spore-formation related protein fused to the fluorescent molecule mCherry. Bar = 10 μm .

progeny cells. Although these pathways overlap (i.e., septation begins as DNA replication nears completion), it is easiest to consider them separately.

Chromosome Replication and Partitioning

Most bacteria have a single circular chromosome. Each circular chromosome has a single site at which replication starts called the **origin of replication**, or simply the origin (figure 7.3). Replication is completed at the terminus, which is located directly opposite the origin. In a newly formed *E. coli* cell, the chromosome is compacted and organized so that the origin and terminus are in opposite halves of the cell. Early in the cell cycle, the origin and terminus move to midcell, and a group of proteins needed for DNA synthesis assemble at the origin to form the **replisome**. DNA replication proceeds in both

directions from the origin. As progeny chromosomes are synthesized, the two newly formed origins move toward opposite ends of the cell, and the rest of the chromosome follows in an orderly fashion.

Although the process of DNA synthesis and movement seems rather straightforward, the mechanism by which chromosomes are partitioned to each daughter cell has not been fully elucidated. Evidence suggests that the mechanism varies with bacterial species. The models include daughter chromosomes being pushed to opposite sides of the cell by the replisome. Other models propose that condensation of daughter chromosomes by structural maintenance of chromosomes (SMC) proteins pulls the DNA molecules to each end. Evidence also exists for involvement of the cytoskeletal protein MreB (murein cluster B) present in rod-shaped microorganisms. MreB is similar to eukaryotic actin and is important in generating

Figure 7.3 Cell Cycle of *E. coli*. Initiation of the cell cycle results from an increase in the mass of a cell, which also results in the accumulation of the DnaA protein, which initiates DNA replication. As the cell readies for DNA replication, the origin of replication migrates to the center of the cell and proteins that make up the replisome assemble. As DNA replication proceeds, newly synthesized chromosomes move toward poles and the cell increases in length. When the cell reaches a certain length (threshold length), initiation of septum formation is triggered and cytokinesis occurs, producing two daughter cells that have inherited one chromosome each. In this illustration, one round of DNA replication is completed before the cell divides. In rapidly growing cultures (generation times of about 20 minutes), second and third rounds of DNA replication are initiated before division of the original cell is completed. Thus the daughter cells inherit partially replicated DNA.

MICRO INQUIRY Why is it important that the origin of replication migrate to the center of the cell prior to replication?

rod-shaped cells. How it might contribute to chromosome segregation is unclear. However, cells with mutations in the gene encoding MreB fail to segregate chromosomes properly. Finally, proteins related to those in a plasmid partitioning system called ParABS have been shown to be involved in chromosome segregation in *C. crescentus*. ◀◀ *Bacterial cytoskeleton* (section 3.6); ▶▶ *The Caulobacteraceae and Hyphomicrobiaceae* (section 22.1) 🌀 *Binary Fission; Bidirectional DNA Replication*

Cytokinesis

Septation is the process of forming a cross wall between two daughter cells. **Cytokinesis**, a term that has traditionally been used to describe the formation of two eukaryotic daughter cells,

is now used to describe this process in all cells. Septation is divided into several steps: (1) selection of the site where the septum will be formed; (2) assembly of the Z ring, which is composed of the cytoskeletal protein FtsZ; (3) assembly of the cell wall-synthesizing machinery (i.e., for synthesis of peptidoglycan and other cell wall constituents); and (4) constriction of the cell and septum formation. Despite the widespread use of FtsZ in cytokinesis, there are bacteria and archaea that lack this protein. How these organisms complete cytokinesis is of considerable interest (**Microbial Diversity & Ecology 7.1**).

▶▶ *Synthesis of peptidoglycan* (section 12.4)

The assembly of the Z ring is a critical step in septation, as it must be formed if subsequent steps are to occur. The FtsZ protein, a homologue of eukaryotic tubulin, is found in most bacteria and many archaea; it forms the Z ring. FtsZ, like tubulin, polymerizes

Microbial Diversity & Ecology

7.1 Cytokinesis Without FtsZ

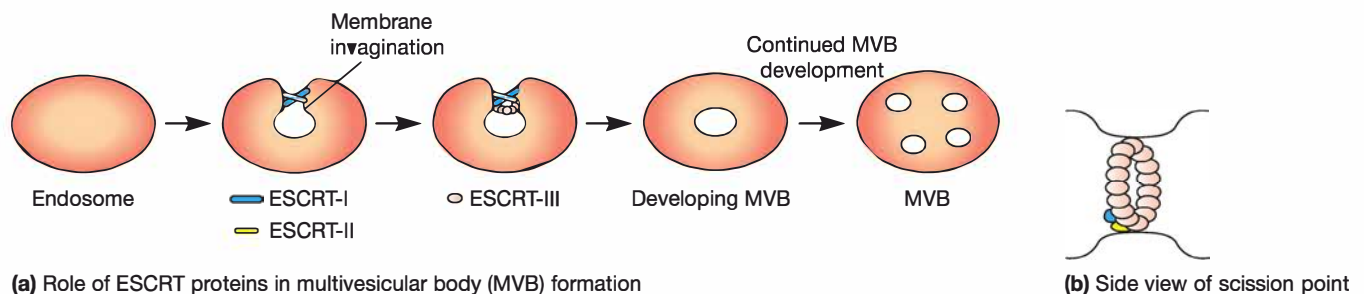

FtsZ is widespread among archaea and bacteria, but it is not universally used during cytokinesis. Some members of both *Archaea* and *Bacteria* lack FtsZ. That raises the question: Without FtsZ, how can these cells divide? Evidence suggests that there are multiple mechanisms. Some archaea do not undergo constriction during cytokinesis. Instead they form an S-layer at midcell, generate a plasma membrane on either side of it, and eventually simply break apart. Other archaea use an even more interesting process—one that involves homologues of important eukaryotic proteins.

Members of the archaeal orders *Desulfurococcales* and *Sulfolobales* undergo cytokinesis using proteins related to the ESCRT proteins of eukaryotes. ESCRT proteins are so named because of their roles in endocytosis: endosomal sorting complex required for transport. ESCRT proteins form four distinct complexes that are involved in the formation of multivesicular bodies (MVB), a type of endosome (see figure 5.10). During MVB formation, some ESCRT proteins cause the endosome membrane to invaginate. Then a complex of ESCRT proteins called ESCRT-III circles the neck formed by the invaginating membrane and brings about membrane scission,

releasing a small vesicle into the developing MVB (box figure). More recently, ESCRT-III have been implicated in the scission event that separates daughter cells during mitosis. Interestingly, the proteins used by the archaeal cells are homologues of ESCRT-III.

The cell cycle and cytokinesis have been best studied in *Sulfolobus* species. These archaea not only make use of ESCRT-III homologues but exhibit another interesting aspect of their cell cycle: temporal separation between DNA replication and segregation and cytokinesis. This is very unlike bacterial cells, where partitioning and cytokinesis overlap. Thus in *Sulfolobus* cells, the cell cycle is reminiscent of a mitotic cell cycle. Their DNA is replicated (S phase), remains unsegregated for some time (G_2), segregates (M), and then cytokinesis occurs (D). Scientists studying the cell cycle of these interesting archaea even refer to the process as mitosis. Should they call it mitosis? Time, more research, and many discussions will tell.

Sources: Bernander, R., and Ettema, T. J. G. 2010. FtsZ-less cell division in archaea and bacteria. *Curr. Opin. Microbiol.* 13:747–52; Bernander, R. 2007. The cell cycle of *Sulfolobus*. *Mol. Microbiol.* 66(3): 557–62.

to form filaments, which are thought to create the meshwork that constitutes the Z ring. Numerous studies show that the Z ring is very dynamic, with portions being exchanged constantly with newly formed, short FtsZ polymers from the cytosol.

In *E. coli*, the MinCDE system limits Z-ring formation to the center of the cell. Three proteins compose the system (MinC, MinD, and MinE). These proteins oscillate from one end of the cell to the other (figure 7.4). This oscillation creates high concentrations of MinC at the poles, where it prevents formation of the Z ring; thus Z-ring formation can occur only at midcell, which lacks MinCDE.

Once the Z ring forms, the rest of the division machinery, sometimes called the **divisome**, is constructed, as illustrated in figure 7.5. First, one or more anchoring proteins link the Z ring to the cell membrane. Then the cell wall-synthesizing machinery is assembled (table 7.1). The final steps in division involve constriction of the cell, accompanied by invagination of the plasma membrane and synthesis of the septal wall. The Z ring appears to play a major role in invagination of the plasma membrane, whereas other components of the divisome are responsible for the remaining events that occur during constriction.

MinD is tagged with green fluorescent protein. MinC, MinD, and MinE form a complex (MinCDE) and move together. At 0 seconds, MinCDE is localized to the right pole.

15 seconds later, MinCDE has moved to the left pole.

After another 15 seconds, the MinCDE has moved back to the right pole, completing a round of oscillation that will repeat until FtsZ is polymerized in the center of the cell.

The same field of cells is observed over time.

Figure 7.4 MinCDE Proteins and Establishment of the Site of Septum Formation. A GFP-MinD fusion protein is shown oscillating from one end of an *E. coli* cell to the other. MinC blocks septum formation. It oscillates with MinD, and since concentrations of MinC are highest at the poles, septum formation is forced to occur at the center of the cell.

MICRO INQUIRY What would be the outcome if FtsZ formed a Z ring that was not in the center of the cell? Consider both the morphology of the daughter cells and the partitioning of chromosomes.

The *E. coli* divisome

Figure 7.5 The Cell Division Apparatus in *E. coli*. The cell division apparatus is composed of numerous proteins. The first step in divisome formation is the polymerization of FtsZ to form the Z ring. FtsA and ZipA proteins anchor the Z ring to the plasma membrane, and then other proteins in the divisome assemble along the Z ring.

The preceding discussion of the cell cycle describes what occurs in slowly growing *E. coli* cells. In these cells, the cell cycle takes approximately 60 minutes to complete. However, *E. coli* can reproduce at a much more rapid rate, completing the entire cell cycle in about 20 minutes, despite the fact that DNA replication always requires at least 40 minutes. *E. coli* accomplishes this by beginning a second round of DNA replication (and sometimes

even a third or fourth round) before the first round of replication is completed. Thus the progeny cells receive a chromosome with two or more replication forks, and replication is continuous because the cells are always copying their DNA. 🌀 *Bacterial Cell Cycle*

Cellular Growth and Determination of Cell Shape

As we have seen, bacterial and archaeal cells have defined shapes that are species specific. These shapes are neither accidental nor random, as demonstrated by the faithful propagation of shape from one generation to the next. In addition, some microbes change their shape under certain circumstances. For instance, *Sinorhizobium meliloti* switches from rod-shaped to Y-shaped cells when living symbiotically with plants. Likewise, *Helicobacter pylori*, the causative agent of gastric ulcers and stomach cancer, changes from its characteristic helical shape to a sphere in stomach infections and in prolonged culture.

To consider the shape of a cell, we must consider the function of the cell wall. The cell wall constrains the turgor pressure exerted by the cytoplasm, thereby preventing the cell from swelling and bursting. Turgor pressure is a term used to describe the force pushing against the cell wall as determined by the osmolarity of the cytoplasmic contents. The component of the bacterial cell wall that is responsible for protecting the cell from lysis is peptidoglycan. The problem faced by bacterial cells is that the strength of the existing peptidoglycan in the cell wall must be maintained as new peptidoglycan subunits are added. Thus understanding peptidoglycan synthesis is critical to understanding the determination of cell shape. ◀◀ *Peptidoglycan structure (section 3.4)*

Peptidoglycan synthesis involves many proteins, including a group of enzymes called **penicillin-binding proteins (PBPs)**. They bear this name because they were first noted for their capacity to bind penicillin. While this property is important, their function is to link strands of peptidoglycan together and catalyze controlled degradation so that new units can be inserted during cell growth. The PBP enzymes that degrade peptidoglycan are called **autolysins**. **Figure 7.6** illustrates some of

Table 7.1 Divisome Proteins and Their Functions

| Divisome Protein | Function |
|--------------------------|---|
| FtsA, ZipA | Anchor Z ring to plasma membrane |
| FtsZ | Forms Z ring |

| FtsN | Thought to trigger constriction initiation |

¹ FtsI is also known as penicillin-binding protein 3 (PBP3).

the components of the peptidoglycan-synthesizing machinery and outlines a general scheme of peptidoglycan synthesis (see figure 12.10 for a more detailed diagram). After the NAG-NAM-pentapeptide building block is constructed, it is ferried across the plasma membrane by a lipid soluble carrier called bactoprenol. Upon release into the periplasmic space, the NAG-NAM-pentapeptide units are inserted into a peptidoglycan strand. The cellular location of autolysin activity and peptidoglycan export is not random and plays an important role in determining cell shape.

We begin our discussion with the simplest shape, the sphere or coccus. While it has been stated that this is the “default” cellular shape, the growth of a spherical cell is more complicated than once thought. New peptidoglycan forms only at the central sep-

tum during growth of the cocci *Enterococcus faecalis* and *Staphylococcus aureus* (figure 7.7a). When daughter cells separate, each has one new and one old hemisphere. As in most bacteria, proper placement of the septum depends on FtsZ localization. In mutant cells without this tubulin homologue, peptidoglycan synthesis occurs in a random pattern around the cell, leading to bloated cells that lyse. Thus FtsZ placement determines the site of cell wall growth by recruiting PBPs and other enzymes needed for peptidoglycan synthesis to the septum.

Most rod-shaped cells undergo a similar process; however, prior to cell division, they elongate (figure 7.7b). In these cells, proteins in the actin homologue MreB family play an essential role. MreB proteins polymerize, creating patches of filaments along the cytoplasmic face of the plasma membrane. Although it is not clear how MreB controls elongation, much information has been gained by studying *Bacillus subtilis*, which has three MreB proteins—MreB, Mbl, and MreBH. Prior to division, cell wall growth occurs in numerous bands around the circumference of the cell. The bands occur along the length of the cell but not at the poles. It has been suggested that MreB functions much like a scaffold inside the cytoplasm upon which the cell wall synthesizing machinery assembles. As the time for commencement of cytokinesis approaches, the FtsZ ring forms at the midcell, specifying peptidoglycan synthesis in this region. In some cells, MreB proteins have been shown to redeploy from the sidewalls to the midcell, so MreB may also contribute to cell wall synthesis during cytokinesis. In any event, cell wall growth switches from the side wall to the septum at this time. Despite the uncertain mechanisms by which MreB proteins function, their importance in determining cell shape is demonstrated by two observations. First, rod-shaped cells in which MreB has been chemically depleted assume a spherical shape. In addition,

1. Peptidoglycan synthesis starts in the cytoplasm with the attachment of uridine diphosphate (UDP) to the sugar *N*-acetylglucosamine (NAG). Some of the UDP-NAG molecules are converted to UDP-NAM. Amino acid addition to NAM is not shown for simplicity.
2. NAM is transferred from UDP to bactoprenol, a carrier embedded in the plasma membrane. NAG is then attached to bactoprenol-NAM generating bactoprenol-NAM-NAG. Bactoprenol carries the NAM-NAG unit across the plasma membrane, delivering it to the periplasm.
3. Autolysins (cyan balls labeled “A”) located at the divisome degrade bonds in the existing peptidoglycan sacculus. This permits the insertion of new NAM-NAG units into the sacculus.

Figure 7.6 Components of the Peptidoglycan Synthesizing Machinery. See figure 12.10 for a detailed diagram of peptidoglycan synthesis.

AI. Spherical cells build new peptidoglycan only at midcell, where the septum will form during division. This leads to daughter cells that have one old and one new cell wall hemisphere.

BI. During growth, prior to division, new cell wall is made along the side of the cell but not at the poles. This placement is thought to be determined by the position of MreB homologues.

BII. As division begins, FtsZ polymerization forms a Z ring and new cell wall growth is confined to the midcell.

BIII. Rod-shaped daughter cells are formed with one new pole and one old pole.

Figure 7.7 Cell Wall Biosynthesis and Determination of Cell Shape in Spherical and Rod-Shaped Cells.

MICRO INQUIRY Which step in the development of rod-shaped cells is essential in determining cell morphology?

while almost all rod-shaped bacteria and archaea synthesize at least one MreB homologue, coccoid-shaped cells lack proteins in the MreB family.

The last cell shape we consider is that of comma-shaped cells, as studied in the aquatic bacterium *Caulobacter crescentus*. In addition to the actin homologue MreB and the tubulin-like protein FtsZ, these cells (and other vibrioid-shaped cells) produce a cytoskeletal protein called crescentin, a homologue of eukaryotic intermediate filaments (see figure 3.32). This protein localizes to one side of the cell, where it slows the insertion of new peptidoglycan units into the peptidoglycan sacculus (figure 7.8). The resulting asymmetric cell wall growth gives rise to the inner curvature that characterizes this cell shape.

►► **Caulobacteraceae and Hyphomicrobiaceae (section 22.1)**

It is clear from these examples that common microbial cell shapes require cytoskeletal proteins that bear startling homology with those of eukaryotes. However, some bacterial shapes appear to be determined by other mechanisms. For example, the spirochete *Borrelia burgdorferi*, which causes Lyme disease, relies on its periplasmic flagella to confer its spiral shape (see figure 21.18). As another example, *Spiroplasma*, a citrus pathogen, has no cell wall or flagella. It relies on contractile cytoplasmic fibrils to give its spiral shape. ►► **Phylum Spirochaetes (section 21.7); Class Mollicutes (Phylum Tenericutes) (section 21.3)**

Figure 7.8 Vibrioid Shape Is Determined by Crescentin in

***Caulobacter crescentus*.** The intermediate filament homologue crescentin polymerizes along the length of the inner curvature of the cell. Cells depleted of crescentin are rod-shaped. Note that *C. crescentus* forms all three types of cytoskeleton protein homologues.

While the study of bacterial cytoskeletal elements and cell shape is inherently interesting, it also has practical aspects. Bacterial cytoskeletal homologues provide a tractable model for the study of more complicated eukaryotic cytoskeletal proteins and their assembly. In addition, these proteins may prove to be valuable targets for drug development. Indeed, molecules that block FtsZ function inhibit growth of the pathogen *Staphylococcus aureus*. ►► **Antimicrobial chemotherapy (chapter 9)**

7.3 Influences of Environmental Factors on Growth

After reading this section, you should be able to:

- Use the terms that describe a microbe's growth range or requirement for each of the factors that influence microbial growth
- Summarize the adaptations of extremophiles to their natural habitats
- Summarize the strategies used by nonextremophiles to acclimate to changes in their environment
- Describe the enzymes observed in microbes that protect them against toxic O₂ products

Almost every year at Yellowstone National Park, a tourist is seriously burned or killed after falling into one of the park's hot springs. Yet, a rich microbial community lives in these same springs, as well as in the hot pots, fumaroles, and other thermal features of the park. Clearly, the adaptations of some microorganisms to extreme and inhospitable environments are truly remarkable. Indeed, microbes are thought to be present nearly everywhere on Earth. Bacteria such as *Bacillus infernus* are able to live over 2.4 km below Earth's surface, without oxygen and at temperatures above 60°C. Other microbes live at great ocean depths or in lakes such as the Great Salt Lake in Utah (USA) that have high sodium chloride concentrations. Microorganisms that grow in such harsh conditions are called **extremophiles**. To extremophiles, the harsh conditions of their habitats are "normal." Many other microbes are not extremophiles; they live in more moderate conditions. However, conditions can vary within any habitat, and microbes must be able to respond to any changes to ensure their survival. To study ecological distribution of microbes, it is important to understand the strategies they use to survive. An understanding of environmental influences on microbes and their activity also aids in the control of microbial growth. ►► *Microorganisms in benthic marine environments* (section 30.2); *The subsurface biosphere* (section 31.4)

In this section, we briefly review the effects of the most important environmental factors on microbial growth. Major emphasis is given to solutes and water activity, pH, temperature, oxygen level, pressure, and radiation. **Table 7.2** summarizes how microorganisms are categorized in terms of their response to these factors. The adaptations microbes have evolved to live in their natural environments also are discussed.

Solutes and Water Activity

Because a selectively permeable plasma membrane separates microorganisms from their environment, they can be affected by changes in the osmotic concentration of their surroundings. If a microorganism is placed in a hypotonic solution (one with a lower osmotic concentration), water will enter the cell and cause it to burst unless something is done to prevent the influx of water or inhibit plasma membrane expansion. Conversely, if it is placed in a hypertonic solution (one with a higher osmotic concentration), water will flow out of the cell. In microbes that have cell walls, the membrane shrinks away from the cell wall—a process called plasmolysis. Dehydration of the cell in hypertonic environments may damage the cell membrane and cause the cell to become metabolically inactive.

Clearly, it is important that microbes be able to respond to changes in the osmotic concentrations of their environment. Microbes in hypotonic environments are protected in part by their cell wall, which prevents over-expansion of the plasma membrane. However, not all microbes have cell walls. Wall-less microbes can be protected by reducing the osmotic concentration of their cytoplasm; this protective measure is also used by many walled microbes to provide protection in addition to their cell walls. Microbes use several mechanisms to lower the osmotic concentration of their cytoplasm. For example, some bacteria have mechanosensitive (MS) channels in their plasma membrane. In a hypotonic environment, the membrane stretches due to an increase in hydrostatic pressure and cellular swelling. MS channels then open and allow solutes to leave. Thus MS channels act as escape valves to protect cells from bursting. Many protists use contractile vacuoles to expel excess water.

Some microbes are adapted to extreme hypertonic environments. These **osmophiles** include **halophiles**, which require the presence of NaCl at a concentration above about 0.2 M (**figure 7.9**). Other osmophiles require high concentrations of sugar or salts such as magnesium sulfate. Extreme halophiles have adapted so completely to hypertonic, saline conditions that they require NaCl concentrations between about 2 M and saturation (about 6.2 M). Members of the archaeal genus *Halobacterium* can be isolated from the Dead Sea (a salt lake between Israel and Jordan), the Great Salt Lake in Utah, and other aquatic habitats with salt concentrations approaching saturation.

Halophiles generally take one of two approaches to living in their high salt habitats, both of which involve the synthesis or uptake of **compatible solutes**. Compatible solutes are molecules that can be kept at high intracellular concentrations without interfering with metabolism and growth. The first approach used by halophiles is to maintain high levels of inorganic compatible solutes such as potassium chloride (KCl) in the cytoplasm. The second approach is to increase the internal osmotic concentration with organic compatible solutes such as choline, betaine, and amino acids such as proline and glutamic acid. The use of compatible solutes extends beyond halophiles. This is also a strategy utilized by many other osmophiles. Furthermore, many microorganisms, whether in hypotonic or hypertonic environments,

Table 7.2 Microbial Responses to Environmental Factors

| Descriptive Term | Definition | Representative Microorganisms |
|----------------------------------|---|---|
| Solute and Water Activity | | |
| Osmotolerant | Able to grow over wide ranges of water activity or osmotic concentration | <i>Staphylococcus aureus</i> , <i>Saccharomyces rouxii</i> |
| Halophile | Requires high levels of sodium chloride, usually above about 0.2 M, to grow | <i>Halobacterium</i> , <i>Dunaliella</i> , <i>Ectothiorhodospira</i> |
| pH | | |
| Acidophile | Growth optimum between pH 0 and 5.5 | <i>Sulfolobus</i> , <i>Picrophilus</i> , <i>Ferroplasma</i> , <i>Acontium</i> |
| Neutrophile | Growth optimum between pH 5.5 and 8.0 | <i>Escherichia</i> , <i>Euglena</i> , <i>Paramecium</i> |
| Alkaliphile | Growth optimum between pH 8.0 and 11.5 | <i>Bacillus alcalophilus</i> , <i>Natronobacterium</i> |
| Temperature | | |
| Psychrophile | Grows at 0°C and has an optimum growth temperature of 15°C or lower | <i>Bacillus psychrophilus</i> , <i>Chlamydomonas nivalis</i> |
| Psychrotroph | Can grow at 0–7°C; has an optimum between 20 and 30°C and a maximum around 35°C | <i>Listeria monocytogenes</i> , <i>Pseudomonas fluorescens</i> |
| Mesophile | Has growth optimum between 20 and 45°C | <i>Escherichia coli</i> , <i>Trichomonas vaginalis</i> |
| Thermophile | Can grow at 55°C or higher; optimum often between 55 and 65°C | <i>Geobacillus stearothermophilus</i> , <i>Thermus aquaticus</i> , <i>Cyanidium caldarium</i> , <i>Chaetomium thermophile</i> |
| Hyperthermophile | Has an optimum between 85 and about 113°C | <i>Sulfolobus</i> , <i>Pyrococcus</i> , <i>Pyrodictium</i> |
| Oxygen Concentration | | |
| Obligate aerobe | Completely dependent on atmospheric O ₂ for growth | <i>Micrococcus luteus</i> , most protists and fungi |
| Facultative anaerobe | Does not require O ₂ for growth but grows better in its presence | <i>Escherichia</i> , <i>Enterococcus</i> , <i>Saccharomyces cerevisiae</i> |
| Aerotolerant anaerobe | Grows equally well in presence or absence of O ₂ | <i>Streptococcus pyogenes</i> |
| Obligate anaerobe | Does not tolerate O ₂ and dies in its presence | <i>Clostridium</i> , <i>Bacteroides</i> , <i>Methanobacterium</i> |
| Microaerophile | Requires O ₂ levels between 2–10% for growth and is damaged by atmospheric O ₂ levels (20%) | <i>Campylobacter</i> , <i>Spirillum volutans</i> , <i>Treponema pallidum</i> |
| Pressure | | |
| Piezophile (barophile) | Growth more rapid at high hydrostatic pressures | <i>Photobacterium profundum</i> , <i>Shewanella benthica</i> |

use compatible solutes to keep the osmotic concentration of their cytoplasm somewhat above that of the habitat so that the plasma membrane is always pressed firmly against their cell wall. For instance, fungi and photosynthetic protists employ the compatible solutes sucrose and polyols (e.g., arabitol, glycerol, and mannitol) for this purpose.

Some of the best-studied halophiles belong to the archaeal genus *Halobacterium*. These extremely halophilic archaea accumulate enormous quantities of potassium and chloride ions in order to remain hypertonic to their environment; the internal potassium concentration may reach 4 to 7 M. To do so, their enzymes, ribosomes, and transport proteins require high

potassium levels for stability and activity. In addition, their plasma membranes and cell walls are stabilized by high concentrations of sodium ion. If the sodium concentration decreases too much, the wall and plasma membrane disintegrate. Such extreme halophiles have successfully adapted to environmental conditions that would destroy most organisms. However, in the process, they have become so specialized that they have lost ecological flexibility and can prosper only in a few extreme habitats. ▶▶ *Halobacteria* (section 20.3)

The presence of solutes such as salts and sugars decreases the availability of water to microbes because the water is “tied up” by its interaction with the solutes. Microbiologists express

Figure 7.9 The Effects of Sodium Chloride on Microbial Growth.

Four different patterns of microbial dependence on NaCl concentration are depicted. The curves are only illustrative and are not meant to provide precise shapes or salt concentrations required for growth.

MICRO INQUIRY What is the difference between halophilic and halotolerant?

quantitatively the degree of water availability by determining **water activity** (a_w). The water activity of a solution is 1/100 the relative humidity of the solution (when expressed as a percent). It is also equivalent to the ratio of the solution's vapor pressure (P_{soln}) to that of pure water (P_{water}). Distilled water has an a_w of 1, milk has an a_w of 0.97, a saturated salt solution has an a_w of 0.75, and the a_w of dried fruits is only about 0.5.

Microorganisms differ greatly in their ability to acclimate to habitats with low water activity. Nonosmophilic microorganisms must expend extra effort to grow in a habitat with a low a_w value because they must maintain a high internal solute concentration to retain water. Some microorganisms can do this and are **osmotolerant**; they grow over wide ranges of water activity but optimally at higher levels. Osmotolerant organisms can be found in all domains of life. For example, *Staphylococcus aureus* is halotolerant, can be cultured in media containing sodium chloride concentration up to about 3 M, and is well adapted for growth on the skin. The yeast *Saccharomyces rouxii* grows in sugar solutions with a_w values as low as 0.6. The photosynthetic protist *Dunaliella viridis* tolerates sodium chloride concentrations from 1.7 M to a saturated solution. In contrast to osmotolerant microbes, osmophilic microbes (e.g., halophilic *Halobacterium* spp.) grow best at low a_w . However, most microorganisms only grow well at water

activities around 0.98 (the approximate a_w for seawater) or higher. This is why drying food or adding large quantities of salt and sugar effectively prevents food spoilage. ► **Controlling food spoilage** (section 41.2)

pH

pH is a measure of the relative acidity of a solution and is defined as the negative logarithm of the hydrogen ion concentration (expressed in terms of molarity).

$$\text{pH} = -\log [\text{H}^+] = \log(1/[\text{H}^+])$$

The pH scale extends from pH 0.0 (1.0 M H^+) to pH 14.0 ($1.0 \times 10^{-14} \text{ M H}^+$), and each pH unit represents a tenfold change in hydrogen ion concentration. **Figure 7.10** shows that microbial habitats vary widely in pH—from pH 0 to 2 at the acidic end to alkaline lakes and soil with pH values between 9 and 10.

Each species has a definite pH growth range and pH growth optimum. **Acidophiles** have their growth optimum between pH 0 and 5.5; **neutrophiles**, between pH 5.5 and 8.0; and **alkaliphiles** (alkalophiles), between pH 8.0 and 11.5. In general, different microbial groups have characteristic pH preferences. Most known bacteria and protists are neutrophiles. Most fungi prefer more acidic surroundings, about pH 4 to 6; photosynthetic protists also seem to favor slight acidity. Many archaea are acidophiles. For example, the archaeon *Sulfolobus acidocaldarius* is a common inhabitant of acidic hot springs; it grows well from pH 1 to 3 and at high temperatures. The archaea *Ferroplasma acidarmanus* and *Picrophilus oshimae* can actually grow very close to pH 0. Alkaliphiles are distributed among all three domains of life. They include bacteria belonging to the genera *Bacillus*, *Micrococcus*, *Pseudomonas*, and *Streptomyces*; yeasts and filamentous fungi; and numerous archaea. Because seawater has a pH of about 8.3, marine microorganisms are alkaliphilic.

Although microorganisms often grow over wide ranges of pH and far from their optima, there are limits to their tolerance. When the external pH is low, the concentration of H^+ is much greater outside than inside, and H^+ will move into the cytoplasm and lower the cytoplasmic pH. Drastic variations in cytoplasmic pH can harm microorganisms by disrupting the plasma membrane or inhibiting the activity of enzymes and membrane transport proteins. Most microbes die if the internal pH drops much below 5.0 to 5.5. Changes in the external pH also can alter the ionization of nutrient molecules and thus reduce their availability to the organism.

Microorganisms respond to external pH changes using mechanisms that maintain a neutral cytoplasmic pH. Several mechanisms for adjusting to small changes in external pH have

Figure 7.10 The pH Scale. The pH scale and examples of substances with different pH values. Several microorganisms are placed at their growth optima. A is archaeon; E, eukaryote; and B, bacterium.

been proposed. Neutrophiles appear to exchange potassium for protons using an antiport transport system. Internal buffering also may contribute to pH homeostasis. However, if the external pH becomes too acidic, other mechanisms come into play. When the pH drops below about 5.5, *Salmonella enterica* serovar Typhimurium and *E. coli* synthesize an array of new proteins as part of what has been called their acidic tolerance response. An ATPase enzyme contributes to this protective response by pumping protons out of the cell, at the expense of ATP. If the external pH decreases to 4.5 or lower, acid shock proteins and heat shock proteins are synthesized. These prevent the denaturation of proteins and aid in refolding denatured proteins in acidic conditions. ◀◀ *Uptake of nutrients* (section 3.3); ▶▶ *Protein maturation and secretion* (section 13.8)

What about microbes that live at pH extremes? Extreme alkaliphiles such as *Bacillus alcalophilus* maintain their internal pH

close to neutrality by exchanging internal sodium ions for external protons. Acidophiles use a variety of measures to maintain a neutral internal pH. These include the transport of cations (e.g., potassium ions) into the cell, thus decreasing the movement of H⁺ into the cell; proton transporters that pump H⁺ out if they get in; and highly impermeable cell membranes.

1. Define pH, acidophile, neutrophile, and alkaliphile.
2. Classify each of the following organisms as an alkaliphile, a neutrophile, or an acidophile: *Staphylococcus aureus*, *Microcystis aeruginosa*, *Sulfolobus acidocaldarius*, and *Pseudomonas aeruginosa* (see table 7.2). Which might be pathogens? Explain your choices.
3. Describe the mechanisms microbes use to maintain an internal neutral pH. Explain how extreme pH values might harm microbes.

Temperature

Microorganisms are particularly susceptible to external temperatures because they cannot regulate their internal temperature. An important factor influencing the effect of temperature on growth is the temperature sensitivity of enzyme-catalyzed reactions. Each enzyme has a temperature at which it functions optimally. At some temperature below the optimum, it ceases to be catalytic. As the temperature rises from this low point, the rate of catalysis increases to that observed for the optimal temperature. The velocity of the reaction roughly doubles for every 10°C rise in temperature. When all enzymes in a microbe are considered together, as the rate of each reaction increases, metabolism as a whole becomes more active and the microorganism grows faster. However, beyond a certain point, further increases actually slow growth, and sufficiently high temperatures are lethal. High temperatures denature enzymes, transport carriers, and other proteins. Temperature also has a significant effect on microbial membranes. At very low temperatures, membranes solidify. At high temperatures, the lipid bilayer simply melts and disintegrates. Thus when organisms are above or below their optimum temperature, both function and cell structure are affected.

Because of these opposing temperature influences, microbial growth has a characteristic temperature dependence with distinct **cardinal temperatures**—minimum, optimum, and maximum growth temperatures (figure 7.11). Although the shape of temperature dependence curves varies, the temperature optimum is always closer to the maximum than to the minimum. The cardinal temperatures are not rigidly fixed. Instead, they depend to some extent on other environmental factors such as pH and available nutrients. For example, *Crithidia fasciculata*, a flagellated protist living in the gut of mosquitoes, grows in a simple medium at 22 to 27°C. However, if its medium is supplemented with extra metals, amino acids, vitamins, and lipids, it can grow at 33 to 34°C.

The cardinal temperatures vary greatly among microorganisms (table 7.3). Optima usually range from 0°C to 75°C, whereas

Figure 7.11 Temperature and Growth. The effect of temperature on growth rate.

microbial growth occurs at temperatures extending from less than -20°C to over 120°C . Some archaea even grow at 121°C (250°F), the temperature normally used in autoclaves. A major factor determining growth range seems to be the availability of water. Even at the most extreme temperatures, microorganisms need liquid water to grow. The growth temperature range for a particular microorganism usually spans about 30 degrees. Some species (e.g., *Neisseria gonorrhoeae*) have a small range; others,

such as *Enterococcus faecalis*, grow over a wide range of temperatures. The major microbial groups differ from one another regarding their maximum growth temperatures. The upper limit for protists is around 50°C. Some fungi grow at temperatures as high as 55 to 60°C. Bacteria and archaea can grow at much higher temperatures than eukaryotes. It has been suggested that eukaryotes are not able to manufacture stable and functional organellar membranes at temperatures above 60°C.

Several terms are used to describe microbes based on their temperature ranges for growth (figure 7.12). Microbes that grow in cold environments are either psychrophiles or psychrotrophs. **Psychrophiles** grow well at 0°C and have an optimum growth temperature of 15°C; the maximum is around 20°C. They are readily isolated from Arctic and Antarctic habitats. Oceans constitute an enormous habitat for psychrophiles because 90% of ocean water is 5°C or colder. The psychrophilic protist *Chlamydomonas nivalis* can actually turn a snowfield or glacier pink with its bright red spores. Psychrophiles are widespread among bacterial taxa and are found in such genera as *Pseudomonas*, *Vibrio*, *Alcaligenes*, *Bacillus*, *Photobacterium*, and *Shewanella*. Psychrophilic microorganisms have adapted to their environment in several ways. Their enzymes, transport systems, and protein synthetic machinery function well at low temperatures. The cell membranes of psychrophilic microorganisms have high levels of unsaturated fatty acids and remain semifluid when cold. Indeed, many psychrophiles begin to leak cellular constituents at temperatures higher than 20°C because of cell membrane disruption. Many psychrophiles accumulate compatible solutes. Rather than protecting against osmotic stress, in this case the compatible solutes decrease the freezing point of the cytosol. Still other psychrophiles use antifreeze proteins to decrease the freezing point of the cytosol.

Psychrotrophs (psychrotolerants) grow at 0°C or higher and typically have maxima at about 35°C. Psychrophilic bacteria and fungi are major causes of refrigerated food spoilage.

Mesophiles are microorganisms that grow in moderate temperatures. They have growth optima around 20 to 45°C and often have a temperature minimum of 15 to 20°C and a maximum of about 45°C. Almost all human pathogens are mesophiles, as might be expected because the human body is a fairly constant 37°C.

Microbes that grow best at high temperatures are thermophiles and hyperthermophiles. **Thermophiles** grow at temperatures between 45 and 85°C, and they often have optima between 55 and 65°C. The vast majority are members of *Bacteria* or *Archaea*, although a few photosynthetic protists and fungi are thermophilic (table 7.3). Thermophiles flourish in many habitats including composts, self-heating hay stacks, hot water lines, and hot springs. **Hyperthermophiles** have growth optima between 85°C and about 113°C. They usually do not grow below 55°C. *Pyrococcus abyssi* and *Pyrodicticum occultum* are examples of marine hyperthermophiles found in hot areas of the seafloor.

Thermophiles and hyperthermophiles differ from mesophiles in many ways. They have heat-stable enzymes and protein synthesis systems that function properly at high temperatures. These proteins are stable for a variety of reasons. Heat-stable proteins have highly organized hydrophobic interiors and more hydrogen and other noncovalent bonds to stabilize their structure. Larger quantities of amino acids such as proline also make polypeptide chains less flexible and more heat stable. In addition, the proteins are stabilized and aided in folding by proteins called chaperones. Nucleoid-associated proteins appear to stabilize the DNA of thermophilic bacteria. Hyperthermophiles have an enzyme called reverse DNA gyrase that changes the topology of their DNA and enhances its stability. The membrane lipids of thermophiles and hyperthermophiles are also quite temperature stable. They tend to be more saturated, more branched, and of higher molecular weight. This increases the melting points of membrane lipids. Recall that archaea have membrane lipids with ether linkages. Such lipids are resistant to hydrolysis at high temperatures. Furthermore, the diglycerol tetraethers observed in the membranes of some archaeal thermophiles span the membrane to form a rigid, stable monolayer. ◀◀ *Archaeal cell envelopes (section 4.2)*

Figure 7.12 Temperature Ranges for Microbial Growth.

Microorganisms are placed in different classes based on their temperature ranges for growth. They are ranked in order of increasing growth temperature range as psychrophiles, psychrotrophs, mesophiles, thermophiles, and hyperthermophiles. Representative ranges and optima for these five types are illustrated.

Retrieve, Infer, Apply

1. What are cardinal temperatures?
2. Why does the growth rate rise with increasing temperature and then fall again at higher temperatures?
3. Define psychrophile, psychrotroph, mesophile, thermophile, and hyperthermophile.
4. What metabolic and structural adaptations for extreme temperatures do psychrophiles and thermophiles have? How might these protect the organisms from their environment?

Oxygen Concentration

The importance of oxygen to the growth of an organism correlates with the processes it uses to conserve energy. Almost all energy-conserving metabolic processes involve the movement of electrons through a series of membrane-associated electron carriers called an electron transport chain (ETC). For chemotrophs, an externally supplied terminal electron acceptor is critical to the functioning of the ETC. In many cases, the terminal electron acceptor is oxygen. ►► *Electron transport chains* (section 10.4)

Almost all multicellular organisms are completely dependent on atmospheric O₂ for growth; that is, they are **obligate aerobes** (table 7.2). Oxygen serves as the terminal electron acceptor for the ETC in the metabolic process called aerobic respiration. In addition, aerobic eukaryotes employ O₂ in the synthesis of sterols and unsaturated fatty acids. **Microaerophiles** such as the foodborne pathogen *Campylobacter jejuni* are damaged by the normal atmospheric level of O₂ (20%) and require O₂ levels in the range of 2 to 10% for growth. **Facultative anaerobes** do not require O₂ for growth but grow better in its presence. In the presence of oxygen, they use O₂ as the terminal electron acceptor during aerobic respiration. **Aerotolerant anaerobes** such as *Enterococcus faecalis* (an opportunistic pathogen that causes urinary tract infections) grow equally well whether O₂ is present or not; they can tolerate O₂, but they do not make use of it. Many have strictly fermentative metabolism and thus do not use O₂ in their energy-conserving processes. In contrast, for strict or **obligate anaerobes** (e.g., members of the

genera *Bacteroides*, *Clostridium*, *Methanococcus*), O₂ is toxic, and they are usually killed by the presence of O₂. Strict anaerobes cannot generate energy through aerobic respiration and employ other metabolic strategies such as fermentation or anaerobic respiration, neither of which requires O₂. The nature of bacterial O₂ responses can be readily determined by growing the bacteria in a solid culture medium or a medium such as thioglycollate broth, which contains a reducing agent to lower O₂ levels (figure 7.13). ►► *Aerobic respiration* (section 11.3); *Anaerobic respiration* (section 11.7); *Fermentation* (section 11.8)

A microbial group may show more than one type of relationship to O₂. All five types are found among bacteria, archaea, and protists. Most fungi are aerobic, but a number of species—particularly among yeasts—are facultative anaerobes. Photosynthetic protists are usually obligate aerobes. Although obligate anaerobes are killed by O₂, they may be recovered from habitats that appear to be oxic. In such cases, they associate with facultative anaerobes that use up the available O₂ and thus make the growth of strict anaerobes possible. For example, the strict anaerobe *Porphyromonas gingivalis* lives in the mouth, where it grows in the anoxic crevices around the teeth. Clearly, the ability to grow in both oxic and anoxic environments provides considerable flexibility and is an ecological advantage.

The different relationships with O₂ are due to several factors, including the inactivation of proteins and the effect of toxic O₂ derivatives. Enzymes can be inactivated when sensitive groups such as sulfhydryls are oxidized. However, even molecules that have evolved to function aerobically can be damaged by O₂. This

is because the unpaired electrons in the outer shell of oxygen make it inherently unstable (see figure A1.2). Toxic O₂ derivatives are formed when cellular proteins such as flavoproteins transfer electrons to O₂. These toxic O₂ derivatives are called reactive oxygen species (ROS), and they can damage proteins, lipids, and nucleic acids. ROS include the superoxide radical, hydrogen peroxide, and the most dangerous hydroxyl radical.

A microorganism must be able to protect itself against ROS or it will be killed. Indeed, neutrophils and macrophages, two important immune system cells, use ROS to destroy invading pathogens. ►► *Phagocytosis* (section 33.5)

Many microorganisms possess enzymes that protect against toxic O₂ products (figure 7.13). Obligate aerobes and

Figure 7.13 Oxygen and Bacterial Growth. Each dot represents an individual bacterial colony within the agar or on its surface. The surface, which is directly exposed to atmospheric oxygen, is oxic. The oxygen content of the medium decreases with depth until the medium becomes anoxic toward the bottom of the tube. The presence and absence of the enzymes superoxide dismutase (SOD) and catalase for each type are shown.

MICRO INQUIRY Why do facultative anaerobes grow best at the surface of the tube while aerotolerant microbes demonstrate a uniform growth pattern throughout the tube?

facultative anaerobes usually contain the enzymes **superoxide dismutase (SOD)** and **catalase**, which catalyze the destruction of super-oxide radical and hydrogen peroxide, respectively. Peroxidase also can be used to destroy hydrogen peroxide.

Strict anaerobes lack these enzymes or have them in very low concentrations and therefore cannot tolerate O_2 . ►► *Redox reactions (section 10.3)*

2. What are the toxic effects of O_2 ? How do aerobes and other oxygen-tolerant microbes protect themselves from these effects?

Pressure

Organisms that spend their lives on land or the surface of water are always subjected to a pressure of 1 atmosphere (atm; 1 atm is ~ 0.1 megapascal, or MPa for short) and are never affected significantly by pressure. Other organisms, including many bacteria and archaea, live in the deep sea (ocean depths of 1,000 m or more), where the hydrostatic pressure can reach 600 to 1,100 atm and the temperature is about 2 to 3°C. These high hydrostatic pressures affect membrane fluidity and membrane-associated function. How do microbes survive under such conditions?

Many microbes found at great ocean depths are **barotolerant**: increased pressure adversely affects them but not as much as it does nontolerant microbes. Some are truly **piezophilic (barophilic)**. A piezophile is defined as an organism that has a maximal growth rate at pressures greater than 1 atm. For instance, a piezophile recovered from the Mariana trench near the Philippines (depth about 10,500 m) grows only at pressures between about 400 to 500 atm when incubated at 2°C.

An important adaptation observed in piezophiles is that they change their membrane lipids in response to increasing pressure. For instance, bacterial piezophiles increase the amount of unsaturated fatty acids in their membrane lipids as pressure increases. They may also shorten the length of their fatty acids. Piezophiles are thought to play important roles in nutrient cycling in the deep sea. Thus far, they have been found among several bacterial genera (e.g., *Photobacterium*, *Shewanella*, *Colwellia*). ►► *Microorganisms in benthic marine environments (section 30.2)*

Radiation

Our world is bombarded with electromagnetic radiation of various types (**figure 7.14**). Radiation behaves as if it were composed of waves like those traveling on the surface of water. The distance between two wave crests or troughs is the wavelength. As the wavelength of electromagnetic radiation decreases, the energy of the radiation increases; gamma rays and X rays are much more

energetic than visible light or infrared waves. Electromagnetic radiation also acts like a stream of energy packets called photons, each photon having a quantum of energy whose value depends on the wavelength of the radiation.

Sunlight is the major source of radiation on Earth. It includes visible light, ultraviolet (UV) radiation, infrared rays, and radio waves. Visible light is a most conspicuous and important aspect of our environment: most life depends on the ability of photosynthetic organisms to trap the light energy of the sun. Almost 60% of the sun's radiation is in the infrared region rather than the visible portion of the spectrum. Infrared is the major source of Earth's heat. At sea level, there is very little ultraviolet radiation at wavelengths below about 290 nm. This is because wavelengths shorter than this are absorbed by O_2 in Earth's atmosphere; this process forms a layer of ozone (O_3) between 40 and 48 km above Earth's surface. The ozone layer absorbs somewhat longer UV rays and reforms O_2 . The even distribution of sunlight throughout the visible spectrum accounts for the fact that sunlight is generally "white."

►► *Phototrophy (section 11.11)*

Many forms of electromagnetic radiation are very harmful to microorganisms. This is particularly true of **ionizing radiation**, radiation of very short wavelength and high energy, which can cause atoms to lose electrons (ionize). Two major forms of ionizing radiation are X rays, which are artificially produced, and gamma rays, which are emitted during natural radioisotope decay. Low levels of ionizing radiation may produce mutations that indirectly result in death, whereas higher levels are directly lethal. Ionizing radiation causes a variety of changes in cells. It breaks

Figure 7.14 The Electromagnetic Spectrum. A portion of the spectrum is expanded at the bottom of the figure.

hydrogen bonds, oxidizes double bonds, destroys ring structures, and polymerizes some molecules.

Although microorganisms are more resistant to ionizing radiation than larger organisms, they are still destroyed by a sufficiently large dose. Indeed, ionizing radiation can be used to sterilize items. However, bacterial endospores and bacteria such as *Deinococcus radiodurans* are extremely resistant to large doses of ionizing radiation. *D. radiodurans* is of particular note. This amazing microbe is able to piece together its genome after it is blasted apart by massive doses of radiation. How it does this is a matter of intense interest to microbiologists. ►► *Radiation (section 8.4); Deinococcus-Thermus (section 21.2)*

Ultraviolet (UV) radiation can kill microorganisms due to its short wavelength (approximately from 10 to 400 nm) and high energy. The most lethal UV radiation has a wavelength of 260 nm, the wavelength most effectively absorbed by and damaging to DNA. The damage caused by UV light can be repaired by several DNA repair mechanisms, as we discuss in chapter 16. Excessive exposure to UV light outstrips the organism's ability to repair the damage and death results. Longer wavelengths of UV light (near-UV radiation; 325 to 400 nm) can also harm microorganisms because they induce the breakdown of the amino acid tryptophan to toxic photoproducts. These toxic photoproducts plus the near-UV radiation itself produce breaks in DNA strands. ►► *Mutations (section 16.1)*

Even visible light, when present in sufficient intensity, can damage or kill microbial cells. Usually pigments called photosensitizers and O_2 are involved. Photosensitizers include pigments such as chlorophyll, bacteriochlorophyll, cytochromes, and flavins, which can absorb light energy and become excited or activated. The excited photosensitizer (P) transfers its energy to O_2 , generating singlet oxygen (1O_2).

Singlet oxygen is a very reactive, powerful oxidizing agent that quickly destroys a cell.

Many microorganisms that are airborne or live on exposed surfaces use carotenoid pigments (see figure 11.30) for protection against photooxidation. Carotenoids effectively quench singlet oxygen; that is, they absorb energy from singlet oxygen and convert it back into the unexcited ground state. Both phototrophic and non-phototrophic microorganisms employ pigments in this way.

7.4 Microbial Growth in Natural Environments

After reading this section, you should be able to:

- Discuss the mechanisms used by microbes to survive starvation
- Distinguish sessile and planktonic microbial life styles
- Describe the formation of biofilms and summarize their importance in natural environments, industrial settings, and medicine
- Define quorum sensing and provide examples of cellular processes regulated by quorum sensing
- Discuss in general terms the communication that occurs between rhizobia and their plant hosts

The growth of microorganisms depends on their tolerance of the environmental conditions in their habitat, as outlined in section 7.3. It also depends on the availability of nutrients. Natural microbial environments—that is, those that are not created by humans—are complex and constantly changing. They expose microbes to many overlapping gradients of nutrients and other environmental factors, including inhibitory substances, which can limit microbial growth. Furthermore, microbes do not exist alone. They often associate with other microbes, sometimes forming biofilms. They frequently form relationships with large organisms such as plants and animals. In this section, we explore three aspects of life in nature: the scarcity of nutrients, biofilms, and the mechanisms used by microbes to communicate among and between species.

Oligotrophic Environments

Many microbes inhabit **oligotrophic** environments—ones in which nutrient levels are low. Many other microbes live in “feast or famine” environments. For both groups of microbes, the ability to survive starvation conditions is paramount. Fortunately, microbes have evolved numerous responses to starvation.

Some bacteria respond to starvation with obvious morphological changes such as endospore formation. Recall that endospores are not only highly resistant to a variety of stressors (e.g., high temperatures and radiation) but are also metabolically dormant. Other microbes become dormant without such a drastic reorganization of the cell. Many eukaryotic microbes and some bacteria form cysts (see figures 22.5 and 25.2). Many become dormant while only decreasing somewhat in overall size. This is often accompanied by protoplast shrinkage and, in bacteria, nucleoid condensation.

In some cases, dormancy is entered in response to decreasing nutrient levels. However, some microbial populations always have a small subset of cells that become dormant spontaneously, even when nutrients are readily available. In these populations, the dormant cells can be thought of as the population's attempt to prepare for future possible starvation conditions. But there is an added benefit to the spontaneous production of dormant cells within an otherwise active population. Some of the dormant cells are resistant to antibiotics. These so-called **persisters**

(a) Biofilm on surface of a stromatolite

(b) Infected tissue after hip replacement

Figure 7.15 Examples of Biofilms. Biofilms form on almost any surface exposed to microorganisms. (a) Biofilm on the surface of a stromatolite in Walker Lake (Nevada, USA), an alkaline lake. The biofilm consists primarily of the cyanobacterium *Calothrix*. (b) Photograph taken during surgery to remove a biofilm-coated artificial joint. The white material is composed of pus, bacterial and fungal cells, and the patient's white blood cells.

survive exposure to an antibiotic even though they do not harbor antibiotic-resistance genes. This is because antibiotics target metabolically active cells; thus dormancy is a mechanism by which bacteria can resist a wide range of antibiotics. Of interest is the observation that biofilms contain persisters.

In many bacteria, the action of a protein called RpoS is central to starvation survival strategies. RpoS is a component of RNA polymerase holoenzyme, the enzyme responsible for binding DNA and initiating RNA synthesis (transcription). RpoS directs the other subunits of the enzyme (collectively called RNA polymerase core enzyme) to the appropriate locations along the chromosome, so that transcription can begin. Specifically, RpoS directs the core enzyme to genes encoding proteins that help the bacterium survive starvation. ▶▶ *Transcription in bacteria* (section 13.5)

The proteins made in response to starvation are called **starvation proteins**. Some increase peptidoglycan cross-linking and cell wall strength. The starvation protein Dps (DNA-binding protein from starved cells) protects DNA. Proteins called chaperone proteins prevent protein denaturation and renature damaged proteins. Because of these and many other mechanisms, starved cells become harder to kill and more resistant to starvation, damaging temperature changes, oxidative and osmotic damage, and toxic chemicals such as chlorine. These changes are so effective that some members of the bacterial population survive starvation for years. There is even evidence that *Salmonella enterica* serovar Typhimurium (*S. Typhimurium*) and some other bacterial pathogens become more virulent when starved. Clearly, these considerations are of great practical importance in medical and industrial microbiology.

Biofilms

Although ecologists observed as early as the 1940s that more microbes in aquatic environments were found attached to surfaces

(sessile) than were free-floating (planktonic), only relatively recently has this fact gained the attention of microbiologists. These attached microbes are members of complex, slime-encased communities called **biofilms**. Biofilms are ubiquitous in nature, where they are most often seen as layers of slime on rocks or other objects in water or at water-air interfaces (**figure 7.15a**). When they form on the hulls of boats and ships, they cause corrosion, which limits the life of the ships and results in economic losses. Of major concern is the formation of biofilms on medical devices such as hip and knee implants (**figure 7.15b**). These biofilms often cause serious illness and failure of the medical device. Biofilm formation is apparently an ancient ability among the microbes, as evidence for biofilms can be found in the fossil record from about 3.4 billion years ago.

Biofilms can form on virtually any surface, once it has been conditioned by proteins and other molecules present in the environment (**figure 7.16**). Initially microbes attach to the conditioned surface but can readily detach. Eventually they form a slimy matrix made up of various polymers, depending on the microbes in the biofilm. The polymers are collectively called extracellular polymeric substances (EPS), and they include polysaccharides, proteins, glycoproteins, glycolipids, and DNA. The EPS matrix allows the microbes to stick more stably to the surface. As the biofilm thickens and matures, the microbes reproduce and secrete additional polymers.

A mature biofilm is a complex, dynamic community of microorganisms. It exhibits considerable heterogeneity due to differences in the metabolic activity of microbes at various locations within the biofilm; some are persister cells (**figure 7.17**). Biofilm microbes interact in a variety of ways. For instance, the waste products of one microbe may be the energy source for another microbe. The cells also use molecules to communicate with each other, as we describe next. Finally, DNA present in the EPS can be taken up by members of the biofilm community. Thus genes can be transferred from one cell (or species) to another.

Figure 7.16 Biofilm Formation.

MICRO INQUIRY What biomolecules make up the extracellular polymeric matrix, and what functions does the matrix serve?

While in the biofilm, microbes are protected from numerous harmful agents such as UV light and antibiotics. This is due in part to the EPS in which they are embedded (figure 7.17), but it also is due to physiological changes. Indeed, numerous proteins found in biofilm cells are not observed when these cells are free-living, planktonic cells, and vice versa. The resistance of biofilm cells to antimicrobial agents has important consequences. When biofilms form on a medical device such as a hip implant (figure 7.15b), treatment with antibiotics often fails, which can lead to serious systemic infections. The treatment failure is in part due to the presence of persisters in the biofilm. The persisters survive antibiotic treatment and then repopulate the biofilm once treatment ceases. Often the only way to manage patients in this situation is by removing the implant. Another problem with biofilms is that cells are regularly sloughed off (figure 7.16). This can have many consequences. For instance, biofilms in a city's water distribution pipes can serve as a source of contamination after the water leaves a water treatment facility. *Biofilms*

Cell-Cell Communication Within Microbial Populations

For decades, microbiologists tended to think of bacterial populations as collections of individual cells growing and behaving independently. But about 40 years ago, two examples of

bacterial cells using molecular signals to communicate with each other in a density-dependent manner were discovered. This is now referred to as **quorum sensing**; a quorum usually refers to the minimum number of members in an organization, such as a legislative body, needed to conduct business.

Figure 7.17 Biofilm Heterogeneity.

The first example of quorum sensing was observed in the Gram-positive, pathogenic bacterium *Streptococcus pneumoniae*. *S. pneumoniae* cells produce and release a small protein (i.e., a peptide) into the environment. As population size increases, the amount of peptide increases. Eventually the concentration of the peptide is high enough to convert some cells in the population from a noncompetent state to a competent state. In the competent state, cells are able to take up DNA, a process called transformation. In addition, the competent cells release a chemical called bacteriocin that lyses the cells in the population that did not become competent. When the noncompetent cells lyse, they release DNA and virulence factors that allow the competent cells to invade tissues in a host organism, causing serious diseases such as pneumonia and meningitis. ►► **Bacterial transformation (section 16.7)**

Although the quorum-sensing system of *S. pneumoniae* was the first discovered, the term was not coined until years later when the quorum-sensing system of a very different bacterium was discovered. The marine luminescent bacterium *Vibrio fischeri* lives

within the light organ of certain fish and squid. It controls its ability to glow by producing a small, diffusible substance called auto-inducer. The autoinducer molecule was later identified as an ***N*-acylhomoserine lactone (AHL)**. It is now known that many Gram-negative bacteria make AHL molecular signals that vary in length and substitution at the third position of the acyl side chain (**figure 7.18**). In many of these species, AHL is freely diffusible across the plasma membrane. Thus at a low cell density, the diffusion gradient favors movement of AHL from the cytoplasm to the outside of the cell. However, when the cell population increases, the diffusion gradient is reversed so that movement of AHL into the cell is favored. Because the influx of AHL is cell density dependent, it enables individual cells to assess population density. When AHL reaches a threshold level inside the cell, it induces the expression of target genes that regulate a number of functions, depending on the microbe. These functions are most effective only if a large number of microbes are present. For instance, the light produced by one *V. fischeri* cell would be invisible and energetically

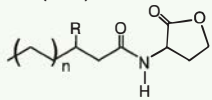

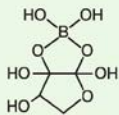

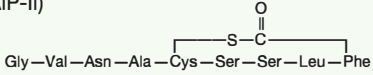

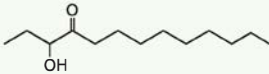

costly, so bioluminescence is inhibited. However, cell densities within the light organ of marine fish and squid reach 10^{10} cells per milliliter. At such densities, light is clearly visible. Thus quorum sensing works to promote bioluminescence at high densities. This provides fish with a flashlight effect. In squid, bioluminescence provides countershading, which protects the squid from predation as it hunts at night. In return, the microbes have a safe and nutrient-enriched habitat (**figure 7.19**).

►► **Quorum sensing by *Vibrio* spp. (section 14.5)**

Since these discoveries, scientists have learned that many of the processes regulated by quorum sensing involve host-microbe interactions such as symbioses and pathogenicity. For instance, the Gram-negative, opportunistic bacterial pathogens *Burkholderia cepacia* and *Pseudomonas aeruginosa* use AHLs to regulate biofilm formation and the expression of virulence factors (**figure 7.18**). These bacteria cause debilitating pneumonia in people who are immunocompromised and are important pathogens in cystic fibrosis patients.

Like *S. pneumoniae*, other Gram-positive bacteria communicate using short peptides called oligopeptides. Examples include *Enterococcus faecalis*, whose oligopeptide signal is used to determine the best time to conjugate (transfer genes). Oligopeptide communication by *Staphylococcus aureus* and *B. subtilis* is also used to trigger the uptake of DNA from the environment.

The discovery of additional molecular signals made by a variety of microbes underscores the importance of cell-cell communication in regulating cellular processes. For instance, while only Gram-negative bacteria are known to make AHLs, both Gram-negative and Gram-positive bacteria make autoinducer-2 (AI-2). The soil microbe *Streptomyces*

| Signal and Structure | Representative Organism | Function Regulated |

^a Other bacteria make a form of AI-2 that lacks boron.

Figure 7.18 Representative Cell-Cell Communication Molecules.

(a) *E. scolopes*, the bobtail squid

(b) Light organ

Figure 7.19 *Euprymna scolopes*. (a) *E. scolopes* is a warm-water squid that remains buried in sand during the day and feeds at night. (b) When feeding, it uses its light organ (boxed, located on its ventral surface) to provide camouflage by projecting light downward. Thus the outline of the squid appears as bright as the water's surface to potential predators looking up through the water column. The light organ is colonized by a large number of *Vibrio fischeri* cells, so autoinducer accumulates to a threshold concentration, triggering light production.

griseus produces a γ -butyrolactone known as A-factor. This small molecule regulates both morphological differentiation and the production of the antibiotic streptomycin. Eukaryotic microbes also rely on cell-cell communication to coordinate key activities within a population. For example, the pathogenic fungus *Candida albicans* secretes farnesoic acid to govern morphology and virulence (figure 7.18).

These examples of cell-cell communication demonstrate what might be called multicellular behavior in that many individual cells communicate and coordinate their activities to act as a unit. Other examples of such complex behavior are pattern formation in colonies (p. 159) and fruiting body formation in the myxobacteria. ►► Order Myxococcales (section 22.4)

Interdomain Communication

The quorum-sensing phenomenon allows members of the same species to communicate with each other. As we describe in chapter 14, this system also allows different *Vibrio* species to communicate. Thus the *Vibrio* system is an example of interspecies communication. Even more dramatic examples of interspecies communication exist, including bacteria and plants “talking” to each other. ►► Quorum sensing by *Vibrio* spp. (section 14.5)

One of the best-studied examples of interdomain communication is observed when members of the genus *Rhizobium* interact with a leguminous plant. A successful interaction ends with the invasion of a plant root by the rhizobial cells. Once inside, the rhizobia differentiate, becoming nitrogen-fixing forms called

bacteroids. Nitrogen-fixation requires considerable energy, and the plant assists the bacterium by helping it meet its energy needs. In return, the bacterium supplies the plant with nitrogen in the form of amino acids.

A successful interaction is initiated when the bacterium and plant “talk” to each other using chemicals they secrete. The plant releases molecules called flavonoids, which are taken up by the bacterium and bind to a bacterial protein called NodD. This activates the production of chemicals by the bacterium called Nod factors. Some Nod factors affect the outer cells of root hairs. Ultimately this causes the root hairs to curl, entrapping the bacteria. Other Nod factors trigger formation of an infection tube, through which the bacteria enter the plant. Thus by “speaking” to each other, both the plant and bacterium form a relationship that is beneficial to both.

7.5 Laboratory Culture of Cellular Microbes

After reading this section, you should be able to:

- Describe the importance of culturing microbes to the study of microorganisms
- Distinguish defined (synthetic) media from complex media and the uses of liquid from solid growth media
- List the characteristics of agar that make it a particularly useful solidifying agent
- Compare and contrast supportive, enriched, selective, and differential media, listing examples of each and describing how each is used
- Discuss the use of enrichment cultures in isolating microbes
- Differentiate the streak-plate, spread-plate, and pour-plate methods for isolating pure cultures
- Use the terms commonly used by microbiologists to describe colony morphology

The complexity of natural microbial habitats has for decades proven to be a significant hurdle for microbiologists to leap. For that reason, microbiology research has depended largely on the ability to grow and maintain microorganisms in the laboratory. Unfortunately, it is estimated that only 1 to 5% of all microbes are currently culturable. Recently nonculture-based alternatives have become available. Yet even with these techniques, an important goal is to eventually isolate microbes from their normal habitat. Thus culturing microbes continues to be an important tool used by microbiologists. ►► *Culturing techniques (section 29.1)*

Culture Media

Culturing microbes is possible only if suitable culture media are available. A **culture medium** is a solid or liquid preparation used to grow, transport, and store microorganisms. To be effective, the medium must contain all the nutrients the microorganism requires for growth. Specialized media are essential in the isolation and identification of microorganisms, the testing of antibiotic sensitivities, water and food analysis, industrial microbiology, and other activities. Although all microorganisms need sources of energy and macro- and micro-nutrients, the precise composition of a satisfactory medium depends on the species being cultivated due to the great variety of nutritional requirements. Knowledge of a microorganism's normal habitat often is useful in selecting an appropriate culture medium because its nutrient requirements reflect its natural surroundings. Frequently a medium is used to select and grow specific microorganisms or to help identify a particular species. Media can also be specifically designed to facilitate the growth of one type of microbe present in a sample from nature (p. 157). ►► *Nutrient uptake (section 3.3)*

Culture media can be classified based on several parameters: the chemical constituents from which they are made, their

Table 7.4 Types of Media

| Basis for Classification | Types |
|--------------------------|---|
| Chemical composition | Defined (synthetic), complex |
| Physical nature | Liquid, semisolid, solid |
| Function | Supportive (general purpose), enriched, selective, differential |

physical nature, and their function (**table 7.4**). The types of media defined by these parameters are described here.

Chemical and Physical Types of Culture Media

A medium in which all chemical components are known is a **defined** or **synthetic medium**. It can be in a liquid form (broth) or solidified by an agent such as agar. Defined media are often used to culture photoautotrophs such as cyanobacteria and photosynthetic protists. These microbes use CO₂ as a carbon source and light as an energy source. Thus they can be grown on media containing sodium carbonate or bicarbonate (sources of CO₂), nitrate or ammonia as a nitrogen source, sulfate, phosphate, and other minerals (**table 7.5**). Many chemorganoheterotrophs also can be grown in defined media. These organisms use reduced organic molecules as carbon and energy sources. Thus a medium with glucose as a carbon source and an ammonium salt as a nitrogen source will support their growth. Not all defined media are as simple as the examples in table 7.5; some are constructed from dozens of components. Defined media are used widely in research, as it is often desirable to know exactly what the microorganism is metabolizing.

Media that contain some ingredients of unknown chemical composition are **complex media**. They are very useful because a single complex medium may be able to meet all the nutritional requirements of many different microorganisms. In addition, complex media often are needed because the nutritional requirements of a particular microorganism are unknown, and thus a defined medium cannot be constructed. Complex media are also used to culture fastidious microbes, microbes with complicated nutritional or cultural requirements.

Most complex media contain undefined components such as peptones, meat extract, and yeast extract. Peptones are protein hydrolysates prepared by partial proteolytic digestion of meat, casein, soya meal, gelatin, and other protein sources. They serve as sources of carbon, energy, and nitrogen. Beef extract and yeast extract are aqueous extracts of lean beef and brewer's yeast, respectively. Beef extract contains amino acids, peptides, nucleotides, organic acids, vitamins, and minerals. Yeast extract is an excellent source of B vitamins as well as nitrogen and carbon compounds. Three commonly used complex media are nutrient broth, tryptic soy broth, and MacConkey agar (**table 7.6**).

| | | | | Sodium chloride | 5.0 |
| | | | | Neutral red | 0.03 |
| MacConkey Agar | | | | Crystal violet | 0.001 |
| | | | | Agar | 13.5 |

Both liquid and solidified media are routinely used in laboratories. However, solidified media are particularly important because they can be used to isolate different microbes from each other to establish pure cultures. As we discuss in chapter 1, this is a critical step in Koch's postulates when demonstrating the relationship between a microbe and a disease. **Agar** is the most commonly used solidifying agent. It is a sulfated polymer composed mainly of D-galactose, 3,6-anhydro-L-galactose, and D-glucuronic acid. It

usually is extracted from red algae. Agar is well suited as a solidifying agent for several reasons. One is that it melts at about 90°C but, once melted, does not harden until it reaches about 45°C. Thus after being melted in boiling water, it can be cooled to a temperature that is tolerated by human hands as well as microbes. Furthermore, microbes growing on agar medium can be incubated at a wide range of temperatures. Finally, agar is an excellent hardening agent because most microorganisms cannot degrade it.

Functional Types of Media

Media such as tryptic soy broth and tryptic soy agar are called general purpose or **supportive media** because they sustain the growth of many microorganisms. Blood and other nutrients may be added to supportive media to encourage the growth of fastidious microbes. These fortified media (e.g., blood agar) are called **enriched media** (figure 7.20).

Selective media allow the growth of particular microorganisms, while inhibiting the growth of others (table 7.7). For

instance, Gram-negative bacteria will grow on media containing bile salts or dyes such as basic fuchsin and crystal violet; however, the growth of Gram-positive bacteria is inhibited. Eosin methylene blue agar and MacConkey agar (table 7.7) are widely used for the detection of *E. coli* and related bacteria in water supplies and elsewhere. These media suppress the growth of Gram-positive bacteria.

Differential media are media that distinguish among different groups of microbes and even permit tentative identification

(a) Blood agar

(b) Chocolate agar

Figure 7.20 Enriched Media. (a) Blood agar culture of bacteria from the human throat. (b) Chocolate agar is used to grow fastidious organisms such as *Neisseria gonorrhoeae*. The brown color is the result of heating red blood cells and lysing them before adding them to the medium. It is called chocolate agar because of its chocolate brown color.

| Table 7.7 Mechanisms of Action of Selective and Differential Media | | |
|--|----------------------------|--|
| Medium | Functional Type | Mechanism of Action |
| Blood agar | Enriched and differential | Blood agar supports the growth of many fastidious bacteria. These can be differentiated based on their ability to produce hemolysins—proteins that lyse red blood cells. Hemolysis appears as a clear zone (β-hemolysis) or greenish halo around the colony (α-hemolysis) (e.g., <i>Streptococcus pyogenes</i> , a β-hemolytic streptococcus). |
| Eosin methylene blue (EMB) agar | Selective and differential | Two dyes, eosin Y and methylene blue, inhibit the growth of Gram-positive bacteria. They also react with acidic products released by certain Gram-negative bacteria when they use lactose or sucrose as carbon and energy sources. Colonies of Gram-negative bacteria that produce large amounts of acidic products have a green, metallic sheen (e.g., fecal bacteria such as <i>E. coli</i>). |
| MacConkey (MAC) agar | Selective and differential | The selective components in MAC are bile salts and crystal violet, which inhibit the growth of Gram-positive bacteria. The presence of lactose and neutral red, a pH indicator, allows the differentiation of Gram-negative bacteria based on the products released when they use lactose as a carbon and energy source. The colonies of those that release acidic products are red (e.g., <i>E. coli</i>). |
| Mannitol salt agar | Selective and differential | A concentration of 7.5% NaCl selects for the growth of staphylococci. Pathogenic staphylococci can be differentiated based on the release of acidic products when they use mannitol as a carbon and energy source. The acidic products cause a pH indicator (phenol red) in the medium to turn yellow (e.g., <i>Staphylococcus aureus</i>). |

of microorganisms based on their biological characteristics. Blood agar is both a differential medium and an enriched one. It distinguishes between hemolytic and nonhemolytic bacteria. Some hemolytic bacteria (e.g., many streptococci and staphylococci isolated from throats) produce clear zones around their colonies because of red blood cell destruction (figure 7.20a). Blood agar is an enriched growth medium in that blood (usually sheep blood) provides protein, carbohydrate, lipid, iron, and a number of growth factors and vitamins necessary for the cultivation of fastidious organisms. MacConkey agar is both differential and selective. Because it contains lactose and neutral red dye, bacteria that catabolize lactose by fermenting it release acidic waste products that make colonies appear pink to red in color. These are easily distinguished from colonies of bacteria that do not ferment lactose.

Cultivation of Aerobes and Anaerobes

Because aerobes need O_2 and anaerobes are killed by it, radically different approaches must be used when they are cultivated. When large volumes of aerobic microorganisms are cultured, either they must be shaken to aerate the culture medium or sterile air must be pumped through the culture vessel. Without aeration, the low solubility of O_2 in liquid would prevent them from obtaining an adequate supply.

Precisely the opposite problem arises with anaerobes: all O_2 must be excluded. This is accomplished in several ways. (1) Anaerobic media containing reducing agents such as thioglycollate or cysteine may be used. The medium is boiled during preparation to dissolve its components and drive off oxygen. The reducing agents eliminate any residual dissolved O_2 in the medium so that anaerobes can grow beneath its surface. (2) Oxygen also may be eliminated from an enclosed work area, often called an anaerobic chamber or anaerobic workstation. Most of the air is removed with a vacuum pump followed by purges with nitrogen gas (figure 7.21). A gas mix containing hydrogen is then introduced into the workstation. In the presence of a palladium catalyst, the hydrogen and last remaining molecules of O_2 react to form water, creating an anoxic environment. Often CO_2 is added to the chamber because many anaerobes require a small amount of CO_2 for best growth. (3) One of the most popular ways of culturing small numbers of anaerobes is by use of a GasPak jar, which also uses hydrogen and a palladium catalyst to remove O_2 (figure 7.22). (4) A similar approach uses plastic bags or pouches containing calcium carbonate and a catalyst, which produce an anoxic, carbon dioxide-rich atmosphere.

Enrichment and Isolation of Pure Cultures

In natural habitats, microorganisms usually grow in complex, mixed populations with many species. This presents a problem for microbiologists because a single type of microorganism cannot be studied adequately in a mixed culture. One needs a **pure** or **axenic culture**, a population of cells arising from a single cell, to characterize an individual species. When isolating microbes from soil or aquatic habitats, microbiologists often begin by setting up conditions that favor growth of the desired microbes; that is, they enrich for the microbes of interest. This is followed by using other methods to obtain an axenic culture arising from a single cell.

Figure 7.21 An Anaerobic Workstation and Incubator. This system contains an oxygen-free work area and an incubator. The interchange compartment on the right of the work area allows materials to be transferred inside without exposing the interior to oxygen. The anoxic atmosphere is maintained largely with a vacuum pump and nitrogen purges. The remaining oxygen is removed by a palladium catalyst and hydrogen. The oxygen reacts with hydrogen to form water, which is absorbed by a desiccant.

Figure 7.22 The GasPak Anaerobic System. Hydrogen and carbon dioxide are generated by a GasPak envelope. The palladium catalyst in the chamber lid catalyzes the formation of water from hydrogen and oxygen, thereby removing oxygen from the sealed chamber.

Enrichment Cultures

The **enrichment culture** technique is a powerful tool that has been used by microbiologists since it was first developed by Sergei Winogradsky and Martinus Beijerinck in the late 1800s. They used enrichment cultures to isolate numerous bacteria with interesting metabolic capabilities such as nitrogen fixation and the use of inorganic molecules (e.g., ammonia) as energy sources. To enrich for these organisms, they considered three factors: (1) a suitable source of the microbes, (2) nutrients that should and should not be included in the culture medium, and (3) environmental conditions provided during the incubation period.

Consider the following. Suppose you wanted to isolate an oil-degrading bacterium and study it in pure culture. A logical source of the bacterium (i.e., an inoculum) would be soil contaminated with oil. The assumption is that such a source would have exposed the indigenous bacteria to oil and selected for those able to use oil as a sole source of energy and carbon. To select for the oil-degrading bacteria, a medium would be used that contained inorganic nitrogen, sulfur, and phosphorus sources but no source of carbon and energy other than the types of molecules typically found in oil. Finally, a temperature, pH, and oxygen level similar to that of the soil environment would be used during incubation.

Despite its utility, the enrichment culture technique is not without problems. It is sometimes difficult to create the proper selective conditions to successfully isolate the desired organisms. Furthermore, even if microbes are successfully cultivated, they may not adequately represent the population as a whole at a sampling site. Generally, enrichment cultures yield the organisms that grow fastest, and these may not be the predominant organisms in the habitat. Finally, enrichment cultures are not pure cultures. They usually contain more than one species having similar characteristics. To obtain a pure culture, one of the methods described next must be used.

Streak Plate

The streak-plate method and similar methods for isolating pure cultures were developed by the German bacteriologist Robert Koch. He used these techniques in a set of steps that now bear his name: Koch's postulates. As we describe in chapter 1, Koch's

Note: This method only works if the spreading tool (usually an inoculating loop) is resterilized after each of steps 1–4.

(a) Steps in a streak plate

(b)

Figure 7.23 Streak-Plate Technique. A typical streaking pattern is shown (a), as well as an example of a streak plate (b).

postulates are used to establish that a microbe is the causative agent of a particular disease. The use of these methods transformed microbiology, and within 20 years of their development, most pathogens responsible for major bacterial diseases had been isolated and identified. Koch reasoned that if cells from a mixture of microbes could be spatially isolated from each other, each cell would give rise to a completely separate **colony**—a macroscopically visible cluster of microorganisms in or on a solid medium. Because each colony arises from a single cell, each colony represents a pure culture.

One method for separating cells is the **streak plate**. In this technique, cells are transferred to the edge of an agar plate with an inoculating loop or swab and then streaked out over the surface in one of several patterns (**figure 7.23**). After the first sector is streaked, the inoculating loop is sterilized and an inoculum for the second sector is obtained from the first sector. A similar process is followed for streaking the third sector, except that the inoculum is from the second sector. Thus this is essentially a dilution process. Eventually very few cells will be on the loop, and single cells will drop from it as it is rubbed along the agar surface. These develop into separate colonies.

Spread Plate and Pour Plate

Spread-plate and pour-plate techniques are similar in that they both dilute a sample of cells before separating them spatially. They differ in that the spread plate spreads the cells on the surface of the agar, whereas the pour plate embeds the cells within the agar. Both methods can be used to determine the number of microorganisms in a sample (p. 165).

For the **spread plate**, a small volume of a diluted mixture containing around 25 to 250 cells is transferred to the center of an agar plate and spread evenly over the surface with a sterile bent rod (**figure 7.24**). The dispersed cells develop into isolated colonies.

The **pour plate** is extensively used with bacteria, archaea, and fungi. It is particularly useful when sampling a heterogeneous population of microbes, some of which might produce colonies that spread over an agar surface if isolated by the streak-plate or spread-plate methods. In the pour-plate method, the original

sample is diluted several times to reduce the microbial population sufficiently

to obtain separate colonies when plating (**figure 7.25**).

Then small volumes of several diluted samples are mixed with liquid agar that has been cooled to about 45°C, and the mixtures are poured immediately into sterile culture dishes. Most microbes

survive a brief exposure to the warm agar. Each cell becomes fixed in place to form an individual colony after the agar hardens.

Although the preparation of serial dilutions is the bane of many microbiology students, it has many applications other than the spread-plate and pour-plate methods. The numbers of cells in a solution can be diluted to the point where no cells are present in the dilution tube. If replicate dilutions are prepared and the number of tubes yielding growth determined, then the number of viable cells in the sample can be estimated by the most probable number method (MPN; see figure 29.3). Similarly, the number of viruses in a solution or the number of antibodies in a blood sample can be determined by first diluting the sample and then testing for the presence of viruses or antibodies. ◀◀ *Cultivation and enumeration of viruses* (section 6.5) ▶▶ *Culturing techniques* (section 29.1); *Antibodies* (section 34.7)

Microbial Growth on Solid Media

Colony development on agar surfaces aids microbiologists in identifying microorganisms because individual species often form colonies of characteristic size and appearance (figure 7.26). When a mixed population has been plated properly, it sometimes is possible to identify the desired colony based on its overall appearance and use it to obtain a pure culture.

It is obvious from the colonies pictured in figure 7.26 that bacteria growing on solid surfaces such as agar can form quite complex and intricate colony shapes. These patterns and colony size depend on many factors,

Figure 7.25 Pour-Plate Technique.

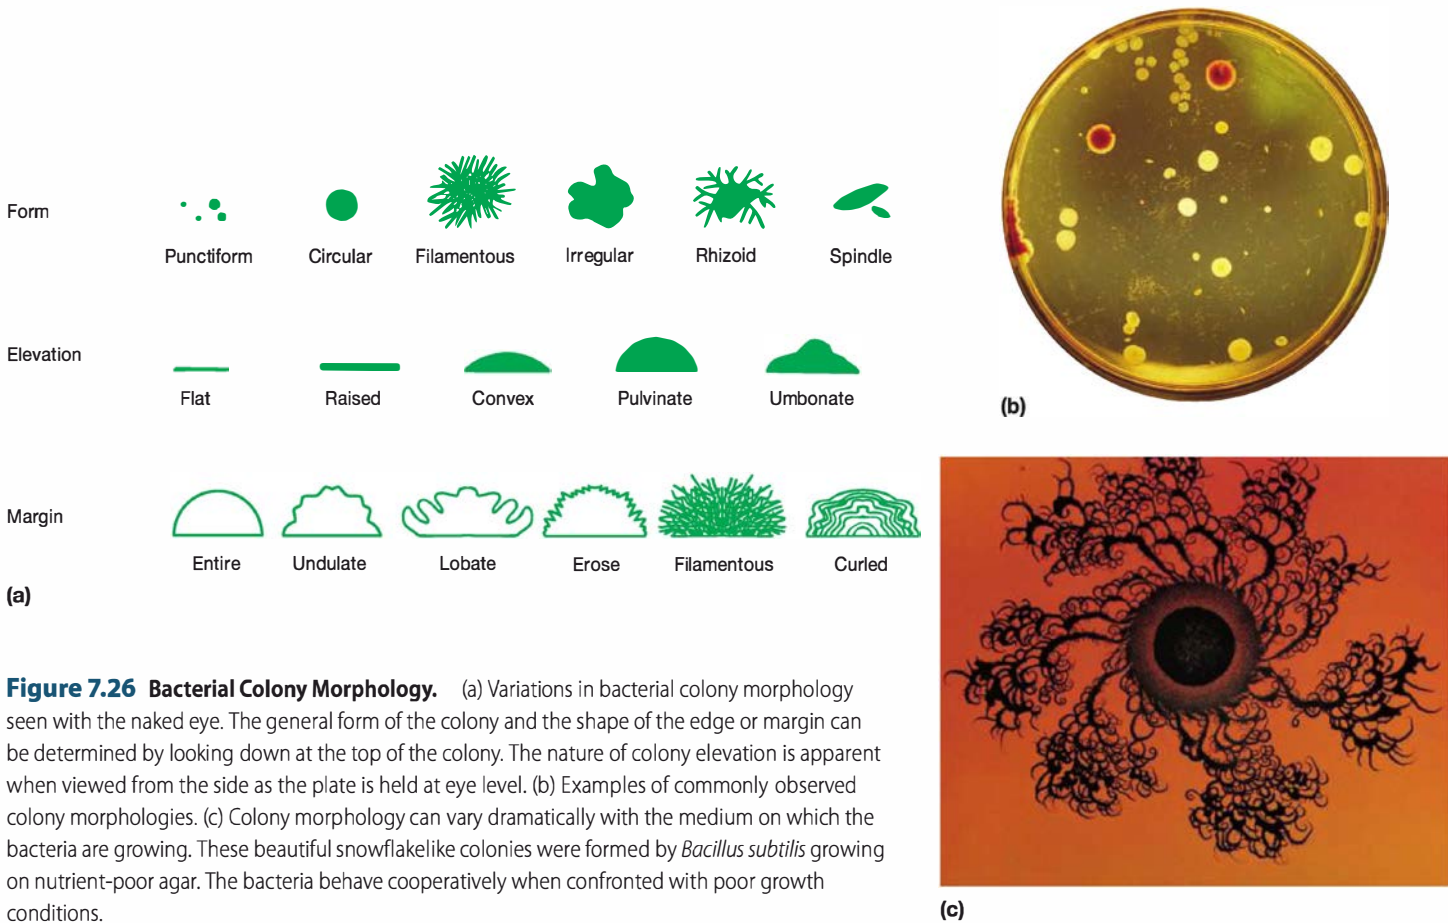

Figure 7.26 Bacterial Colony Morphology. (a) Variations in bacterial colony morphology seen with the naked eye. The general form of the colony and the shape of the edge or margin can be determined by looking down at the top of the colony. The nature of colony elevation is apparent when viewed from the side as the plate is held at eye level. (b) Examples of commonly observed colony morphologies. (c) Colony morphology can vary dramatically with the medium on which the bacteria are growing. These beautiful snowflakelike colonies were formed by *Bacillus subtilis* growing on nutrient-poor agar. The bacteria behave cooperatively when confronted with poor growth conditions.

including nutrient diffusion and availability, bacterial chemotaxis, the presence of liquid on the surface, and hardness of the agar. Cell-cell communication is important as well. Much research is currently focused on understanding the formation of bacterial colonies.

2. What are peptones, yeast extract, beef extract, thioglycollate, and agar? Why are they used in media?
3. Describe four ways in which anaerobes may be cultured.
4. What are pure cultures and why are they important? How are spread plates, streak plates, and pour plates prepared?
5. It is known that microbial growth varies within a colony. What factors might cause these variations?
6. How might an enrichment culture be used to isolate bacteria capable of growing photoautotrophically from a mixed microbial assemblage?

7.6 Growth Curve: When One Becomes Two and Two Become Four...

After reading this section, you should be able to:

- Describe the four phases of a microbial growth curve observed when microbes are grown in a batch culture
- Describe three hypotheses proposed to account for the decline in cell numbers during the death phase of a growth curve
- Predict how the presence of viable but nonculturable cells in food or water systems might impact public health
- Correlate changes in nutrient concentrations in natural environments with the four phases of a microbial growth curve
- Relate growth rate constant to generation (doubling) time and suggest how these values might be used by microbiologists doing basic research or working in industrial settings

In section 7.2, we commented on the changes in bacterial cell size that accompany its preparation for cell division. This is one type of growth of concern to microbiologists. However, microbiologists are more frequently concerned with the increase in population size that follows cell division. Therefore the term growth is also used to refer to growth in the size of a population.

Figure 7.27 Microbial Growth Curve in a Closed System. The four phases of the growth curve are identified on the curve.

MICRO INQUIRY Identify the regions of the growth curve in which (1) nutrients are rapidly declining and (2) wastes accumulate.

Population growth is often studied by analyzing the growth of microbes in liquid (broth) culture. When microorganisms are cultivated in broth, they usually are grown in a **batch culture**; that is, they are incubated in a closed culture vessel with a single batch of medium. Because no fresh medium is provided during incubation, nutrient concentrations decline and concentrations of wastes increase. Population growth of microbes reproducing by binary fission in a batch culture can be plotted as the logarithm of the number of viable cells versus the incubation time. The resulting curve has four distinct phases (**figure 7.27**), which we examine in this section. Although this is “life in the lab,” microbes do encounter conditions in their natural environments that mimic what occurs in a batch culture. Furthermore, humans routinely create artificial environments for microbes (e.g., the fermentation vessel in a pharmaceutical plant) that are batch cultures. Therefore understanding the growth curve is of paramount importance.

Lag Phase

When microorganisms are introduced into fresh culture medium, usually no immediate increase in cell number occurs. This period is called the **lag phase**. It is not a time of inactivity; rather cells are synthesizing new components. This can be necessary for a variety of reasons. The cells may be old and depleted of ATP, essential cofactors, and ribosomes; these must be synthesized before growth can begin. The medium may be different from the one the microorganism was growing in previously. In this case, new enzymes are needed to use different nutrients. Possibly the microorganisms have been injured and require time to recover. Eventually however, the cells begin to replicate

their DNA, increase in mass, and divide. As a result, the number of cells in the population begins to increase.

Exponential Phase

During the **exponential (log) phase**, microorganisms are growing and dividing at the maximal rate possible given their genetic potential, the nature of the medium, and the environmental conditions. Their rate of growth is constant during the exponential phase; that is, they are completing the cell cycle and doubling in number at regular intervals (**figure 7.27**). The population is most uniform in terms of chemical and physiological properties during this phase; therefore exponential phase cultures are usually used in biochemical and physiological studies. The growth rate during log phase depends on several factors, including nutrient availability. When microbial growth is limited by the low concentration of a required nutrient, the final net growth or yield of cells increases with the initial amount of the limiting nutrient present (**figure 7.28a**). The rate of growth also increases with nutrient concentration (**figure 7.28b**) but in a hyperbolic manner much like that seen with many enzymes (*see figure 10.17*). The shape of the curve is thought to reflect the rate of nutrient uptake by microbial transport proteins. At sufficiently high nutrient levels, the transport systems are saturated, and the growth rate does not rise further with increasing nutrient concentration.

◀◀ *Uptake of nutrients (section 3.3)*

Stationary Phase

In a closed system such as a batch culture, population growth eventually ceases and the growth curve becomes horizontal (**figure 7.27**). This **stationary phase** is attained by most bacteria at a population level of around 10^9 cells per milliliter. Protist cultures often have maximum concentrations of about 10^6 cells per milliliter. Final population size depends on nutrient availability and other factors, as well as the type of microorganism. In stationary phase, the total number of viable microorganisms remains constant. This may result from a

Figure 7.28 Nutrient Concentration and Growth. (a) The effect of changes in limiting nutrient concentration on total microbial yield. At sufficiently high concentrations, total growth will plateau. (b) The effect on growth rate.

balance between cell division and cell death, or the population may simply cease to divide but remain metabolically active.

One obvious reason microorganisms enter the stationary phase is nutrient limitation; if an essential nutrient is severely depleted, population growth will slow and eventually stop. Thus the stationary phase is similar to growth in oligotrophic environments, as described in section 7.4. Interestingly, many of the survival strategies used in oligotrophic environments are also used by populations in the stationary phase of the growth cycle.

Microbes enter the stationary phase for other reasons besides nutrient limitation. Aerobic organisms often are limited by O_2 availability. Oxygen is not very soluble and may be depleted so quickly that only the surface of a culture will have an O_2 concentration adequate for growth. Population growth also may cease due to the accumulation of toxic waste products. This seems to limit the growth of many cultures growing in the absence of O_2 . For example, streptococci can produce so much lactic acid and other organic acids from sugar fermentation that their medium becomes acidic and growth is inhibited. Finally, some evidence exists that growth may cease when a critical population level is reached. Thus entrance into the stationary phase may result from several factors operating in concert.

Senescence and Death

Cells growing in batch culture cannot remain in stationary phase indefinitely. Eventually they enter a phase that for many years was described simply as the “death phase” (figure 7.27). During this phase, the number of viable cells often declines exponentially, with cells dying at a constant rate. It was assumed that detrimental environmental changes such as nutrient deprivation and the buildup of toxic wastes caused irreparable harm to the cells. That is, even when bacterial cells were transferred to fresh medium, no cellular growth was observed. Because loss of viability was often not accompanied by a loss in total cell number, it was assumed that cells died but did not lyse.

This view is currently being debated. There are two alternative hypotheses. Some microbiologists think the cells are only temporarily unable to grow, at least under the laboratory conditions used. This phenomenon, in which the cells are called **viable but nonculturable (VBNC)**, is thought to be the result of a genetic response triggered in starving, stationary phase cells. Once the appropriate conditions are available (e.g., a change in temperature or passage through an animal), VBNC microbes resume growth. VBNC microorganisms could pose a public health threat, as many assays that test for food and drinking water safety are culture based.

The second alternative to a simple death phase is **programmed cell death**. In contrast to the VBNC hypothesis whereby cells are genetically programmed to survive, programmed cell death predicts that a fraction of the microbial population is genetically programmed to die after growth ceases. In this case, some cells die and the nutrients they leak enable the eventual growth of those cells in the population that did not initiate cell death. The dying cells are thus “altruistic”—they sacrifice themselves for the benefit of the larger population.

The view that the death phase is best described as an exponential decline in viability is also being questioned. Long-term growth

Figure 7.29 Prolonged Decline in Cell Numbers. Instead of a distinct death phase, successive waves of genetically distinct subpopulations of microbes better able to use the released nutrients and accumulated toxins survive. Each successive solid or dashed blue curve represents the growth of a new subpopulation.

experiments reveal that some microbes have a very gradual decline in the number of culturable cells. This decline can last months to years (figure 7.29). During this time, the bacterial population continually evolves so that actively reproducing cells are those best able to use the nutrients released by their dying brethren and best able to tolerate the accumulated toxins. This dynamic process is marked by successive waves of genetically distinct variants. Thus natural selection can be witnessed within a single culture vessel.

Mathematics of Growth

Knowledge of microbial growth rates during the exponential phase is indispensable to microbiologists. Growth rate studies contribute to basic physiological and ecological research, and are applied in industry. The quantitative aspects of exponential phase growth discussed here apply to microorganisms that divide by binary fission.

During the exponential phase, each microorganism is dividing at constant intervals. Thus the population doubles in number during a specific length of time called the **generation (doubling) time (g)**. This can be illustrated with a simple example. Suppose that a culture tube is inoculated with one cell that divides every 20 minutes (table 7.8). The population will be 2 cells after 20 minutes,

| Table 7.8 An Example of Exponential Growth | | | | |
|--|-----------------|------------|---|-----------------|
| Time ¹ | Division Number | 2^n | Population ² ($N_0 \times 2^n$) | $\log_{10} N_t$ |
| 0 | 0 | $2^0 = 1$ | 1 | 0.000 |
| 20 | 1 | $2^1 = 2$ | 2 | 0.301 |
| 40 | 2 | $2^2 = 4$ | 4 | 0.602 |
| 60 | 3 | $2^3 = 8$ | 8 | 0.903 |
| 80 | 4 | $2^4 = 16$ | 16 | 1.204 |

¹ The hypothetical culture begins with one cell having a 20-minute generation time.

² Number of cells in the culture.

Figure 7.30 Exponential Microbial Growth. Four generations of growth are plotted directly (—) and in the logarithmic form (—). The growth curve is exponential, as shown by the linearity of the log plot.

4 cells after 40 minutes, and so forth. Because the population is doubling every generation, the increase in population is always 2^n where n is the number of generations. The resulting population increase is exponential; that is, logarithmic (figure 7.30).

The mathematics of growth during the exponential phase are illustrated in figure 7.31, which shows the calculation of two

important values. The **growth rate constant (k)** is the number of generations per unit time and is often expressed as generations per hour. It can be used to calculate the generation time. As can be seen in figure 7.31, the generation time is simply the reciprocal of the growth rate constant. The generation time can also be determined directly from a semilogarithmic plot of growth curve data (figure 7.32). Once this is done, it can be used to calculate the growth rate constant.

Generation times vary markedly with the microbial species and environmental conditions. They range from less than 10 minutes (0.17 hours) to several days (table 7.9). Generation times in nature are usually much longer than in culture.

Retrieve, Infer, Apply

1. Define microbial growth.
2. Describe the four phases of the growth curve and discuss the causes of each.
3. Why would cells that are vigorously growing when inoculated into fresh culture medium have a shorter lag phase than those that have been stored in a refrigerator?
4. Contrast and compare the viable but nonculturable status of microbes with that of programmed cell death as a means of responding to prolonged starvation.
5. Calculate the growth rate constant and generation time of a culture that increases in the exponential phase from 5×10^2 to 1×10^8 in 12 hours.
6. Suppose the generation time of a bacterium is 90 minutes and the number of cells in a culture is 10^3 cells at the start of the log phase. How many bacteria will there be after 8 hours of exponential growth?

Calculation of the growth rate constant

Let N_0 = the initial population number

N_t = the population at time t

n = the number of generations in time t

For populations reproducing by binary fission

$$N_t = N_0 \times 2^n$$

Solving for n , the number of generations, where all logarithms are to the base 10,

$$\log N_t = \log N_0 + n \cdot \log 2, \text{ and}$$

$$n = \frac{\log N_t - \log N_0}{\log 2} = \frac{\log N_t - \log N_0}{0.301}$$

The growth rate constant (k) is the number of generations per unit time ($\frac{n}{t}$). Thus

$$k = \frac{n}{t} = \frac{\log N_t - \log N_0}{0.301t}$$

Calculation of generation (doubling) time

If a population doubles, then

$$N_t = 2N_0$$

Substitute $2N_0$ into the growth rate constant equation and solve for

$$k = \frac{\log (2N_0) - \log N_0}{0.301g} = \frac{\log 2 + \log N_0 - \log N_0}{0.301g}$$

$$k = \frac{1}{g}$$

The generation time is the reciprocal of the growth rate constant.

$$g = \frac{1}{k}$$

Figure 7.31 Calculation of the Growth Rate Constant and Generation Time. The calculations are only valid for the exponential phase of growth, when the growth rate is constant.

Figure 7.32 Generation Time Determination. The generation time can be determined from a microbial growth curve. The population data are plotted with the logarithmic axis used for the number of cells. The time to double the population number is then read directly from the plot. The log of the population number can also be plotted against time on regular axes.

7.7 Measurement of Microbial Population Size

After reading this section, you should be able to:

- Evaluate direct cell counts, viable counting methods, and cell mass measurements for determining population size
- Explain why plate count results are expressed in terms of colony forming units (CFU)
- Design appropriate approaches for measuring the population size of different types of samples

There are many ways to measure microbial growth to determine growth rate constants and generation times. Either population number or mass may be followed because growth leads to increases in both. Here the most commonly employed techniques

Table 7.9 Examples of Generation Times¹

| Microorganism | Incubation Temperature (°C) | Generation Time (Hours) |
|-----------------------------------|-----------------------------|-------------------------|
| Bacteria | | |
| <i>Escherichia coli</i> | 40 | 0.35 |
| <i>Bacillus subtilis</i> | 40 | 0.43 |
| <i>Staphylococcus aureus</i> | 37 | 0.47 |
| <i>Pseudomonas aeruginosa</i> | 37 | 0.58 |
| <i>Clostridium botulinum</i> | 37 | 0.58 |
| <i>Mycobacterium tuberculosis</i> | 37 | ≈12 |
| <i>Treponema pallidum</i> | 37 | 33 |

| Fungi | | |
| <i>Saccharomyces cerevisiae</i> | 30 | 2 |
| <i>Monilia fructicola</i> | 25 | 30 |

¹ Generation times differ depending on the growth medium and environmental conditions used.

for determining population size are examined and the advantages and disadvantages of each noted. No single technique is always best; the most appropriate approach depends on the experimental situation.

Direct Measurement of Cell Numbers

The most obvious way to determine microbial numbers is by **direct counts** using a counting chamber (e.g., Petroff-Hausser counting chamber and hemacytometers). This approach is easy, inexpensive, and relatively quick. It also gives information about the size and morphology of microorganisms. Counting chambers consist of specially designed slides and coverslips; the space between the slide and coverslip creates a chamber of known depth. On the bottom of the chamber is an etched grid that facilitates counting the cells (**figure 7.33**). The number of microorganisms in a sample can be calculated by taking into

Figure 7.33 The Petroff-Hausser Counting Chamber. (a) Side view of the chamber showing the cover glass and the space beneath it that holds a bacterial suspension. (b) A top view of the chamber. The grid is located in the center of the slide. (c) An enlarged view of the grid. The bacteria in several of the central squares are counted, usually at $\times 400$ to $\times 500$ magnification. The average number of bacteria in these squares is used to calculate the concentration of cells in the original sample.

account the chamber's volume and any dilutions made of the sample before counting. One disadvantage of using counting chambers is that to determine population size accurately, the microbial population must be relatively large and evenly dispersed because only a small volume of the population is sampled.

The number of bacteria in aquatic samples is frequently determined from direct counts after the bacteria have been trapped on membrane filters. In the membrane filter technique, the sample is first filtered through a black polycarbonate membrane filter. Then the bacteria are stained with nucleic acid fluorescent stains such as acridine orange or DAPI and observed microscopically (see figure 29.5). Alternatively, fluorescently labeled dyes that are specific for members of a given taxon may be used. The stained

cells are easily observed against the black background of the membrane filter and can be counted when viewed with an epifluorescence microscope. Direct cell counts of environmental samples almost invariably result in higher cell densities than do methods that rely on culturing. This is because only a small percentage (about 1%) of cells growing in nature can be cultivated in the laboratory. **◀◀ Fluorescence microscopes (section 2.2)**

Flow cytometry is increasingly being used to directly count microbes and to gain detailed information about them. A flow cytometer creates a stream of cells so narrow that one cell at a time passes through a beam of laser light. As each cell passes through the beam, the light is scattered. Scattered light is detected by the flow cytometer. Because cells are separated in space, each light-scattering event is detected independently. Thus the number of light-scattering events represents the number of cells in the sample (see figure 29.4). Cells of differing size, internal complexity, and other characteristics within a population can also be counted. This usually involves the use of fluorescent dyes or fluorescently labeled antibodies. These more sophisticated uses of flow cytometry can provide valuable information about characteristics of the population of cells. **▶▶ Flow cytometry (section 36.3)**

Microorganisms also can be directly counted with electronic counters such as the Coulter counter. In the Coulter counter, a microbial suspension is forced through a small hole. Electrical current flows through the hole, and electrodes placed on both sides of the hole measure electrical resistance. Every time a microbial cell passes through the hole, electrical resistance increases (i.e., the conductivity drops), and the cell is counted.

Traditional methods for directly counting microbes in a sample usually yield cell densities that are much higher than the plating methods described next in part because direct counting procedures do not distinguish dead cells from culturable cells. Newer methods for direct counts help alleviate this problem. Commercially prepared fluorescent dyes can differentiate between live and dead cells, making it possible to count directly the number of live and dead microorganisms in a sample (see figures 2.13a and 29.2). Unfortunately, the method is not completely accurate. Just as scientists have difficulty defining life, so too do they have difficulty deciding when a cell is truly dead (figure 7.34).

Viable Counting Methods

Several plating methods can be used to determine the number of viable microbes in a sample. These are referred to as either **viable counting methods** or **plate counts** because they count only those cells that are able to reproduce when cultured. Two commonly used procedures are the spread-plate and the pour-plate techniques, which are described in section 7.5. When using these methods to determine population size, the samples should yield between 25 and 250 colonies per plate for accurate counting. Once the number of colonies is known, the original number of viable microorganisms in the sample can be calculated from that number and the sample dilution. For example, if

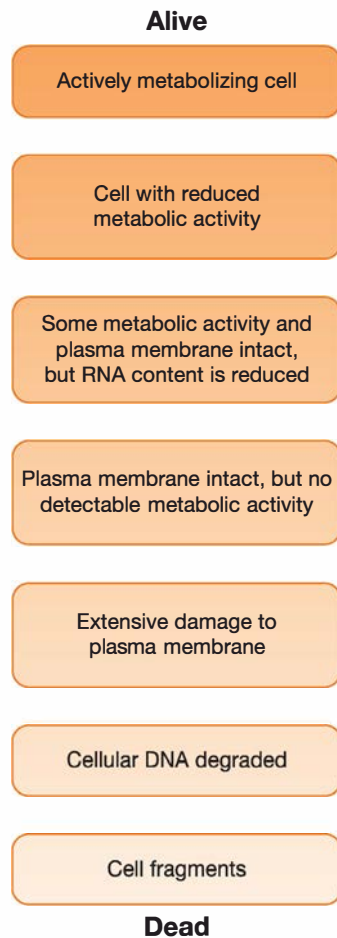

Figure 7.34 Alive or Dead? Microbiologists have traditionally defined microbes as being dead when they could not be cultured. However, they have come to realize that cells may be inactive or damaged and therefore unable to reproduce temporarily. With time and appropriate conditions, the cells may recover and begin to reproduce. Various criteria have been used to establish these states; however, microbiologists are still unable to define the point at which a microbe is truly dead and cannot be resuscitated.

1.0 milliliter of a solution diluted by a factor of 1×10^6 yielded 150 colonies (i.e., 1.5×10^2 colonies), then the original sample contained around 1.5×10^8 cells per milliliter. However, because it is not possible to be certain that each colony arose from an individual cell, the results are often expressed in terms of **colony forming units (CFU)**, rather than the number of microorganisms.

Another commonly used plating method first traps bacteria in aquatic samples on a membrane filter. The filter is then placed on an agar medium or on a pad soaked with liquid media (**figure 7.35**) and incubated until each cell forms a separate colony. A colony count gives the number of microorganisms in the filtered sample, and selective media can be used to select for specific microorganisms (**figure 7.36**). This technique is especially useful in analyzing water purity. ►► *Water purification and sanitary analysis (section 43.1)*

Plating techniques are simple, sensitive, and widely used for viable counts of bacteria and other microorganisms in samples of food, water, and soil. However, several problems can lead to inaccurate counts. The population will be underestimated if clumps of cells are not broken up and microorganisms well dispersed. The hot agar used in the pour-plate technique may injure or kill sensitive cells; thus spread plates sometimes give higher counts than pour plates. A major problem is that plate counts will be artificially low if the medium employed cannot support growth of all the viable microorganisms present. This is a common problem encountered by microbial ecologists trying to understand the makeup of microbial communities. In such studies, the number of cells observed by microscopy is often much higher than the population size determined by plate counts. This discrepancy is sometimes referred to as “the great plate count anomaly” and is discussed in detail in chapter 29. ►► *Assessing microbial diversity (section 29.2)*

Sometimes plate counts cannot be used to measure population size. For instance, plate counts are not helpful if the microbe cannot be cultured on solid media or if large colonies overgrow the surface of the plate, making it impossible to get an accurate

Figure 7.35 The Membrane Filtration Procedure. Membranes with different pore sizes are used to trap different microorganisms. Incubation times for membranes also vary with the medium and microorganism.

MICRO INQUIRY Why is it important to have no more than about 250 colonies on the plate when counting colonies to determine population size?

count. In these cases, another approach is used: **most probable number (MPN)** determination. In this method, numerous replicates of several dilutions of a culture are made and added to tubes containing a suitable liquid growth medium. After incubation, each tube is examined to determine if growth occurred. It is assumed that the last tube in the dilution series that demonstrates growth was inoculated with between one and 10 cells, while the next tube had between 11 and 100 cells, and so on. If no growth is observed, then the tube is assumed not to have received any cells. In this way, the number of cells in the original sample is estimated (*for an example, see figure 29.3*). MPN values are most commonly used when a selective medium can be employed that supports the growth of a specific type of microbe. It is often used in assessing microbial density in water samples. ►► *Culturing techniques (section 29.1)*

Measurement of Cell Mass

Techniques for measuring changes in cell mass also can be used to determine population size. One approach is the determination of microbial dry weight. Cells growing in liquid medium are collected by centrifugation, washed, dried in an oven, and weighed. This is an especially useful technique for measuring the growth of filamentous fungi. However, it is time-consuming and not very sensitive. Because bacteria weigh so little, it may be necessary to centrifuge several hundred milliliters of culture to collect a sufficient quantity.

A more rapid and sensitive method for measuring cell mass is spectrophotometry (**figure 7.37**). Spectrophotometry depends on the fact that microbial cells scatter light that strikes them. Because microbial cells in a population are of roughly constant size, the amount of scattering is directly proportional to the biomass of cells present and indirectly related to cell number. When the concentration of bacteria reaches about a million (10^6) cells per milliliter, the medium appears slightly cloudy or turbid. Further increases in concentration result in greater turbidity, and less light is transmitted through the medium. The extent of light scattering (i.e., decrease in transmitted light) can be measured by a spectrophotometer and is called the absorbance (optical density) of the medium. Absorbance is almost linearly related to cell concentration at absorbance levels less than about 0.5. If the sample exceeds this value, it must first be diluted and then absorbance measured. Thus population size can be easily measured as long as the population is high enough to give detectable turbidity.

Cell mass can also be estimated by measuring the concentration of some cellular substance, as long as its concentration

Figure 7.36 Colonies on Membrane Filters. Membrane-filtered samples grown on a variety of media. (a) Standard nutrient media for a total bacterial count. An indicator colors colonies dark red for easy counting. (b) Fecal coliform medium for detecting fecal coliforms that form blue colonies. (c) Wort agar for the culture of yeasts and molds.

Figure 7.37 Turbidity and Microbial Mass Measurement.

Determination of microbial mass by measurement of light absorption. As the population and turbidity increase, more light is scattered and the absorbance reading given by the spectrophotometer increases.

is constant in each cell. For example, a sample of cells can be analyzed for total protein or nitrogen. An increase in the microbial population will be reflected in higher total protein levels. Similarly, chlorophyll determinations can be used to measure phototrophic protist and cyanobacterial populations, and the quantity of ATP can be used to estimate the amount of living microbial mass.

Retrieve, Infer, Apply

1. Briefly describe each technique by which microbial population numbers may be determined and give its advantages and disadvantages.
2. When using direct cell counts to follow the growth of a culture, it may be difficult to tell when the culture enters the phase of senescence and death. Why?
3. Why are plate count results expressed as colony forming units?
4. For each of the following, which enumeration technique would you use? Explain your choice. (a) A pure culture of *Staphylococcus aureus*; (b) a water sample that needs to be checked for *E. coli* contamination; (c) a sample of yogurt.

7.8 Continuous Culture of Microorganisms

After reading this section, you should be able to:

- Distinguish batch culture and continuous culture
- Differentiate chemostats and turbidostats
- Discuss the relationship between the dilution rate of a chemostat and population size and growth rate

In section 7.6, our focus is on closed systems called batch cultures in which nutrients are not renewed nor wastes removed. Exponential (logarithmic) growth lasts for only a few generations and soon stationary phase is reached. However, it is possible to grow microorganisms in a system with constant environmental conditions maintained through continual provision of nutrients and removal of wastes. Such a system is called a **continuous culture system**. These systems can maintain a microbial population in exponential growth, growing at a known rate and at a constant biomass concentration for extended periods. Continuous culture systems make possible the study of microbial growth at very low nutrient levels, concentrations close to those present in natural environments. These systems are essential for research in many areas, particularly microbial ecology. For example, interactions between microbial species in environmental conditions resembling those in a freshwater lake or pond can be modeled. Continuous culture systems also are used in food and industrial microbiology. Two major types of continuous culture systems commonly are used: chemostats and turbidostats. ►► *Microbiology of food (chapter 41); Biotechnology and industrial microbiology (chapter 42)*

Chemostats

A **chemostat** is constructed so that the rate at which a sterile medium is fed into a culture vessel is the same as the rate at which the medium containing microorganisms is removed (**figure 7.38**). The culture medium for a chemostat has a limited quantity of an essential nutrient (e.g., a vitamin). Because one nutrient is limiting, growth rate is determined by the rate at which sterile medium is fed into the growth chamber; the final cell density depends on

Figure 7.38 A Chemostat. Schematic diagram of the system. The fresh medium contains a limiting amount of an essential nutrient. Although not shown, usually the incoming medium is mechanically mixed with that already in the culture vessel. Growth rate is determined by the flow rate of medium through the culture vessel.

the concentration of the limiting nutrient. The rate of nutrient exchange is expressed as the dilution rate (D), the rate at which medium flows through the culture vessel relative to the vessel volume, where f is the flow rate (milliliter/hr) and V is the vessel volume (milliliter).

$$D = f/V$$

For example, if f is 30 milliliters/hr and V is 100 milliliters, the dilution rate is 0.30 hr^{-1} .

Both population size and generation time are related to the dilution rate (**figure 7.39**). When dilution rates are very low, only a limited supply of nutrient is available and the microbes can conserve only a limited amount of energy. Much of that energy must be used for cell maintenance, not for growth and reproduction. Slightly higher dilution rates make more nutrients available to the microbes. When the dilution rate provides enough nutrients for both maintenance and reproduction, the cell density will begin to rise. In other words, the growth rate can increase (and the generation time can decrease) when the total available energy provided by the nutrient supply exceeds the **maintenance energy**. Notice in figure 7.39 that for a wide range of dilution rates, the cell density remains stable. This is because the limiting nutrient is almost completely depleted by the rapid reproductive rate of the cells (as seen by the decreasing generation times). However,

Figure 7.39 Chemostat Dilution Rate and Microbial Growth.

The effects of changing the dilution rate in a chemostat.

MICRO INQUIRY Why does the cell density stay relatively constant over such a large range of dilution rates?

if the dilution rate is too high, microorganisms can actually be washed out of the culture vessel before reproducing because the dilution rate is greater than the maximum growth rate.

Turbidostats

The second type of continuous culture system, the **turbidostat**, has a photocell that measures the turbidity (defined as the amount of light scattered) of the culture in the growth vessel. The flow rate of media through the vessel is automatically regulated to maintain a predetermined turbidity. Because turbidity is related to cell density, the turbidostat maintains a desired cell density. Turbidostats differ from chemostats in several ways. The dilution rate in a turbidostat varies, rather than remaining constant, and a turbidostat's culture medium contains all nutrients in excess. That is, none of the nutrients is limiting. A turbidostat operates best at high dilution rates; a chemostat is most stable and effective at lower dilution rates.

Retrieve, Infer, Apply

1. How does a continuous culture system differ from a closed culture system (i.e., a batch culture)?
2. Describe how chemostats and turbidostats operate. How do they differ?
3. What is the dilution rate? What is maintenance energy? How are they related?

Key Concepts

7.1 Reproductive Strategies

- Many eukaryotic microbes are capable of carrying out both sexual and asexual reproduction. The former involves meiosis and the latter, mitosis.
- The most common type of cell division observed among bacteria and archaea is binary fission. During binary fission, the cell elongates, the chromosome is replicated, and then it segregates to opposite poles of the cell prior to the formation of a septum, which divides the cell into two progeny cells (**figure 7.1**).
- Other bacterial reproductive strategies include budding, and baeocyte and spore formation (**figure 7.2**).

7.2 Bacterial Cell Cycle

- Two overlapping pathways function during the bacterial cell cycle: the pathway for chromosome replication and segregation, and the pathway for septum formation (**figure 7.3**).
- In bacterial cells, chromosome replication begins at a single site called the origin of replication. Many models for partitioning of the progeny chromosomes have been developed. Some suggest that homologues of eukaryotic cytoskeletal proteins are involved.

- Septum formation in most bacteria is accomplished by Z ring formation and assembly of cell wall-synthesizing machinery at the center of the cell, as directed by Min proteins (**figures 7.4 and 7.5**).
- In rapidly dividing cells, initiation of DNA synthesis may occur before the previous round of synthesis is completed. This shortens the time needed for completing the cell cycle.
- The shape of bacterial and archaeal cells is maintained by the cell wall. This has been best studied in bacteria, where the cytoskeletal proteins FtsZ and MreB (in rod-shaped bacteria) are involved in determining where peptidoglycan will be synthesized. In cocci, FtsZ and peptidoglycan synthesis localize to the midcell. In rods, when cells are lengthening prior to cell division, MreB localizes along the length of the cell, and peptidoglycan synthesis occurs there as a result. During cell division, FtsZ localization confines peptidoglycan synthesis to the midcell (**figure 7.7**).

7.3 Influences of Environmental Factors on Growth

- Solute concentrations can adversely affect microbes by causing lysis or plasmolysis. Most bacteria, photosynthetic protists, and fungi have rigid cell walls that help protect them from osmotic stress. By synthesizing cytoplasmic compatible solutes, they can remain hypertonic relative to

their habitats. Solutes also affect microbes because they interact with water, making it less available for microbial activities. The amount of water available to microorganisms is expressed as the water activity (a_w). Most microorganisms do not grow well at water activities below 0.98; osmotolerant organisms survive and even flourish at low a_w values. Halophiles actually require high sodium chloride concentrations for growth (figure 7.9 and table 7.2).

- Each microbial species has an optimum pH for growth and can be classified as an acidophile, neutrophile, or alkalophile (figure 7.10 and table 7.2).
- Microorganisms have distinct temperature ranges for growth with minima, maxima, and optima—the cardinal temperatures. These ranges are determined by the effects of temperature on the rates of catalysis, protein denaturation, and membrane disruption. There are five major classes of microorganisms with respect to temperature preferences: (1) psychrophiles, (2) psychrotrophs (psychrotolerants), (3) mesophiles, (4) thermophiles, and (5) hyperthermophiles (figures 7.11 and 7.12 and tables 7.2 and 7.3).
- Microorganisms can be placed into at least five different categories based on their response to the presence of O_2 : obligate aerobes, microaerophiles, facultative anaerobes, aerotolerant anaerobes, and strict or obligate anaerobes (figure 7.13 and table 7.2). Oxygen can become toxic because of the production of hydrogen peroxide, superoxide radical, and hydroxyl radical. These are destroyed by the enzymes superoxide dismutase, catalase, and peroxidase.
- Most deep-sea microorganisms are barotolerant, but some are piezophilic and require high pressure for optimal growth.
- High-energy or short-wavelength radiation harms organisms in several ways. Ionizing radiation—X rays and gamma rays—ionizes molecules and destroys DNA and other cell components. Ultraviolet (UV) radiation induces DNA damage. Visible light can provide energy for the formation of reactive singlet oxygen, which will destroy cells.

7.4 Microbial Growth in Natural Environments

- Microbial growth in natural environments is profoundly affected by nutrient limitations and other adverse factors. Microbes are often found in oligotrophic environments. They have evolved strategies to survive in these habitats, including spore formation and other types of dormancy, and the production of starvation proteins.
- Many microbes form biofilms—aggregations of microbes growing on surfaces and held together by extracellular polymeric substances (EPS) (figures 7.16 and 7.17). Life in a biofilm has several advantages, including protection from harmful agents.
- Bacteria often use chemical signals to communicate with one another in a density-dependent way and carry out a particular activity only when a certain population density

is reached. This phenomenon is called quorum sensing (figure 7.18).

- Some bacteria are able to communicate via chemicals with large organisms such as plants. A well-studied example is the rhizobium-plant interaction.

7.5 Laboratory Culture of Cellular Microbes

- To culture microbes in the lab, appropriate media and environmental conditions must be used.
- Culture media can be constructed completely from chemically defined components (defined media or synthetic media) or constituents, such as peptones and yeast extract, whose precise composition is unknown (complex media). Culture media can be solidified by the addition of agar, a complex polysaccharide from red algae.
- Culture media can be classified based on function. Supportive media are used to culture a wide variety of microbes. Enriched media are supportive media that contain additional nutrients needed by fastidious microbes. Selective media contain components that select for the growth of some microbes. Differential media contain components that allow microbes to be differentiated from each other, usually based on some metabolic capability.
- Aerobes are cultivated by supplying oxygen. Anaerobes are cultivated using media and methods that exclude oxygen (figures 7.21 and 7.22).
- Enrichment cultures are usually the first step in isolating pure cultures. They use selective conditions (media, environmental conditions) to promote the growth of certain microbes. After enrichment, pure cultures usually are obtained by isolating individual cells with any of three plating techniques: the streak-plate, spread-plate, and pour-plate methods. The streak-plate technique uses an inoculating loop to spread cells across an agar surface. The spread-plate and pour-plate methods usually involve diluting a culture or sample and then plating the dilutions. In the spread-plate technique, cells are spread on an agar surface; in the pour-plate technique, the cells are first mixed with cooled agar-containing media before being poured into a Petri dish (figures 7.23–7.25).
- Microorganisms growing on solid surfaces tend to form colonies with distinctive morphology (figure 7.26).

7.6 Growth Curve: When One Becomes Two and Two Become Four...

- Growth is an increase in cellular constituents and results in an increase in cell size, cell number, or both.
- When microorganisms are grown in a batch culture, the resulting growth curve usually has four phases: lag, exponential (log), stationary, and death (figure 7.27).
- In the exponential phase, the population number of cells undergoing binary fission doubles at a constant interval called the generation or doubling time (figure 7.30). The growth rate constant (k) is the reciprocal of the generation time (figure 7.31).

7.7 Measurement of Microbial Population Size

- Microbial populations can be counted directly with counting chambers, flow cytometers, electronic counters, or fluorescence microscopy. However, it is sometimes difficult to discern if cells are living or dead (figures 7.33 and 7.34).
- Viable counting techniques (plate counts) such as the spread-plate, the pour-plate, or the membrane filter method can be employed (figure 7.35).

- Population size also can be determined by measuring microbial mass through the measurement of dry weight, turbidity, or the amount of a cell component (figure 7.37).

7.8 Continuous Culture of Microorganisms

- Microorganisms can be grown in an open system in which nutrients are constantly provided and wastes removed.
- A continuous culture system can maintain a microbial population in log phase. There are two types of these systems: chemostats and turbidostats (figure 7.38).

Hypothesize, Compare, Invent

1. As an alternative to diffusible signals, suggest another mechanism by which bacteria might quorum sense.
2. If you wished to obtain a pure culture of bacteria that could degrade benzene and use it as a carbon and energy source, how would you proceed?
3. Design an experiment to determine if a slow-growing microbial culture is in lag phase or exponential phase.
4. Suggest one specific mechanism underlying the observation that the cardinal temperatures of some microbes change depending on other environmental conditions (e.g., pH).
5. Consider cell-cell communication: bacteria that “subvert” and “cheat” have been described. Describe a situation in which it would be advantageous for one species to subvert another, that is, degrade an intercellular signal made by another species. Also, describe a scenario whereby bacterial cheaters—defined as bacteria that do not make a molecular signal but profit by the uptake and processing of signal made by another microbe—might have a growth advantage.
6. Suppose you discovered a new bacterial strain from the permafrost of Alaska. You are able to culture the bacterium, but it grows very slowly. What characteristics of the bacterium would you determine to see if you could optimize its growth rate? Explain your choices.
7. Because many persistent bacterial infections involve biofilms, there is great interest in developing strategies to prevent their formation and eliminate them once they have formed. The red alga *Delisea pulchra* produces a class of compounds known as halogenated furanones that inhibit biofilm formation by *Pseudomonas aeruginosa*, *E. coli*, *B. subtilis*, *Staphylococcus epidermidis*, and *Streptococcus* spp. In these microbes, the algal furanones inhibit cell-cell signaling. While furanones also inhibit biofilm formation in the food-borne pathogen *Salmonella enterica* serovar Typhimurium, they do not alter cell-cell signaling. How does the inhibition of intercellular communication inhibit biofilm formation in *P. aeruginosa* and others? Do you think the fact that the furanones fail to interrupt cell-cell communication in *Salmonella* means that these bacteria do not use intercellular signaling when constructing biofilms? What alternative explanations might explain the loss of biofilm formation without influencing cell-cell communication? Suggest a use for the algal furanones in a food-processing facility.

Control of Microorganisms in the Environment

Bacterial Kamikazes Seek Out and Destroy Pathogens

There is no hiding anymore for the evasive pathogen *Pseudomonas aeruginosa*. Researchers have created a predator drone that can detect *P. aeruginosa*, a leading cause of hospital-acquired infections, and kill it. Using the tools of synthetic biology, scientists at Nanyang Technical University in Singapore engineered the common *Escherichia coli* bacterium to detect chemical communication signals—acyl homoserine lactones (AHLs)—produced by *P. aeruginosa* and, in turn, produce a novel protein antibiotic, pyocin S5. Sensing the AHLs, the engineered *E. coli* mass-produce the pyocin S5, resulting in its explosive release. The result is a lot of dead *P. aeruginosa*, along with the destruction of the *E. coli* drone. This innovative use of synthetic biology introduces an exciting extension of “biological” control. It paves a new way for eliminating bacteria that are difficult to control by conventional disinfection techniques.

P. aeruginosa is notorious for hiding in water supplies, bathrooms, and even soaps used for hand washing. It can then infect humans (especially those who are immunocompromised), colonizing the respiratory and gastrointestinal tracts where it rapidly develops resistance to conventional antibiotics. This use of engineered bacteria enables bacterial eradication with surgical precision and no effect on the remaining host microbiota. The predator drone grows and reproduces until it finds its pathogen targets, and then it is destroyed along with the pathogens. Perhaps someday you will see “Kamikaze Soap” in the grocery store.

In this chapter, we address the control and destruction of microorganisms, a topic of immense practical importance. Although most microorganisms are beneficial, some microbial activities have undesirable consequences, such as food spoilage and disease. Therefore it is essential to be able to kill a wide variety of microorganisms or inhibit their growth to minimize their destructive effects. The goal is twofold: (1) to destroy

Bacteriophage Killers. Colonies of *Bacillus anthracis* are attacked and killed by a highly specific gamma-phage. A single drop of gamma-phage applied to the 24-hour old culture of *B. anthracis* resulted in the large clearing, or plaque (arrow), where the bacteriophage lysed the host bacteria. The bacteriophage will continue to infect and replicate until no host cells remain.

pathogens and prevent their transmission, and (2) to reduce or eliminate microorganisms responsible for the contamination of water, food, and other substances.

Microorganism control continues to be a hot topic as microorganisms evolve to resist current strategies. Control efforts have a substantial role in public health to prevent disease as well as in therapeutic use to treat disease. Thus this chapter focuses on the control of microorganisms by physical, chemical, and biological agents (such as engineered bacteria). In general, any chemical, physical, or biological product that controls microorganisms is referred to as an **antimicrobial agent**. Chemotherapeutic agents that are used inside the body to treat human disease are discussed in chapter 9.

Readiness Check:

Based on what you have learned previously, you should be able to:

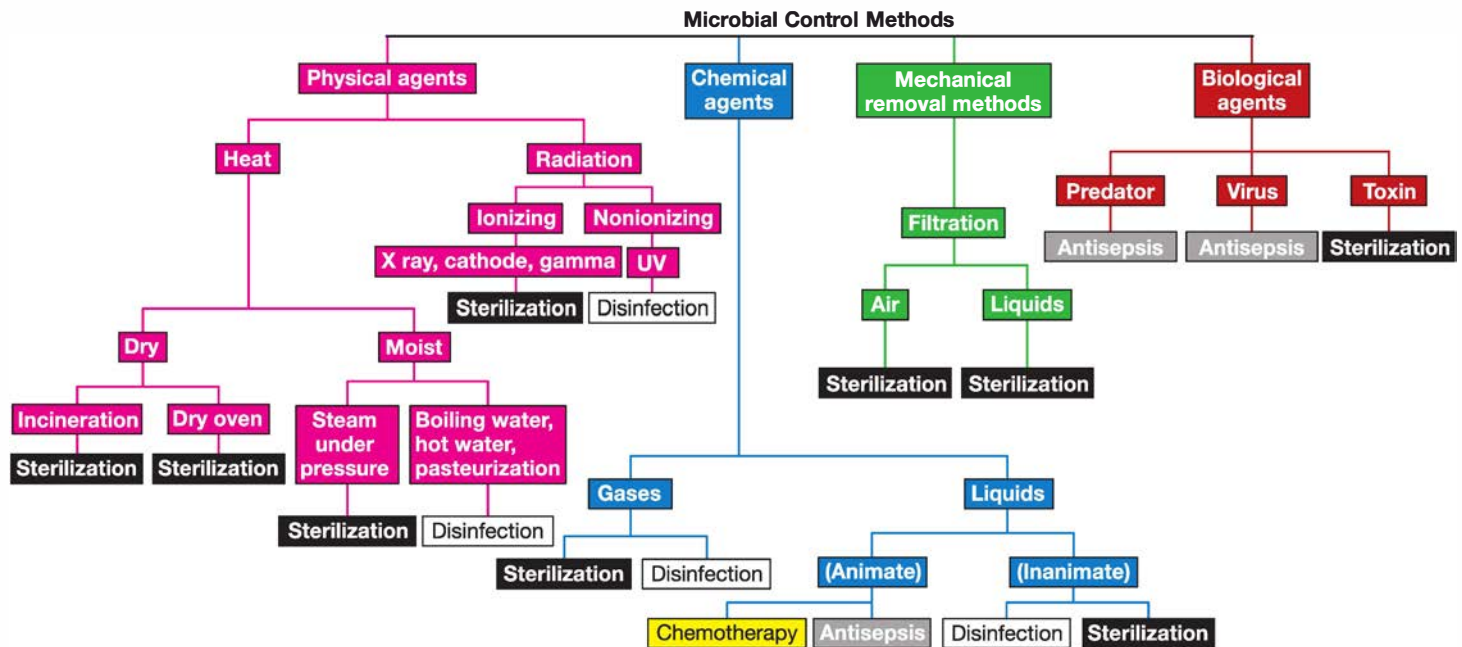

- ✓ Identify the structures and their functions of bacteria, protists, fungi, viruses, and prions, including their replication processes and energy requirements (sections 3.2–3.8, 5.1–5.7, 6.1–6.7, 7.1–7.7)

8.1 Principles of Microbial Control

After reading this section, you should be able to:

- Compare and contrast actions of disinfection, antisepsis, chemotherapy, and sterilization
- Distinguish between cidal (killing) and static (inhibitory) agents

The principles of microbial control are rooted in microbial nutrition, growth, and development, which are discussed in chapter 7. If you can starve or poison, or inhibit or prevent growth or replication, you can control microorganisms. Of course, it is not as simple as this sounds. Subtle differences in population, degree of killing, and even what is used to remove microorganisms result in a somewhat complex vocabulary. Terminology is especially important when the control of microorganisms is discussed

Disinfection: The destruction or removal of vegetative pathogens but not bacterial endospores. Usually used only on inanimate objects.

Sterilization: The complete removal or destruction of all viable microorganisms. Used on inanimate objects.

Antisepsis: Chemicals applied to body surfaces to destroy or inhibit vegetative pathogens.

Chemotherapy: Chemicals used internally to kill or inhibit growth of microorganisms within host tissues.

Figure 8.1 Microbial Control Methods.

MICRO INQUIRY Which types of agents can be used for sterilization? Which can be used for antisepsis? What is the difference?

because words such as *disinfectant* and *antiseptic* often are used loosely, and as we shall see, they have different meanings. The situation is even more confusing because a particular treatment can either inhibit growth or kill, depending on the conditions. The types of control agents and their uses are outlined in **figure 8.1**. In general, to control microorganisms a **biocide** must be evaluated so as to determine the specific parameters under which it will be effective.

Sterilization (Latin *sterilis*, unable to produce offspring or barren) is the process by which all living cells, spores, and acellular entities (e.g., viruses, viroids, and prions) are either destroyed or removed from an object or habitat. A sterile object is totally free of viable microorganisms, spores, and other infectious agents. When sterilization is achieved by a chemical agent, the chemical is called a **sterilant**. In contrast, **disinfection** is the killing, inhibition, or removal of microorganisms that may cause disease; disinfection is the substantial reduction of the total microbial population and the destruction of potential pathogens. **Disinfectants** are agents, usually chemical, used to carry out disinfection and normally used only on inanimate objects. A disinfectant does not necessarily sterilize an object because viable spores and a few microorganisms may remain. **Sanitization** is closely related to disinfection. In sanitization, the microbial population is reduced to levels that are considered

safe by public health standards. The inanimate object is usually cleaned as well as partially disinfected. For example, sanitizers are used to clean eating utensils in restaurants. ◀◀ **Viroids and satellites** (section 6.6); **Prions** (section 6.7)

It also is frequently necessary to control microorganisms on or in living tissue with chemical agents. **Antisepsis** (Greek *anti*, against, and *sepsis*, putrefaction) is the destruction or inhibition of microorganisms on living tissue; it is the prevention of infection or sepsis. **Antiseptics** are chemical agents applied to tissue to prevent infection by killing or inhibiting pathogen growth; they also reduce the total microbial population. Because they must not destroy too much host tissue, antiseptics are generally not as toxic as disinfectants. The exposure of microorganisms to increasing biocide concentrations decreases the number of viable organisms. **Figure 8.2** shows three possible population reduction curves resulting from three different biocides. The shape of the curve reflects various conditions that influence biocide effectiveness. Note that in each case, the eventual decline in viable microorganisms can occur as a staged decline of viability from antisepsis to sterilization. **Chemotherapy** is the use of chemical agents to kill or inhibit the growth of microorganisms within host tissue and is the topic of chapter 9.

A suffix can be employed to denote the type of antimicrobial agent. Substances that kill organisms often have the suffix *-cide*

Figure 8.2 Impact of Biocide Exposure. Three exponential plots of survivors versus time of biocide exposure, indicating the potential kinetics of biocide action. Note how the general terms referencing microbial control are reflected by decreasing numbers of microbes. For example, sterilization refers to the absence of viable organisms regardless of biocide kinetics.

(Latin *cida*, to kill); a cidal agent kills pathogens (and many non-pathogens) but not necessarily endospores. A disinfectant or antiseptic can be particularly effective against a specific group, in which case it may be called a **bactericide**, **fungicide**, or **viricide**. Other chemicals do not kill but rather prevent growth. If these agents are removed, growth will resume. Their names end in *-static* (Greek *statikos*, causing to stand or stopping); for example, **bacteriostatic** and **fungistatic**.

Retrieve, Infer, Apply

1. Define the following terms: sterilization, sterilant, disinfection, disinfectant, sanitization, antisepsis, antiseptic, chemotherapy, biocide.
2. What is the difference between bactericidal and bacteriostatic? To which category do you think most household cleaners belong? Why?

8.2 The Pattern of Microbial Death

After reading this section, you should be able to:

- Calculate the decimal reduction time (D value)
- Correlate antisepsis, sanitization, disinfection, and sterilization with agent effectiveness

A microbial population is not killed instantly when exposed to a lethal agent. Population death is generally exponential (logarithmic); that is, the population is reduced by the same fraction at constant intervals (**table 8.1**). If the logarithm of the population number remaining is plotted against the time of exposure of the microorganism to the agent, a straight-line plot will result (**figure 8.3**). When the population has been greatly reduced, the rate of killing may slow due to the survival of a more resistant strain of the microorganism.

It is essential to have a precise measure of an agent's killing efficiency. One such measure is the **decimal reduction time (D)** or **D value**. The decimal reduction time is the time required to kill 90% of the microorganisms or spores in a sample under specified conditions. For example, in a semilogarithmic plot of the population remaining versus the time of heating, the D value is the time required for the line to drop by one log cycle or tenfold (**figure 8.3a**). It is also possible to determine the temperature change at a given D value that decreases the microbial population by one log cycle (90%). This temperature change is referred to as the **Z value** and is predicted from a semilogarithmic plot of D values versus temperature (**figure 8.3b**).

To study the effectiveness of a lethal agent, one must be able to decide when microorganisms are dead, which may present some challenges. A microbial cell is often defined as dead if it does not grow when inoculated into culture medium that would normally support its growth. In like manner, an inactive virus cannot infect a suitable host. This definition has flaws, however. It has been demonstrated that when

Table 8.1 A Theoretical Microbial Heat-Killing Experiment

| Minute | Microbial Number at Start of Minute | Microorganisms Killed in 1 Minute (90% of Total) ¹ | Microorganisms at End of 1 Minute | Log ₁₀ of Survivors |
|--------|-------------------------------------|---|-----------------------------------|--------------------------------|
| 1 | 10 ⁶ | 9 × 10 ⁵ | 10 ⁵ | 5 |
| 2 | 10 ⁵ | 9 × 10 ⁴ | 10 ⁴ | 4 |

| 6 | 10 ¹ | 9 | 1 | 0 |
| 7 | 1 | 0.9 | 0.1 | –1 |

¹ Assume that the initial sample contains 10⁶ vegetative microorganisms per milliliter and that 90% of the organisms are killed during each minute of exposure. The temperature is 121°C.

Figure 8.3 The Pattern of Microbial Death. (a) An exponential plot of the survivors versus the minutes of exposure to heating at 121°C. In this example, the D value is 1 minute. The data are from table 8.1. (b) An exponential plot of D values versus temperature. The temperature change at a given D value that reduces the population by one log unit is known as the Z value.

MICRO INQUIRY Examine graph (a). How long would it take to kill one-half of the original population of microorganisms? Keep in mind that the Y axis is exponential.

bacteria are exposed to certain conditions, they can remain alive but are temporarily unable to reproduce (see figure 7.43). When in this state, these persister cells are often referred to as viable but nonculturable (VBNC) (see figure 7.34). In conventional tests to demonstrate killing by an antimicrobial agent, VBNC bacteria would be thought to be dead. This is a serious problem because the bacteria may regain their ability to reproduce and cause infection after a period of recovery. **Senescence and death** (section 7.6)

8.3 Mechanical Removal Methods

After reading this section, you should be able to:

- Explain the mechanism by which filtration removes microorganisms
- Propose filtration methods based on percentage of microorganism to be removed

Filtration is an excellent way to reduce the microbial population in solutions of heat-sensitive material and can be used to sterilize various liquids and gases (including air). Rather than directly destroying contaminating microorganisms, the filter simply removes them. There are two types of filters. **Depth**

filters consist of fibrous or granular materials that have been bonded into a thick layer filled with twisting channels of small diameter. The solution containing microorganisms is sucked through this layer under vacuum, and microbial cells are removed by physical screening or entrapment and by adsorption to the surface of the filter material. Depth filters are made of diatomaceous earth (Berkefield filters), unglazed porcelain (Chamberland filters), asbestos, or other similar materials.

Membrane filters have replaced depth filters for many purposes. These filters are porous membranes, a little over 0.1 mm thick, made of cellulose acetate, cellulose nitrate, polycarbonate, polyvinylidene fluoride, or other synthetic materials. Although a wide variety of pore sizes are available, membranes with pores about 0.2 μm in diameter are used to remove most vegetative cells, but not viruses, from liquids ranging in volume from less than 1 milliliter to many liters. The membranes can be held in special holders (figure 8.4), and their use is often preceded by the use of depth filters made of glass fibers to remove larger particles that might clog the membrane filter. The liquid is pulled or forced through the filter with a vacuum or with pressure from a syringe, peristaltic pump, or nitrogen gas and collected in previously sterilized containers. Membrane filters remove microorganisms by

Figure 8.4 Membrane Filter Sterilization. The liquid to be sterilized is pumped through a membrane filter and into a sterile container. (a) Schematic representation of a membrane filtration setup that uses a vacuum pump to force liquid through the filter. The inset shows a cross section of the filter and its pores, which are too small for microbes to pass through. (b) Cross section of a membrane filtration unit. Several membranes are used to increase its capacity.

MICRO INQUIRY How might one verify that filtration removed all microorganisms?

Figure 8.5 Membrane Filter. *Enterococcus faecalis* resting on a polycarbonate membrane filter with 0.4 μm pores ($\times 5,900$).

screening them out much as a sieve separates large sand particles from small ones (figure 8.5). These filters are used to sterilize pharmaceuticals, ophthalmic solutions, culture media, oils, antibiotics, and other heat-sensitive solutions.

Air also can be filtered to remove microorganisms. Two common examples are N-95 disposable masks used in hospitals and labs, and cotton plugs on culture vessels that let air in but keep microorganisms out. N-95 masks exclude 95% of particles that are larger than 0.3 μm . Other important examples are **biological safety cabinets**, which employ **high-efficiency particulate air (HEPA) filters** (a type of depth filter made from fiberglass) to remove 99.97% of particles 0.3 μm or larger by both physical retention and electrostatic interactions. HEPA filters can also be made to adsorb viruses. HEPA filters are available that remove viruses that are 0.1 μm and smaller; they are used to sterilize air. Laminar flow biological safety cabinets or hoods force air through HEPA filters, then project a vertical curtain of sterile air across the cabinet opening. This protects a worker from microorganisms being handled within the cabinet and prevents contamination of the room (figure 8.6). A person uses these cabinets when working with dangerous agents such as *Mycobacterium tuberculosis*, pathogenic fungi, or tumor viruses. They are also employed in research labs and industries, such as the pharmaceutical industry, when a sterile working environment is needed.

8.4 Physical Control Methods

After reading this section, you should be able to:

- Describe the application of heat and radiation to control microorganisms
- Explain the mechanisms by which heat and radiation kill microbes
- Design novel antimicrobial control applications using heat and radiation to sterilize

Heat and other physical agents are normally used to control microbial growth and sterilize objects, as can be seen from the operation of the autoclave. The most frequently employed physical agents are heat and radiation.

Heat

Moist heat readily destroys viruses, bacteria, and fungi (table 8.2). Moist heat kills by degrading nucleic acids and denaturing enzymes and other essential proteins. It also disrupts cell membranes. Exposure to boiling water for 10 minutes is sufficient to destroy vegetative cells and eukaryotic spores. Unfortunately, the temperature of boiling water (100°C or 212°F at sea level) is not sufficient to destroy bacterial spores, which may survive hours of boiling. Therefore boiling can be used for disinfection of drinking water and objects not harmed by water, but boiling does not sterilize.

To destroy bacterial endospores, moist heat sterilization must be carried out at temperatures above 100°C, and this requires the use of saturated steam under pressure. Steam sterilization is carried out with an **autoclave** (figure 8.7), a device somewhat like a fancy pressure cooker. The development of the autoclave by Charles Chamberland in 1884 tremendously stimulated the growth of microbiology as a science. Water is boiled to produce steam, which is released into the autoclave's chamber (figure 8.7b). The air initially present in the chamber is forced out until the chamber is filled with saturated steam and the outlets are closed. Hot, saturated steam continues to enter until the chamber reaches the desired temperature

| Table 8.2 Approximate Conditions for Moist Heat Killing | | |
|---|-----------------------|---|
| Organism | Vegetative Cells | Spores |
| Yeasts | 5 minutes at 50–60°C | 5 minutes at 70–80°C |
| Molds | 30 minutes at 62°C | 30 minutes at 80°C |
| Bacteria ¹ | 10 minutes at 60–70°C | 2 to over 800 minutes at 100°C 0.5–12 minutes at 121°C |
| Viruses | 30 minutes at 60°C | |

¹ Conditions for mesophilic bacteria.

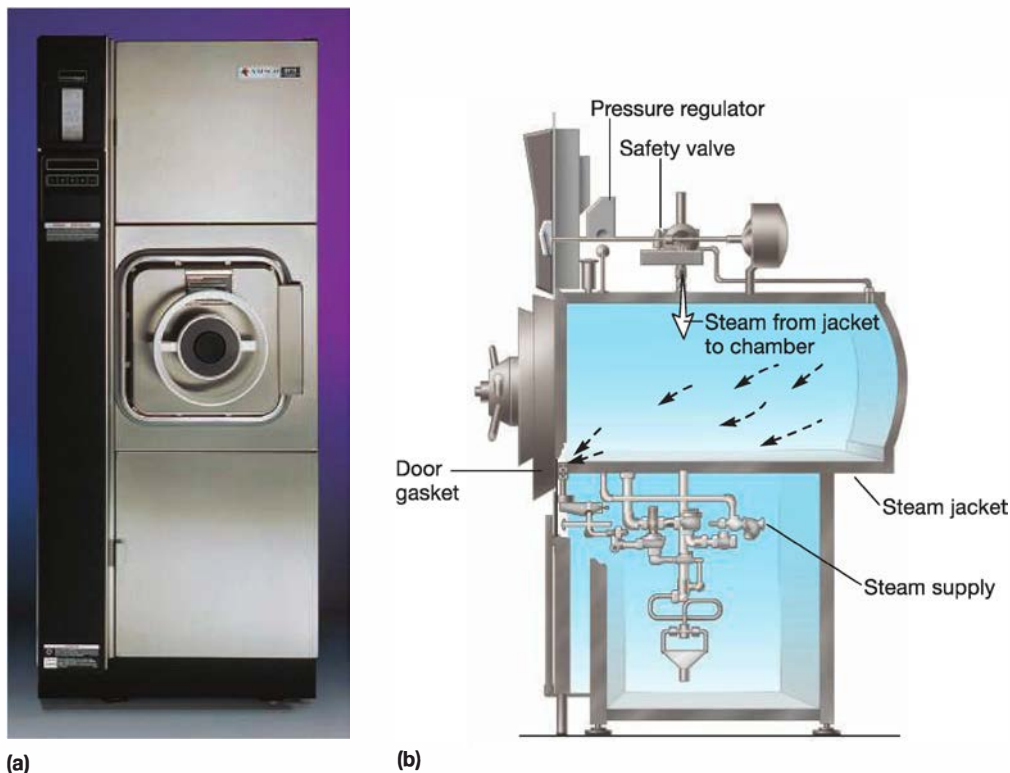

Figure 8.7 The Autoclave. (a) A modern, automatically controlled autoclave or sterilizer. (b) Longitudinal cross section of a typical autoclave showing some of its parts and the pathway of steam.

and pressure, usually 121°C and 15 pounds of pressure. At this temperature, saturated steam destroys all vegetative cells and spores in a small volume of liquid within 10 to 12 minutes. Treatment is continued for at least 15 minutes to provide a margin of safety. Of course, larger containers of liquid such as flasks and carboys require much longer treatment times.

Autoclaving must be carried out properly or the processed materials will not be sterile. If all air has not been flushed out of the chamber, it will not reach 121°C, even though it may reach a pressure of 15 pounds. The chamber should not be packed too tightly because the steam needs to circulate freely and contact everything in the autoclave. Bacterial spores will be killed only if they are kept at 121°C for 10 to 12 minutes. When a large volume of liquid must be sterilized, an extended sterilization time is needed because it takes longer for the center of the liquid to reach 121°C; 5 liters of liquid may require about 70 minutes. In view of these potential difficulties, a biological indicator is often autoclaved along with other material. This indicator commonly consists of a culture tube containing a sterile ampule of medium and a paper strip covered with spores of *Geobacillus stearothermophilus*. After autoclaving, the ampule is aseptically broken and the culture incubated for several days. If the test bacterium does not grow in the medium, the sterilization run has been successful. Sometimes indicator tape or paper that changes color upon sufficient heating is autoclaved with a load of material. These approaches that indicate heating has occurred are convenient and save time but

are not as reliable as techniques that kill bacterial spores.

Many heat-sensitive substances, such as milk, are treated with controlled heating at temperatures well below boiling, a process known as **pasteurization** in honor of its developer, Louis Pasteur. In the 1860s the French wine industry was plagued by the problem of wine spoilage, which made wine storage and shipping difficult. Pasteur examined spoiled wine under the microscope and detected microorganisms that looked like the bacteria responsible for lactic acid and acetic acid fermentations; these bacteria do not form spores. He then discovered that a brief heating at 55 to 60°C would destroy these microorganisms and preserve wine for long periods. In 1886 the German chemists V. H. Soxhlet and F. Soxhlet adapted the technique for preserving milk and reducing milk-transmissible diseases. Milk pasteurization was introduced in the United States in 1889.

Milk, beer, and many other beverages are now pasteurized. Pasteurization does not sterilize a beverage, but it does kill any pathogens present and drastically slows spoilage by reducing the level of nonpathogenic spoilage microorganisms (see figure 41.2).

Some materials cannot withstand the high temperature of the autoclave, and spore contamination precludes the use of other methods to sterilize them. For these materials, a process of intermittent sterilization, also known as **tyndallization** (for John Tyndall, the British physicist who used the technique to destroy heat-resistant microorganisms in dust) is used. The process also uses steam (30–60 minutes) to destroy vegetative bacteria. However, steam exposure is repeated for a total of three times with 23- to 24-hour incubations between steam exposures. The incubations permit remaining spores to germinate into heat-sensitive vegetative cells that are then destroyed upon subsequent steam exposures.

Many objects are best sterilized in the absence of water by dry heat sterilization. Some items are sterilized by incineration. For instance, inoculating loops, which are used routinely in the laboratory, can be sterilized in a small, bench-top incinerator (figure 8.8). Other items are sterilized in an oven at 160 to 170°C for 2 to 3 hours. Microbial death results from the oxidation of cell constituents and denaturation of proteins. Dry air heat is less effective than moist heat. The spores of *Clostridium botulinum*, the cause of botulism, are killed in 5 minutes at 121°C by moist heat but only after 2 hours at 160°C by dry heat. However, dry heat has some definite advantages. It does not corrode glassware and metal

Figure 8.8 Dry Heat Incineration. Bench-top incinerators are routinely used to sterilize inoculating loops used in microbiology laboratories.

instruments as moist heat does, and it can be used to sterilize powders, oils, and similar items. Despite these advantages, dry heat sterilization is slow and not suitable for heat-sensitive materials such as many plastic and rubber items.

Retrieve, Infer, Apply

1. Describe how an autoclave works. What conditions are required for sterilization by moist heat? What three things must one do when operating an autoclave to help ensure success?
2. In the past, spoiled milk was responsible for a significant proportion of infant deaths. Why is untreated milk easily spoiled?

Radiation

Ultraviolet (UV) radiation around 260 nm (see figure 7.14) is quite lethal. UV radiation causes thymine-thymine dimerization of DNA, preventing replication and transcription (see figure 16.5). However, UV does not penetrate glass, dirt films, water, and other substances very effectively. Because of this disadvantage, UV radiation is used as a sterilizing agent only in a few specific situations. UV lamps are sometimes placed on the ceilings of rooms or in biological safety cabinets to sterilize the air and any exposed surfaces. Because UV radiation burns the skin and damages eyes, the UV lamps are off when the areas are in use. Commercial UV units are available for water treatment. Pathogens and other microorganisms are destroyed when a thin layer of water is passed under the lamps. ►► *Water purification and sanitary analysis* (section 43.1)

Ionizing radiation is an excellent sterilizing agent and penetrates deep into objects. Ionizing

radiation consists of waves and particles that are of sufficient energy to dislodge electrons from atoms or molecules, producing chemically reactive free radicals. The free radicals react with nearby matter to weaken or destroy it. Ionizing radiation will destroy bacterial spores and all microbial cells; however, ionizing radiation is not always effective against viruses. Gamma radiation from a cobalt 60 source and accelerated electrons from high-voltage electricity are used in the cold sterilization of antibiotics, hormones, sutures, and plastic disposable supplies such as syringes. Gamma radiation and electron beams have also been used to sterilize and “pasteurize” meat and other foods (figure 8.9). Irradiation can eliminate the threat of such pathogens as *E. coli* O157:H7, which causes a life-threatening intestinal disease; *Staphylococcus aureus*, which causes skin and blood infections, and readily colonizes medical devices used on patients; and *Campylobacter jejuni*, which contaminates poultry, causing human intestinal disease when undercooked meat is eaten. Based on the results of numerous studies, both the U.S. Food and Drug Administration and the World Health Organization have approved irradiated food and declared it safe for human consumption. Currently irradiation is being used to treat poultry, beef, pork, veal, lamb, fruits, vegetables, and spices. ►► *Human diseases caused by bacteria* (chapter 39); *Controlling food spoilage* (section 41.2)

Retrieve, Infer, Apply

1. List the advantages and disadvantages of ultraviolet light and ionizing radiation as sterilizing agents. Provide a few examples of how each is used for this purpose.
2. What is the correlation between radiation “energy” and the mechanisms of sterilization?

Figure 8.9 Sterilization with Ionizing Radiation. An irradiation machine that uses radioactive cobalt 60 as a gamma radiation source to sterilize fruits, vegetables, meats, fish, and spices.

8.5 Chemical Control Agents

After reading this section, you should be able to:

- Describe the use of phenolics, alcohols, halogens, heavy metals, quaternary ammonium chlorides, aldehydes, and oxides to control microorganisms
- Explain the mechanisms of action for phenolics, alcohols, halogens, heavy metals, quaternary ammonium chlorides, aldehydes, and oxides
- Design novel antimicrobial control applications using phenolics, alcohols, halogens, heavy metals, quaternary ammonium chlorides, aldehydes, and oxides

Physical agents are generally used to sterilize objects. Chemicals, on the other hand, are more often employed in disinfection and antisepsis. The proper use of chemical agents is essential to laboratory and hospital safety. Chemicals also are employed to prevent microbial growth in food, and certain chemicals are used to treat infectious disease. The use of chemical agents for chemotherapy in humans is covered in chapter 9. Here we discuss chemicals used outside the body.

Many different chemicals are available for use as disinfectants, and each has its own advantages and disadvantages. Ideally the disinfectant must be effective against a wide variety of infectious agents (Gram-positive and Gram-negative bacteria, acid-fast bacteria, bacterial spores, fungi, and viruses) at low concentrations and in the presence of organic matter. Although the chemical must be toxic for infectious agents, it should not be toxic to people or corrosive for common materials. In practice, this balance between effectiveness and low toxicity for animals is hard to achieve. Some chemicals are used despite their low effectiveness because they are relatively nontoxic. The ideal disinfectant should be stable upon storage, odorless or with a pleasant odor, and soluble in water and lipids for penetration into microorganisms; have a low surface tension so that it can enter cracks in surfaces; and be relatively inexpensive.

Other chemicals are used as antiseptics. Recall that antiseptics are less toxic to humans than disinfectants and as such may be less effective at killing all the microorganisms that disinfectants can kill. In general, antiseptics should reduce the number of pathogens on human tissue to prevent infection. Examples of antiseptics include hand sanitizers, silver threads woven into clothing, and dilute iodine solutions that can be sprayed onto wounds. Antiseptics are meant to be used in the absence of thorough cleaning with soap and water. One potentially serious problem is the overuse of antiseptics. For instance, resistance to the antibacterial agent triclosan (found in products such as deodorants, mouthwashes, soaps, cutting boards, and baby toys) has become a problem. For example, *P. aeruginosa* actively pumps the antiseptic out of the cell. There is now evidence that extensive use of triclosan also increases the frequency of bacterial resistance to antibiotics. Thus overuse of antiseptics can have unintended harmful consequences. ▶▶ *Mechanisms of drug resistance* (section 16.9)

The properties and uses of several groups of common disinfectants and antiseptics are surveyed next. Many of the characteristics of disinfectants and antiseptics are summarized in **tables 8.3** and **8.4**. Structures of some common agents are shown in **figure 8.10**.

Phenolics

Phenol was the first widely used antiseptic and disinfectant. In 1867 Joseph Lister employed it to reduce the risk of infection during surgery. Today phenol and phenol derivatives (phenolics) such as cresols, xylenols, and orthophenylphenol are used as disinfectants in laboratories and hospitals. The commercial disinfectant Lysol is made of a mixture of phenolics. Phenolics act by denaturing proteins and disrupting cell membranes. They have some real advantages as disinfectants: phenolics are tuberculocidal, effective in the presence of organic material, and remain active on surfaces long after application. However, they have a disagreeable odor and can cause skin irritation. The newer phenolic, triclosan (figure 8.10), is often used in hand sanitizers due to its effective blockage of bacterial fatty acid synthesis.

Alcohols

Alcohols are among the most widely used disinfectants and antiseptics. They are bactericidal and fungicidal but not sporicidal; some enveloped viruses are also destroyed. The two most popular alcohol germicides are ethanol and isopropanol, usually used in about 60 to 80% concentration. They act by denaturing proteins and possibly by dissolving membrane lipids. A 10- to 15-minute soaking is sufficient to disinfect small instruments.

Halogens

A halogen is any of the five elements (fluorine, chlorine, bromine, iodine, and astatine) in group VIIA of the periodic table. They exist as diatomic molecules in the free state and form saltlike compounds with sodium and most other metals. The halogens iodine and chlorine are important antimicrobial agents. Iodine is used as a skin antiseptic and kills by oxidizing cell constituents and iodinating cell proteins. At higher concentrations, it may even kill some spores. Iodine often is applied as tincture of iodine, 2% or more iodine in a water-ethanol solution of potassium iodide. Although it is an effective antiseptic,

the skin may be damaged, a stain is left, and iodine allergies can result.

Iodine can be complexed with an organic carrier to form an **iodophor**.

Iodophors are water soluble, stable, and nonstaining, and release iodine slowly to minimize skin burns and irritation. They are used in hospitals for cleansing preoperative skin and in hospitals and laboratories for disinfecting. Some popular brands are Wescodyne for skin and laboratory disinfection, and Betadine for wounds.

Table 8.3 Activity Levels of Selected Biocides

| Class | Use Concentration of Active Ingredient | Activity Level ¹ |
|-------------------------------|--|-----------------------------|
| Gas | | |
| Ethylene oxide | 450–500 mg/L ² | High |
| Liquid | | |
| Glutaraldehyde, aqueous | 2–8% | High to intermediate |
| Formaldehyde + alcohol | 8 + 70% | High to intermediate |
| Stabilized hydrogen peroxide | 6–30% | High to intermediate |
| Formaldehyde, aqueous | 6–8% | High to intermediate |
| Iodophors, high concentration | 5,000–10,000 mg/L ³ | High to intermediate |
| Iodophors, low concentration | 75–150 mg/L ³ | Intermediate to low |
| Iodine + alcohol | 0.5 + 70% | Intermediate |
| Chlorine compounds | 500–5,000 mg/L ⁴ | Intermediate |
| Phenolic compounds, aqueous | 0.5–3% | Intermediate to low |
| Iodine, aqueous | 1% | Intermediate |
| Alcohols (ethyl, isopropyl) | 62–70% | Intermediate |
| Quaternary ammonium compounds | 0.1–0.2% aqueous | Low |
| Chlorhexidine | 0.75–4% | Low |
| Hexachlorophene | 1–3% | Low |
| Mercurial compounds | 0.1–0.2% | Low |

1 High-level disinfectants destroy vegetative bacterial cells including *M. tuberculosis*, bacterial endospores, fungi, and viruses. Intermediate-level disinfectants destroy all of the above except spores. Low-level agents kill bacterial vegetative cells except for *M. tuberculosis*, fungi, and medium-sized lipid-containing viruses (but not bacterial endospores or small, nonlipid viruses).

2 In autoclave-type equipment at 55 to 60°C.

3 Available iodine.

4 Free chlorine.

Chlorine is the usual disinfectant for municipal water supplies and swimming pools, and is employed in the dairy and food industries. It may be applied as chlorine gas (Cl_2), sodium hypochlorite (bleach, NaOCl), or calcium hypochlorite [$\text{Ca}(\text{OCl})_2$], all of which yield hypochlorous acid (HOCl):

The result is oxidation of cellular materials and destruction of vegetative bacteria and fungi. Death of almost all microorganisms usually occurs within 30 minutes. One potential problem is that chlorine reacts with organic compounds to form carcinogenic trihalomethanes, which must be monitored in drinking water. Some wastewater treatment facilities recover the chlorine from the water prior to discharge to prevent the formation of trihalomethanes.

Chlorine is also an excellent disinfectant for individual use because it is effective, inexpensive, and easy to employ. Small quantities of drinking water can be disinfected with halazone tablets. Halazone (parasulfone dichloramidobenzoic acid) slowly releases chloride when added to water and disinfects it in about a half hour. It is frequently used by campers lacking access to uncontaminated drinking water. Of note is the fact that household bleach (diluted to 10% in water, 10-minute contact time) can be used to disinfect surfaces contaminated by human body fluids and that it is made more effective by the addition of household vinegar.

Heavy Metals

For many years the ions of heavy metals such as mercury, silver, arsenic, zinc, and copper were used as germicides. These have now been superseded by other less toxic and more effective germicides (many heavy metals are more bacteriostatic than

Table 8.4 Relative Efficacy of Commonly Used Disinfectants and Antiseptics

| Class | Disinfectant ¹ | Antiseptic | Comment |
|-------------------------------|---------------------------|------------|--|
| Gas | | | |
| Ethylene oxide | 3–4 | 0 | Sporicidal; toxic; good penetration; requires relative humidity of 30% or more; microbicidal activity varies with apparatus used; absorbed by porous material; dry spores highly resistant; presoaking is most desirable |
| Liquid | | | |
| Glutaraldehyde, aqueous | 3 | 0 | Sporicidal; active solution unstable; toxic |
| Stabilized hydrogen peroxide | 3 | 0 | Sporicidal; solution stable up to 6 weeks; toxic orally and to eyes; mildly skin toxic; little inactivation by organic matter |
| Formaldehyde + alcohol | 3 | 0 | Sporicidal; noxious fumes; toxic; volatile |
| Formaldehyde, aqueous | 1–2 | 0 | Sporicidal; noxious fumes; toxic |
| Phenolic compounds | 3 | 0 | Stable; corrosive; little inactivation by organic matter; irritates skin |
| Chlorine compounds | 1–2 | 0 | Fast action; inactivation by organic matter; corrosive; irritates skin |
| Alcohol | 1 | 3 | Rapidly microbicidal except for bacterial spores and some viruses; volatile; flammable; dries and irritates skin |
| Iodine – alcohol | 0 | 4 | Corrosive; very rapidly microbicidal; causes staining; irritates skin; flammable |
| Iodophors | 1–2 | 3 | Somewhat unstable; relatively bland; staining temporary; corrosive |
| Iodine, aqueous | 0 | 2 | Rapidly microbicidal; corrosive; stains fabrics; stains and irritates skin |
| Quaternary ammonium compounds | 1 | 0 | Inactivated by soap and anionics; compounds absorbed by fabrics; old or dilute solution can support growth of Gram-negative bacteria |
| Hexachlorophene | 0 | 2 | Insoluble in water, soluble in alcohol; not inactivated by soap; weakly bactericidal |
| Chlorhexidine | 0 | 3 | Soluble in water and alcohol; weakly bactericidal |
| Mercurial compounds | 0 | ± | Greatly inactivated by organic matter; weakly bactericidal |

¹ Subjective ratings of practical usefulness in a hospital environment: 4 is maximal usefulness; 0 is little or no usefulness; ± signifies that the substance is sometimes useful.

bactericidal). There are a few exceptions. In some hospitals, a 1% solution of silver nitrate is added to the eyes of infants to prevent ophthalmic gonorrhea. Silver sulfadiazine is used on burns. Copper sulfate is an effective algicide in lakes and swimming pools. Heavy metals combine with proteins, often with their sulfhydryl groups, and inactivate them. They may also precipitate cell proteins.  *Gonorrhea* (section 39.3)

Quaternary Ammonium Compounds

Quaternary ammonium compounds are detergents that have broad spectrum antimicrobial activity and are effective disinfectants used for decontamination purposes. **Detergents** (Latin

detergere, to wipe away) are organic cleansing agents that are amphipathic, having both polar hydrophilic and nonpolar hydrophobic components. The hydrophilic portion of a quaternary ammonium compound is a positively charged quaternary nitrogen; thus quaternary ammonium compounds are cationic detergents. Their antimicrobial activity is the result of their ability to disrupt microbial membranes; they may also denature proteins.

Cationic detergents such as benzalkonium chloride and cetylpyridinium chloride kill most bacteria but not *M. tuberculosis* or spores. They have the advantages of being stable and nontoxic, but they are inactivated by hard water and soap. Cationic detergents are often used as disinfectants for food utensils and small instruments, and as skin antiseptics.

Figure 8.10 Disinfectants and Antiseptics. The structures of some frequently used disinfectants and antiseptics.

MICRO INQUIRY Why is it important that all of these compounds are relatively hydrophobic?

Aldehydes

Both of the commonly used aldehydes, formaldehyde and glutaraldehyde (figure 8.10), are highly reactive molecules that combine with nucleic acids and proteins, and inactivate them, probably by cross-linking and alkylating molecules (figure 8.11). They are sporicidal and can be used as chemical sterilants. Formaldehyde is usually dissolved in water or alcohol before use. A 2% buffered solution of glutaraldehyde is an effective disinfectant. It is less irritating than formaldehyde and is used to disinfect hospital and laboratory equipment. Glutaraldehyde usually disinfects objects within about 10 minutes but may require as long as 12 hours to destroy all spores.

Sterilizing Gases

Many heat-sensitive items such as disposable plastic Petri dishes and syringes, heart-lung machine components, sutures, and catheters are sterilized with ethylene oxide gas (figure 8.10). Ethylene oxide (EtO) is both microbicidal and sporicidal. It is a very strong alkylating agent that kills by reacting with functional groups of DNA and proteins to block replication and enzymatic activity. It is a particularly effective sterilizing agent because it rapidly penetrates packing materials, even plastic wraps.

Sterilization is carried out in an ethylene oxide sterilizer, which resembles an autoclave in appearance. It controls the EtO concentration, temperature, and humidity (figure 8.12). Because pure EtO is explosive, it is usually supplied in a 10 to 20% concentration mixed with either CO_2 or dichlorodifluoromethane. The EtO concentration, humidity, and temperature influence the rate of sterilization. A clean object can be sterilized if treated for 5 to 8 hours at 38°C or 3 to 4 hours at 54°C when the relative humidity is maintained at 40 to 50% and the EtO concentration at 700 mg/L. Because it is so toxic to humans, extensive aeration of the sterilized materials is necessary to remove residual EtO.

Betapropiolactone (BPL) is occasionally employed as a sterilizing gas. In the liquid form, it has been used to sterilize vaccines and blood products. BPL decomposes to an inactive form after several hours and is therefore not as difficult to eliminate as EtO. It also destroys microorganisms more readily than ethylene oxide but does not penetrate materials well and may be carcinogenic. For these reasons, BPL has not been used as extensively as EtO.

Vaporized hydrogen peroxide (VHP) can also be used to decontaminate biological safety cabinets, operating rooms, and other large facilities. VHP is produced from a solution of hydrogen peroxide in water that is passed over a vaporizer to achieve a vapor concentration between 140 and 1,400 parts per million

(ppm), depending on the agent to be destroyed. VHP is then introduced as a sterilizing vapor into the enclosure for some time, depending on the size of the enclosure and the materials within. Hydrogen peroxide and its oxy-radical by-products are toxic (75 ppm are dangerous to human health) and kill a wide variety of microorganisms. During the course of the decontamination process, VHP breaks down to water and oxygen, both of which are harmless. Other advantages of VHP are that it can be used at a wide range of temperatures (4 to 80°C) and does not damage most nonliving materials.

Figure 8.11 Effects of Glutaraldehyde. Glutaraldehyde polymerizes and then interacts with amino acids in proteins (left) or in peptidoglycan (right). As a result, the proteins are alkylated and cross-linked to other proteins, which inactivates them. The amino groups in peptidoglycan are also alkylated and cross-linked, which prevents them from participating in other chemical reactions such as those involved in peptidoglycan synthesis.

MICRO INQUIRY Why are cross-linking agents such as glutaraldehyde often called “fixatives” or are said to “fix the cells”?

Retrieve, Infer, Apply

1. Why are most antimicrobial chemical agents disinfectants rather than sterilants? What general characteristics should one look for in a disinfectant?
2. Construct a table that compares the chemical nature, mechanism of action, mode of application, common uses and effectiveness, and advantages and disadvantages between: phenolics, alcohols, halogens, heavy metals, quaternary ammonium compounds, aldehydes, and ethylene oxide.
3. Which disinfectants or antiseptics would be used to treat the following: laboratory bench top, drinking water, patch of skin before surgery, small medical instruments (probes, forceps, etc.)? Explain your choices.
4. How do phenolic agents differ from the other chemical control agents described in this chapter?
5. Which physical or chemical agent would be the best choice for sterilizing the following items: glass pipettes, tryptic soy broth tubes, nutrient agar, antibiotic solution, interior of a biological safety cabinet, wrapped package of plastic Petri plates? Explain your choices.

(a)

(b)

Figure 8.12 An Ethylene Oxide Sterilizer. (a) An automatic ethylene oxide (EtO) sterilizer. (b) Schematic of an EtO sterilizer. Items to be sterilized are placed in the chamber, and EtO and carbon dioxide are introduced. After the sterilization procedure is completed, the EtO and carbon dioxide are pumped out of the chamber and air enters.

8.6 Evaluation of Antimicrobial Agent Effectiveness

After reading this section, you should be able to:

- Predict the effects of (1) microbial population size and composition, (2) temperature, (3) exposure time, and (4) local environmental conditions on antimicrobial agent effectiveness
- Describe the processes used to measure microbial killing rates, dilution testing, and in-use testing of antimicrobial agents

The assessment of antimicrobial agent effectiveness is a complex process regulated by two different federal agencies. The Environmental Protection Agency regulates disinfectants, whereas agents used on humans and animals are under the control of the Food and Drug Administration. They establish the guidelines under which effectiveness of agents is measured. Importantly, there are a number of variables that must also be considered when evaluating antimicrobial agent effectiveness.

Destruction of microorganisms and inhibition of microbial growth are not simple matters because the effectiveness of an antimicrobial agent (an agent that kills microorganisms or inhibits their growth) is affected by at least six factors.

1. **Population size.** Because an equal fraction of a microbial population is killed during each interval, a larger population requires a longer time to die than does a smaller one (table 8.1 and figure 8.3).
2. **Population composition.** The effectiveness of an agent varies greatly with the nature of the organisms being treated because microorganisms differ markedly in susceptibility. Bacterial spores are much more resistant to most antimicrobial agents than are vegetative forms, and younger cells are usually more readily destroyed than mature organisms. Some species are able to withstand adverse conditions better than others. For instance, *M. tuberculosis*, which causes tuberculosis, is much more resistant to antimicrobial agents than most other bacteria.
3. **Concentration or intensity of an antimicrobial agent.** Often, but not always, the more concentrated a chemical agent or intense a physical agent, the more rapidly microorganisms are destroyed. However, agent effectiveness usually is not directly related to concentration or intensity. Over a short range, a small increase in concentration leads to an exponential rise in effectiveness; beyond a certain point, increases may not raise the killing rate much at all. Sometimes an agent is more effective at lower concentrations. For example, 70% ethanol is more bacteriocidal than 95% ethanol because the activity of ethanol is enhanced by the presence of water.
4. **Contact time.** The longer a population is exposed to a microbicidal agent, the more organisms are killed (figures 8.2 and 8.3). To achieve sterilization, contact time should be long enough to reduce the probability of survival by at least 6 logs.
5. **Temperature.** An increase in the temperature at which a chemical acts often enhances its activity. Frequently a lower concentration of disinfectant or sterilizing agent can be used at a higher temperature.
6. **Local environment.** The population to be controlled is not isolated but surrounded by environmental factors that may either offer protection or aid in its destruction. For example, because heat kills more readily at an acidic pH, acidic foods and beverages such as fruits and tomatoes are easier to pasteurize than more alkaline foods such as milk. A second important environmental factor is organic

matter, which can protect microorganisms against physical and chemical disinfecting agents. Biofilms are a good example. The organic matter in a biofilm protects the biofilm's microorganisms. Furthermore, it has been clearly documented that bacteria in biofilms are altered physiologically, and this makes them less susceptible to many antimicrobial agents. Because of the impact of organic matter, it may be necessary to clean objects, especially medical and dental equipment, before they are disinfected or sterilized. ◀◀ *Biofilms (section 7.4)*

The actual testing of antimicrobial agents often begins with an initial screening to see if they are effective and at what concentrations. This may be followed by more realistic in-use testing. The best-known disinfectant screening test is the **phenol coefficient test** in which the potency of a disinfectant is compared with that of phenol. A series of dilutions of phenol and the disinfectant being tested are prepared. Standard amounts of *Salmonella enterica* serovar Typhi and *Staphylococcus aureus* are added to each dilution; the dilutions are then placed in a 20 or 37°C water bath. At 5-minute intervals, samples are withdrawn from each dilution and used to inoculate a growth medium, which is incubated and examined for growth. Growth in the medium indicates that the dilution at that particular time of sampling did not kill the bacteria. The highest dilution (i.e., the lowest concentration) that kills the bacteria after a 10-minute exposure but not after 5 minutes is used to calculate the phenol coefficient. The higher the phenol coefficient value, the more effective the disinfectant under these test conditions. A value greater than 1 means that the disinfectant is more effective than phenol.

The phenol coefficient test is a useful initial screening procedure, but the phenol coefficient can be misleading if taken as a direct indication of disinfectant potency during normal use. This is because the phenol coefficient is determined under carefully controlled conditions with pure bacterial cultures, whereas disinfectants are normally used on complex populations in the presence of organic matter and with significant variations in environmental factors such as pH, temperature, and presence of salts.

To more realistically estimate disinfectant effectiveness, other tests are often used. The rates at which selected bacteria are destroyed with various chemical agents may be experimentally determined and compared. A **use dilution test** can also be carried out. Stainless steel carriers are contaminated with one of three specific bacterial species under carefully controlled conditions. The carriers are dried briefly, immersed in the test disinfectants for 10 minutes, transferred to culture media, and incubated for 2 days. The disinfectant concentration that kills the bacteria on at least 59 out of 60 carriers (a 95% level of confidence) is determined. Disinfectants also can be tested under conditions designed to simulate normal in-use situations. In-use testing techniques allow a more accurate determination of the proper disinfectant concentration for a particular situation.

Retrieve, Infer, Apply

1. Briefly explain how the effectiveness of antimicrobial agents varies with population size, population composition, concentration or intensity of the agent, contact time, temperature, and local environmental conditions.
2. How does being in a biofilm affect an organism's susceptibility to antimicrobial agents?
3. Suppose hospital custodians have been assigned the task of cleaning all showerheads in patient rooms to prevent the spread of infectious disease. What two factors would have the greatest impact on the effectiveness of the disinfectant the custodians use? Explain what that impact would be.
4. Briefly describe the phenol coefficient test.
5. Why might it be necessary to employ procedures such as the use dilution and in-use tests?

8.7 Biological Control of Microorganisms

After reading this section, you should be able to:

- Propose predation, competition, and other methods for biological control of microorganisms that infect humans
- Suggest alternative decontamination and medical therapies using viruses of bacteria, fungi, and protozoa

The emerging field of biological control of microorganisms demonstrates great promise. Scientists are learning to exploit natural control processes such as predation of one microorganism on another, viral-mediated lysis, and toxin-mediated killing. While these control mechanisms occur in nature, their approval and use by humans is relatively new. Studies evaluat-

ing control of the human intestinal pathogens *Salmonella* spp., *Shigella* spp., and *E. coli* by Gram-negative predators such as *Bdellovibrio* spp. suggest that poultry farms may be sprayed with the predator to reduce potential contamination. Another biological control method had its start in the early 1900s at the Pasteur Institute in France. Felix d'Herelle isolated bacteriophage from patients recovering from bacillary dysentery. After numerous tests in vitro, d'Herelle concluded that the bacteriophage participated in the destruction of the bacteria causing dysentery. Bacteriophage therapies were well on the way of development when penicillin ushered in the age of antibiotics. The control of human pathogens using bacteriophage is regaining wide support and appears to be effective in the eradication of a number of bacterial species by lysing the pathogenic host. It is well known today that the phage produce lytic enzymes (lysins) that attack bacterial cell walls, facilitating their release from their specific bacterial host. A large research effort is underway to evaluate phage and phage lysins as bacterial control methods. This seems intuitive, knowing that the virus lyses its specific bacterial host, yet unnerving when one thinks about maybe swallowing, injecting, or applying a virus (albeit a bacteriophage) to the human body. The use of microbial toxins (such as bacteriocins) to control susceptible populations suggests yet another method for potential control of other microorganisms.

◀◀ *Viruses and other acellular infectious agents (chapter 6);*

Retrieve, Infer, Apply

1. How would you explain to a patient that a virus can be used to eliminate a bone infection caused by bacteria that do not respond to antibiotics?
2. Propose the use of specific bacterial, viral, or fungal products that might be used to kill other, more virulent bacteria, viruses, or fungi.

Key Concepts

8.1 Principles of Microbial Control

- Sterilization is the process by which all living cells, viable spores, viruses, viroids, and prions are either destroyed or removed from an object or habitat. Disinfection is the killing, inhibition, or removal of microorganisms (but not necessarily endospores) that can cause disease.
- The main goal of disinfection and antisepsis is the removal, inhibition, or killing of pathogenic microbes. Both processes also reduce the total number of microbes. Disinfectants are chemicals used to disinfect inanimate objects; antiseptics are used on living tissue.
- Antimicrobial agents that kill organisms often have the suffix *-cide*, whereas agents that prevent growth and reproduction have the suffix *-static*.

8.2 The Pattern of Microbial Death

- Microbial death is usually exponential or logarithmic (**figure 8.3**).
- The decimal reduction time measures an agent's killing efficiency. It represents the time needed to kill 90% of the microbes under specified conditions.

8.3 Mechanical Removal Methods

- Microorganisms can be efficiently removed by filtration with either depth filters or membrane filters (**figure 8.4**).
- Biological safety cabinets with high-efficiency particulate filters sterilize air by filtration (**figure 8.6**).

8.4 Physical Control Methods

- Moist heat kills by degrading nucleic acids, denaturing enzymes and other proteins, and disrupting cell membranes.
- Although treatment with boiling water for 10 minutes kills vegetative forms, an autoclave must be used to destroy endospores by heating at 121°C and 15 pounds of pressure (figure 8.7).
- Glassware and other heat-stable items may be sterilized by dry heat at 160 to 170°C for 2 to 3 hours.
- Radiation of short-wavelength or high-energy ultraviolet and ionizing radiation can be used to sterilize objects (figure 8.9).

8.5 Chemical Control Agents

- Chemical agents usually act as disinfectants or antiseptics because they cannot readily destroy bacterial spores. Disinfectant effectiveness depends on concentration, treatment duration, temperature, and presence of organic material (tables 8.3 and 8.4).
- Phenolics and alcohols are popular disinfectants and antiseptics that act by denaturing proteins and disrupting cell membranes (figure 8.10).
- Halogens (iodine and chlorine) kill by oxidizing cellular constituents; cell proteins may also be iodinated. Iodine is applied as a tincture or iodophor. Chlorine may be added to water as a gas, hypochlorite, or an organic chlorine derivative.
- Heavy metals tend to be bacteriostatic agents. They are employed in specialized situations such as the use of silver nitrate in the eyes of newborn infants and copper sulfate in lakes and pools.

- Cationic detergents (e.g., quaternary ammonium compounds) are often used as disinfectants and antiseptics; they disrupt membranes and denature proteins.
- Aldehydes such as formaldehyde and glutaraldehyde can sterilize as well as disinfect because they kill spores.
- Ethylene oxide gas penetrates plastic wrapping material and destroys all life forms by reacting with proteins. It is used to sterilize packaged, heat-sensitive materials.
- Vaporized hydrogen peroxide is used to decontaminate enclosed spaces (e.g., safety cabinets and small rooms). The vaporized hydrogen peroxide is a vapor that can be circulated throughout the space. The peroxide and its oxy-radical by-products are toxic to most microorganisms.

8.6 Evaluation of Antimicrobial Agent Effectiveness

- The effectiveness of a disinfectant or sterilizing agent is influenced by population size, population composition, concentration or intensity of the agent, exposure duration, temperature, and nature of the local environment.
- The presence of a biofilm can dramatically alter the effectiveness of an antimicrobial agent.
- The phenol coefficient test is frequently used to evaluate the effectiveness of antimicrobial agents. However, it does so using conditions that do not replicate real-life use.
- Other procedures used to determine the effectiveness of disinfectants include measurement of killing rates with germicides, use dilution testing, and in-use testing.

8.7 Biological Control of Microorganisms

- Control of microorganisms by natural means such as through predation, viral lysis, and toxins is emerging as a promising field.

Compare, Hypothesize, Invent

1. Throughout history, spices have been used as preservatives and to cover up the smell or taste of food that is slightly spoiled. The success of some spices led to a magical, ritualized use, and possession of spices was often limited to priests or other powerful members of the community.
 - a. Choose a spice and trace its use geographically and historically. What is its common use today?
 - b. Spices grow and tend to be used predominantly in warmer climates. Explain.
2. Design an experiment to determine whether an antimicrobial agent is acting as a cidal or static agent. How would you determine whether an agent is suitable for use as an antiseptic rather than as a disinfectant?
3. Suppose you tested the effectiveness of disinfectants with the phenol coefficient test and obtained the results shown in the “Bacterial Growth After Treatment” table. What disinfectant can you safely say is the most effective? Can you determine its phenol coefficient from these results?
4. The death of *Geobacillus stearothermophilus* spores is routinely used to assess the effectiveness of sterilization procedures. In this procedure, endospores are exposed to the sterilization process (e.g., autoclaving) and then plated on germination medium. If sterilization has been successful, no growth occurs. This requires about 2 days. Yung and Ponce have developed a new approach that yields results within 15 minutes after sterilization. Their technique is based on the release of dipicolinic acid (DPA)

Bacterial Growth After Treatment

| Dilution | Disinfectant A | Disinfectant B | Disinfectant C |
|----------|----------------|----------------|----------------|
| 1/20 | — | — | — |
| 1/40 | + | — | — |
| 1/80 | + | — | + |
| 1/160 | + | + | + |
| 1/320 | + | — | + |

from the spore coat by germinating cells. DPA release is monitored microscopically after endospores are placed in media containing alanine and terbium ion (Tb^{3+}). Alanine triggers germination and Tb^{3+} binds DPA, which then fluoresces green when illuminated with UV light. Design an experiment in which this new method could be shown to be as reliable as the culture-based approach. What other sterilization procedures besides autoclaving could this technique be used to monitor?

Antimicrobial Chemotherapy

A Teaspoon of Sugar Helps the Bacteria Go Down

A song in the musical *Mary Poppins* suggests sweetening off-tasting medicine to make it a bit more palatable. Certainly, no one would argue that adding sugar to medications helps to hide the taste. However, adding sugar to antibiotics may also offer a new treatment approach for those who suffer from chronic and recurrent infectious disease. Studies at Boston University have demonstrated that including sugars that activate bacterial metabolism makes biofilm bacteria (such as those found on intravenous and urinary catheters) more susceptible to the action of antibiotics. The studies evaluated “persister” bacteria from biofilms whose metabolic activity is substantially reduced, making them appear to be dormant, as they are not culturable. Many bacteria, including staphylococci, streptococci, mycobacteria, and *Escherichia coli*, become persisters and unresponsive to antibiotics during biofilm development. Persister cells are not necessarily antibiotic-resistant; they haven’t mutated, nor have they acquired antibiotic resistance genes. Persisters are less sensitive to antibiotics because their metabolism is so slow. Using fructose or mannitol, investigators were able to coax persister *E. coli* and *Staphylococcus aureus* cells to increase the activity of their electron transport systems and trick them into importing a lethal antibiotic. The scientists demonstrated that *E. coli* and *S. aureus* persisters were unaffected by gentamicin alone. However, when these biofilm persister cells were treated with sugar and gentamicin together, they were reduced by 99.9%. This novel approach suggests that biofilm persister cells, although dormant, can be stimulated with sugars to increase their metabolism and respiration, and ultimately their membrane transport systems, to take in a common antibiotic that otherwise has no effect on persisters.

As evidenced by the vexing problem of bacterial antibiotic resistance, very few people living in the industrialized West reach adulthood without having taken an antibiotic. But what does the term antibiotic really mean? **Antibiotic** (Greek *anti*, against, and *bios*, life) refers

Many antimicrobial medications are available to combat infections. Nonetheless, they fall into a limited number of classes based on their modes of action.

to microbial products and their derivatives that kill susceptible microorganisms or inhibit their growth. Drugs such as the sulfonamides are sometimes called antibiotics although they are synthetic chemotherapeutic agents. The rise in antibiotic resistance among microbes (discussed in chapter 16) has forced modern medicine to develop new drugs and rethink antimicrobial strategies. This chapter introduces the principles of **antimicrobial chemotherapy** and briefly reviews the characteristics of selected antibacterial, antifungal, antiprotozoan, and antiviral drugs.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Identify the major structures and their functions of bacteria, protists, fungi, and viruses (sections 3.2–3.8, 5.1–5.7, 6.1–6.2, and 7.1–7.7)
- ✓ Compare the various growth and replication processes of viruses and bacteria (sections 6.3, 6.5, and 7.1–7.8)

9.1 The Development of Chemotherapy

After reading this section, you should be able to:

- Trace the general history of antimicrobial chemotherapy
- Propose natural sources of new antimicrobial agents

The modern era of chemotherapy began with the work of the German physician Paul Ehrlich (1854–1915). Ehrlich was fascinated with dyes that specifically bind to microbial cells. He reasoned that one of the dyes could be a chemical that would selectively destroy pathogens without harming human cells—a “magic bullet.” By 1904 Ehrlich found that the dye trypan red was active against the trypanosome that causes African sleeping sickness (see figure 25.6) and could be used therapeutically. Subsequently Ehrlich and a young Japanese scientist named Sahachiro Hata tested a variety of arsenic-based chemicals on syphilis-infected rabbits and found that arsphenamine was active against the syphilis spirochete. Arsphenamine was made available in 1910 under the trade name Salvarsan. Soon

hundreds of compounds were being tested for their selective toxicity and therapeutic potential.

In 1927 Gerhard Domagk screened a vast number of chemicals for other “magic bullets” and discovered that Prontosil red, a new dye for staining leather, protected mice completely against pathogenic streptococci and staphylococci without apparent toxicity. Jacques and Therese Trefouel later showed that the body metabolized the dye to sulfanilamide. Domagk received the 1939 Nobel Prize in Physiology or Medicine for his discovery of sulfonamides, or sulfa drugs.

Penicillin, the first true antibiotic because it is a natural microbial product, was first discovered in 1896 by a twenty-one-year-old French medical student named Ernest Duchesne. His work was forgotten until Alexander Fleming accidentally rediscovered penicillin in 1928. After returning from a weekend vacation, Fleming noticed that a Petri plate of staphylococci also had mold growing on it and there were no bacterial colonies surrounding it (**figure 9.1**). Although the precise events are still unclear, it has been suggested that a *Penicillium notatum* spore had contaminated the Petri dish before it had been inoculated with the staphylococci. The mold apparently grew before the bacteria and produced penicillin. The bacteria nearest the fungus were lysed. Fleming correctly deduced that the mold produced a diffusible substance, which he called penicillin. Unfortunately, Fleming could not demonstrate that penicillin remained active in vivo long enough to destroy pathogens and he dropped the research.

In 1939 Howard Florey and Ernst Chain, professors at Oxford University, obtained the *Penicillium* culture from Fleming and set about purifying the antibiotic. Norman Heatley, a biochemist, was enlisted to help. He devised the original assay, culture, and purification techniques needed to produce crude penicillin for further experimentation. When purified penicillin was injected into mice infected with streptococci or staphylococci, almost all the mice survived. Florey and Chain's success was reported in 1940, and subsequent human trials were equally successful.

Fleming, Florey, and Chain received the Nobel Prize in 1945 for the discovery and production of penicillin.

The discovery of penicillin stimulated the search for other antibiotics. Selman Waksman, while at Rutgers University, announced in 1944 that he and his associates had found a new

antibiotic, streptomycin, produced by *Streptomyces griseus* (see **figure 24.15**). This discovery arose from the careful screening of about 10,000 strains of soil bacteria and fungi. The importance of streptomycin cannot be understated, as it was the first drug to successfully treat tuberculosis. Waksman received the Nobel Prize in 1952, and his success led to a worldwide search for other antibiotic-producing soil microorganisms. Chloramphenicol, neomycin, oxytetracycline, and tetracycline were isolated from other *Streptomyces* species by 1953 (see **table 24.3**).

Retrieve, Infer, Apply

1. Why would a mold secrete an antibiotic?
2. Louis Pasteur is often credited with saying, “Chance favors the prepared mind.” How does this apply to Fleming?

9.2 General Characteristics of Antimicrobial Drugs

After reading this section, you should be able to:

- Explain the difference between a narrow and broad-spectrum drug
- Correlate drug action with cidal and static effects

As Ehrlich so clearly saw, a successful chemotherapeutic agent has **selective toxicity**: it kills or inhibits the microbial pathogen while damaging the host as little as possible. The degree of selective toxicity may be expressed in terms of (1) the therapeutic dose—the drug level required for clinical treatment of a particular infection, and (2) the toxic dose—the drug level at which the agent becomes too toxic for the host. The **therapeutic index** is the ratio of the toxic dose to the therapeutic dose. The larger the therapeutic index, the better the chemotherapeutic agent in general.

A drug that disrupts a microbial structure or function not found in host cells often has greater selective toxicity and a higher therapeutic index. For example, penicillin inhibits bacterial cell wall peptidoglycan synthesis but has little effect on host cells because they lack cell walls; therefore penicillin's therapeutic index is high. A drug may have a low therapeutic index because it inhibits the same process in host cells or damages the host in other ways. The undesirable effects on the host, or side effects, are of many kinds and may involve almost any organ system. Because side effects can be severe, chemotherapeutic agents must be administered with great care.

Some bacteria and fungi naturally produce many of the commonly employed antibiotics (**table 9.1**). In contrast, several important chemotherapeutic agents, such as sulfonamides, trimethoprim, ciprofloxacin, isoniazid, and dapsone, are synthetic—manufactured by chemical procedures independent of microbial activity. Some antibiotics are semisynthetic—natural antibiotics that have been structurally modified by the addition of chemical groups to make them less susceptible to stomach acids and inactivation by pathogens (e.g., ampicillin and methicillin).

Figure 9.1 Bacteriocidal Action of Penicillin. The *Penicillium* mold colony secretes penicillin that kills the *Staphylococcus aureus* streaked nearby.

Table 9.1 Properties of Some Common Antibacterial Drugs

| Antibiotic Group | Primary Effect | Mechanism of Action | Members | Spectrum | Common Side Effects |
|--|----------------|---|--|---|---|
| Cell Wall Synthesis Inhibition | | | | | |
| Penicillins | Cidal | Inhibit transpeptidation enzymes involved in cross-linking the polysaccharide chains of peptidoglycan Activate cell wall lytic enzymes | Penicillin G, penicillin V, methicillin Ampicillin, carbenicillin | Narrow (Gram-positive) Broad (Gram-positive, some Gram-negative) | Allergic reactions (diarrhea, anemia, hives, nausea, renal toxicity) |
| Cephalosporins | Cidal | Same as above | Cephalothin, cefoxitin, cefaperazone, ceftriaxone | Broad (Gram-positive, some Gram-negative) | Allergic reactions, thrombophlebitis, renal injury |
| Vancomycin | Cidal | Prevents transpeptidation of peptidoglycan subunits by binding to D-Ala-D-Ala amino acids at the end of peptide side chains. Thus it has a different binding site than that of the penicillins. | Vancomycin | Narrow (Gram-positive) | Ototoxic (tinnitus and deafness), nephrotoxic, allergic reactions |
| Protein Synthesis Inhibition | | | | | |
| Aminoglycosides | Cidal | Bind to small ribosomal subunit (30S) and interfere with protein synthesis by directly inhibiting synthesis and causing misreading of mRNA | Neomycin, kanamycin, gentamicin Streptomycin | Broad (Gram-negative, mycobacteria) Narrow (aerobic Gram-negative) | Ototoxic, renal damage, loss of balance, nausea, allergic reactions |
| Tetracyclines | Static | Same as aminoglycosides | Oxytetracycline, chlortetracycline | Broad (including rickettsia and chlamydia) | Gastrointestinal upset, teeth discoloration, renal and hepatic injury |
| Macrolides | Static | Bind to 23S rRNA of large ribosomal subunit (50S) to inhibit peptide chain elongation during protein synthesis | Erythromycin, clindamycin | Broad (aerobic and anaerobic Gram-positive, some Gram-negative) | Gastrointestinal upset, hepatic injury, anemia, allergic reactions |
| Chloramphenicol | Static | Same as macrolides | Chloramphenicol | Broad (Gram-positive and -negative, rickettsia and chlamydia) | Depressed bone marrow function, allergic reactions |
| Nucleic Acid Synthesis Inhibition | | | | | |
| Quinolones and Fluoroquinolones | Cidal | Inhibit DNA gyrase and topoisomerase II, thereby blocking DNA replication | Norfloxacin, ciprofloxacin, Levofloxacin | Narrow (Gram-negatives better than Gram-positives) Broad spectrum | Tendonitis, headache, light-headedness, convulsions, allergic reactions |
| Rifampin | Cidal | Inhibits bacterial DNA-dependent RNA polymerase | R-Cin, rifacilin, rifamycin, rimactane, rimpin, siticox | <i>Mycobacterium</i> infections and some Gram-negatives (e.g., <i>Neisseria meningitidis</i> and <i>Haemophilus influenzae</i> b) | Nausea, vomiting, diarrhea, fatigue, anemia, drowsiness, headache, mouth ulceration, liver damage |

Continued

Table 9.1 Properties of Some Common Antibacterial Drugs (*continued*)

| Cell Membrane Disruption | | | | | |
|--------------------------|--|---|---|---|---|
| Polymyxin B | Cidal | Binds to plasma membrane and disrupts its structure and permeability properties | Polymyxin B, polymyxin topical ointment | Narrow—mycobacterial infections, principally leprosy | Can cause severe kidney damage, drowsiness, dizziness |
| Antimetabolites | | | | | |
| Sulfonamides | Static | Inhibit folic acid synthesis by competing with <i>p</i> -aminobenzoic acid (PABA) | Silver sulfadiazine, sulfamethoxazole, sulfanilamide, sulfasalazine | Broad spectrum | Nausea, vomiting, and diarrhea; hypersensitivity reactions such as rashes, photosensitivity |
| Trimethoprim | Static | Blocks folic acid synthesis by inhibiting the enzyme tetrahydrofolate reductase | Trimethoprim (in combination with a sulfamethoxazole) | Broad spectrum | Same as sulfonamides but less frequent |
| Dapsone | Static | Thought to interfere with folic acid synthesis | Dapsone | Narrow—mycobacterial infections, principally leprosy | Back, leg, or stomach pains; discolored fingernails, lips, or skin; breathing difficulties, fever, loss of appetite, skin rash, fatigue |
| Isoniazid | Cidal if bacteria are actively growing, static if bacteria are dormant | Exact mechanism is unclear but thought to inhibit lipid synthesis (especially mycolic acid); putative enoyl-reductase inhibitor | Isoniazid | Narrow—mycobacterial infections, principally tuberculosis | Nausea, vomiting, liver damage, seizures, “pins and needles” in extremities (peripheral neuropathy) |

Drugs vary considerably in their range of effectiveness. Many are **narrow-spectrum drugs**; that is, they are effective only against a limited variety of pathogens (table 9.1). Others are **broad-spectrum drugs** that attack many different kinds of bacteria. In addition, many semisynthetic drugs have a broader spectrum of antibiotic activity than does their parent molecule. This is particularly true of the semisynthetic penicillins (e.g., ampicillin, amoxicillin) as compared to the naturally produced penicillin G and penicillin V. Drugs may also be classified based on the general microbial group they act against: antibacterial, antifungal, antiprotozoan, and antiviral. A few agents can be used against more than one group; for example, sulfonamides are active against bacteria and some protozoa. Finally, chemotherapeutic agents can be either **cidal** or **static**. Static agents reversibly inhibit growth; if the agent is removed, the microorganisms will recover and grow again. **Senescence and death** (section 7.6)

Although a cidal agent kills the target pathogen, it may be static at low levels. The effect of an agent also varies with the target species: an agent may be cidal for one species and static for another. Because static agents do not directly destroy the pathogen, elimination of the infection depends on

the host’s own immunity mechanisms. A static agent may not be effective if the host is immunosuppressed. Some idea of the effectiveness of a chemotherapeutic agent against a pathogen can be obtained from the **minimal inhibitory concentration (MIC)**. The MIC is the lowest concentration of a drug that prevents growth of a particular pathogen. On the other hand, the **minimal lethal concentration (MLC)** is the lowest drug concentration that kills the pathogen. A cidal drug generally kills pathogens at levels only two to four times the MIC, whereas a static agent kills at much higher concentrations, if at all.

Retrieve, Infer, Apply

1. Define the following: selective toxicity, therapeutic index, side effect, narrow-spectrum drug, broad-spectrum drug, synthetic and semisynthetic antibiotics, cidal and static agents, minimal inhibitory concentration, and minimal lethal concentration.
2. How do semisynthetic antibiotics commonly differ from their parent molecules?
3. Use the MIC and MLC concepts to distinguish between cidal and static agents.

9.3 Determining the Level of Antimicrobial Activity

After reading this section, you should be able to:

- Explain how to determine the level of antibacterial drug activity using the dilution susceptibility test, the disk diffusion test, and the Etest®
- Predict antimicrobial drug levels in vivo from in vitro data

Determination of antimicrobial effectiveness against specific pathogens is essential for proper therapy. Testing can show which agents are most effective against a pathogen and give an estimate of the proper therapeutic dose.

Dilution Susceptibility Tests

Dilution susceptibility tests can be used to determine MIC and MLC values. Antibiotic dilution tests can be done in both agar and broth. In the broth dilution test, a series of broth tubes (usually Mueller-Hinton broth) containing antibiotic concentrations in the range of 0.1 to 128 µg per milliliter (two-fold dilutions) is inoculated with a standard density of the test organism. The lowest concentration of the antibiotic resulting in no growth after 16 to 20 hours of incubation is the MIC. The MLC can be ascertained if the tubes showing no growth are then cultured into fresh medium lacking antibiotic. The lowest antibiotic concentration from which the microorganisms do

not subsequently grow is the MLC. The agar dilution test is very similar to the broth dilution test. Plates containing Mueller-Hinton agar and various amounts of antibiotic are inoculated and examined for growth. Several automated systems for susceptibility testing and MIC determination with broth or agar cultures have been developed.

Disk Diffusion Tests

If a rapidly growing microbe such as the Gram-positive *Staphylococcus* or the Gram-negative *Pseudomonas* is being tested, a disk diffusion technique may be used to save time and media. The principle behind this assay is fairly simple. When an antibiotic-impregnated, paper disk is placed on agar previously inoculated with the test bacterium, the antibiotic diffuses radially outward through the agar, producing an antibiotic concentration gradient. The antibiotic is present at high concentrations near the disk and affects even minimally susceptible microorganisms; whereas, resistant organisms will grow up to the disk. As the distance from the disk increases, the antibiotic concentration decreases and only more susceptible pathogens are harmed. A clear zone or ring forms around an antibiotic disk after incubation if the agent inhibits bacterial growth. The wider the zone surrounding a disk, the more susceptible the pathogen is. Zone width also is a function of the antibiotic's initial concentration, its solubility, and its diffusion rate through agar. Thus zone width cannot be used to compare directly the effectiveness of different antibiotics.

The **Kirby-Bauer method** is the disk diffusion test most often used. It was developed in the early 1960s by William Kirby, A. W. Bauer, and their colleagues. Freshly grown bacteria are used to inoculate the entire surface of a Mueller-Hinton agar plate. After the agar surface has dried for about 5 minutes, the appropriate antibiotic test disks are placed on it, either with sterilized forceps or with a multiple applicator device (**figure 9.2**). After 16 to 18 hours of incubation at 35°C, the diameters of the zones of inhibition are measured to the nearest millimeter.

Kirby-Bauer test results are interpreted using a table that relates zone diameter to the degree of microbial resistance (**table 9.2**). The values in table 9.2 were derived by finding the MIC values and zone diameters for many different microbial species. A plot of MIC (on a logarithmic scale) versus zone inhibition

The Kirby-Bauer Method. (a) A

multiple antibiotic disk dispenser and (b) disk diffusion test results.

Table 9.2 Inhibition Zone Diameter of Selected Chemotherapeutic Drugs

| Chemotherapeutic Drug | Disk Content | ZONE DIAMETER (NEAREST MM) | | |
|--|-------------------|----------------------------|--------------|-------------|
| | | Resistant | Intermediate | Susceptible |
| Carbenicillin (with <i>Proteus</i> spp. and <i>E. coli</i>) | 100 µg | ≤17 | 18–22 | ≥23 |
| Carbenicillin (with <i>Pseudomonas aeruginosa</i>) | 100 µg | ≤13 | 14–16 | ≥17 |
| Erythromycin | 15 µg | ≤13 | 14–17 | ≥18 |
| Penicillin G (with staphylococci) | 10 U ¹ | ≤20 | 21–28 | ≥29 |
| Penicillin G (with other microorganisms) | 10 U | ≤11 | 12–21 | ≥22 |
| Streptomycin | 10 µg | ≤11 | 12–14 | ≥15 |
| Sulfonamides | 250 or 300 µg | ≤12 | 13–16 | ≥17 |

¹ One milligram of penicillin G sodium = 1,600 units (U).

Figure 9.3 Interpretation of Kirby-Bauer Test Results. The relationship between the MICs of a hypothetical drug and the size of the zone around a disk in which microbial growth is inhibited is plotted to predict drug effectiveness. As the sensitivity of microorganisms to the drug increases, the MIC value decreases and the inhibition zone grows larger. Suppose that this drug varies from 7 to 28 µg/mL in the body during treatment. Dashed line A shows that any pathogen with a zone of inhibition less than 12 mm in diameter will have an MIC value greater than 28 µg/mL and will be resistant to drug treatment. A pathogen with a zone diameter greater than 17 mm will have an MIC less than 7 µg/mL and will be sensitive to the drug (see line B). Zone diameters between 12 and 17 mm indicate intermediate sensitivity and usually signify resistance.

diameter (arithmetic scale) is prepared for each antibiotic (figure 9.3). These plots are then used to find the zone diameters corresponding to the drug concentrations actually reached in the body. If the zone diameter for the lowest level reached in the body is smaller than that seen with the test pathogen, the patho-

gen should have an MIC value low enough to be destroyed by the drug. A pathogen with too high an MIC value (too small a zone diameter) is resistant to the agent at concentrations that can normally be achieved in the body.

The Etest®

The Etest® from bioMérieux S.A. may be used in sensitivity testing under a majority of conditions. It is particularly convenient for use with anaerobic pathogens that grow relatively poorly in broth culture but quite well on agar. Thus agar-grown anaerobes that would not be evaluated by the Kirby-Bauer method (broth culture transferred to plates) can be tested for antimicrobial sensitivity by directly applying the Etest® strips to anaerobe-inoculated agar plates. In general, bacteria to be tested for antimicrobial sensitivities are individually inoculated on the entire surface of an agar medium and then Etest® strips are placed on the surface so that they extend out radially from the center (figure 9.4). Each strip contains a gradient of an antibiotic and is labeled with a scale of MIC values. The lowest concentration in the strip lies at the center of the plate. After 24 to 48 hours of incubation, an elliptical zone of inhibition appears. As shown in figure 9.4, MICs are determined from the point of intersection between the inhibition zone and the strip's scale of MIC values.

1. How can dilution susceptibility tests and disk diffusion tests be used to determine microbial drug sensitivity?
2. Briefly describe the Kirby-Bauer test and its purpose.
3. What would you surmise if you examined a Kirby-Bauer assay and found individual colonies of the plated microbe growing within the zone of inhibition?
4. How is the Etest® carried out? When might it be used instead of the Kirby-Bauer test?

Figure 9.4 Etest®. An example of a bacterial culture plate with Etest® strips arranged in a radial pattern with the concentration minimum at the center of the plate. The MIC value is read at the point where the inhibition ellipse intersects the scale on the strip, as shown by the arrow in this example. Etest® is a registered trademark of bioMérieux S.A. or one of its subsidiaries.

MICRO INQUIRY Based on these zones of diffusion, which Etest® strip contains the most effective antibiotic against this microbe? Which is the least effective?

9.4 Antibacterial Drugs

After reading this section, you should be able to:

- Compare antibacterial drug mechanisms of action
- Correlate lack of microbial growth with selective toxicity
- Relate side effect toxicity of antibacterial drugs to mechanism of action
- Explain the relative effectiveness of various antibacterial agents based on drug target

Since Fleming's discovery of penicillin, many antibiotics have been discovered. However, most antibiotics fall into a limited number of classes. Part of the challenge in developing new antibiotics is to find bacterial structures or processes not already targeted. These novel targets have the best chance of beating antimicrobial resistance, at least for a while. Here we present some of the more common antibiotics according to their functional/structural class.

Inhibitors of Cell Wall Synthesis

The most selective antibiotics are those that interfere with bacterial cell wall synthesis. Drugs such as penicillins, cephalosporins, vancomycin, and bacitracin have a high therapeutic index because they target structures and functions not found in eukaryotic cells. ❖❖ *Bacterial cell walls* (section 3.4)

Penicillins

Most penicillins (e.g., penicillin G or benzylpenicillin) are derivatives of 6-aminopenicillanic acid and differ from one another with respect to the side chain attached to the amino group (figure 9.5). The most crucial feature of the molecule is the **β -lactam ring**, which is essential for bioactivity. Many penicillin-resistant bacteria produce **penicillinases** (also called **β -lactamases**), enzymes that inactivate the antibiotic by hydrolyzing a bond in the β -lactam ring.

The structure of the penicillins resembles the terminal D-alanyl-D-alanine found on the peptide side chain of the peptidoglycan subunit. It is thought that this structural similarity blocks the enzyme catalyzing the transpeptidation reaction that forms the peptidoglycan cross-links (see figure 12.10). Thus formation of a complete cell wall is blocked, leading to osmotic lysis. This mechanism is consistent with the observation that penicillins act only on growing bacteria that are synthesizing new peptidoglycan. However, the mechanism of penicillin action is actually more complex. Penicillins also bind to several periplasmic proteins (penicillin-binding proteins, or PBPs) and may also destroy bacteria by activating their own autolytic enzymes. Penicillin may also stimulate proteins called bacterial holins to form holes or lesions in the plasma membrane, leading directly to membrane leakage and cell death.

Penicillins differ from each other in several ways. The two naturally occurring penicillins, penicillin G and penicillin V, are narrow-spectrum drugs (figure 9.5). Penicillin G is effective against bacteria that cause gonorrhea and some cases of meningitis (the Gram-negative *Neisseria gonorrhea* and *N. meningitis*, respectively), as well as Gram-positive pathogens such as streptococci and staphylococci. However, because of increasing resistance, the Centers for Disease Control and Prevention (CDC) recommends treating gonorrhea with an additional antibiotic. Penicillin G must be administered by injection (parenterally) because it is destroyed by stomach acid. Penicillin V is similar to penicillin G in spectrum of activity but can be given orally because it is more resistant to stomach acid. The semisynthetic penicillins have a broader spectrum of activity. Ampicillin can be administered orally and is effective against Gram-negative bacteria such as *Haemophilus* (middle-ear infections), *Salmonella* (gastroenteritis), and *Shigella* (dysentery). Carbenicillin and ticarcillin are potent against *Pseudomonas* and *Proteus* (wound and respiratory infections).

An increasing number of bacteria have become resistant to natural penicillins and many of the semisynthetic analogues. Physicians sometimes prescribe specific semisynthetic penicillins that

Figure 9.5 Penicillins. The structures and characteristics of representative penicillins. All are derivatives of 6-aminopenicillanic acid; in each case, the shaded portion of penicillin G is replaced by the side chain indicated. The β -lactam ring is also shaded (blue).

MICRO INQUIRY What is the difference between penicillin G and penicillin V? How do the semisynthetic penicillins differ from their parent compounds?

are not destroyed by β -lactamases to combat antibiotic-resistant pathogens. These include methicillin (figure 9.5), nafcillin, and oxacillin. However, this practice has been confounded by the emergence of methicillin-resistant bacteria. ►► *Human diseases caused by bacteria (chapter 39)*

Although penicillins are the least toxic of the antibiotics, about 1 to 5% of the adults in the United States develop allergies to them. Occasionally, a person will die of a violent allergic reaction. ►► *Hypersensitivities (section 34.10)*

Cephalosporins

Cephalosporins are a family of antibiotics originally isolated in 1948 from the fungus *Cephalosporium*. They contain a β -lactam structure that is very similar to that of the penicillins (figure 9.6). As might be expected from their structural similarities to penicillins, cephalosporins also inhibit the transpeptidation reaction during peptidoglycan synthesis. They are broad-spectrum drugs frequently given to patients with penicillin allergies; however, about 10% of patients allergic to penicillin are also allergic to cephalosporins.

Vancomycin and Teicoplanin

Vancomycin is a glycopeptide antibiotic produced by the bacterium *Streptomyces orientalis*. It is a cup-shaped molecule composed of a peptide linked to a disaccharide. The peptide portion blocks the transpeptidation reaction by binding specifically to the D-alanyl-D-alanine terminal sequence on the pentapeptide portion of peptidoglycan (figure 9.7). The antibiotic is bactericidal for the Gram-positive bacteria *Staphylococcus* and some members of the genera *Clostridium* (gangrene), *Bacillus* (food poisoning), *Streptococcus* (“strep” throat), and *Enterococcus* (urinary tract infections). It is given both orally and intravenously, and has been particularly important in the treatment of antibiotic-resistant staphylococcal and enterococcal infections. However, vancomycin-resistant strains of *Enterococcus* have become widespread, and cases of resistant *Staphylococcus aureus* have appeared. In these microbes, resistance is conferred when bacteria change the terminal D-alanine to either D-lactate or a D-serine residue, thus altering the target of the antibiotic. Vancomycin resistance poses a serious public health threat: vancomycin has been considered the “drug of last resort” in cases of antibiotic-resistant *S. aureus*. The mechanisms by which microbes acquire antibiotic resistance are discussed in chapter 16.

Teicoplanin, another glycopeptide antibiotic, is produced by *Actinoplanes teichomyceticus*. It is similar in structure and mechanism of action to vancomycin but has fewer side effects. It is active against staphylococci, enterococci, streptococci, clostridia, *Listeria*, and many Gram-positive pathogens. The diseases caused by these microbes are covered in chapter 39.

Protein Synthesis Inhibitors

Many antibiotics inhibit protein synthesis by binding with the bacterial ribosome and other components of protein synthesis. Because these drugs discriminate between bacterial and eukaryotic ribosomes, their therapeutic index is fairly high but not as high as that of cell wall synthesis inhibitors. Several different steps in protein synthesis can be affected by drugs in this category. ►► *Translation in bacteria (section 13.7)*

Figure 9.6 Cephalosporin Antibiotics. These drugs are derivatives of 7-aminocephalosporanic acid and contain a β -lactam ring.

MICRO INQUIRY Do you think cephalosporin antibiotics are susceptible to degradation by β -lactamase enzymes? Explain.

Figure 9.7 Vancomycin. The cup-shaped vancomycin molecule binds to the D-alanyl-D-alanine terminal sequence of peptidoglycan.

Aminoglycosides

Although considerable variation in structure occurs among several important **aminoglycoside antibiotics**, all contain a cyclohexane ring and amino sugars (**figure 9.8a**). Streptomycin, kanamycin, neomycin, and tobramycin are synthesized by different species of the bacterial genus *Streptomyces*, whereas gentamicin comes from a related genus, *Micromonospora purpurea*. Streptomycin's usefulness has decreased greatly due to widespread drug resistance, but it may still be effective when other aminoglycosides should not be used (e.g., due to interactions with other drugs). Gentamicin is used to treat Gram-negative *Proteus*, *Escherichia*, *Klebsiella*, and *Serratia* infections. Aminoglycosides can be quite toxic, however, and can cause hearing and renal damage, loss of balance, nausea, and allergic reactions. Even when not genetically resistant to antibiotics, bacteria can resist the effects of antibiotics by severely slowing their metabolism, minimizing nutrient uptake and thus antibiotic uptake. These “persister” cells can survive freely and hidden in biofilms. Recall from the chapter 9 opening story, though, that scientists have tricked persister cells to uptake aminoglycosides along with various sugar nutrients, causing their death.

(a)

Aminoglycosides bind to the 30S (small) ribosomal subunit to interfere with protein synthesis. These antibiotics are bactericidal and tend to be most effective against Gram-negative pathogens. It is thought that by binding to bacterial ribosomes, aminoglycosides allow an incorrect amino acid to be brought to the ribosome by transfer RNA (tRNA). This yields a protein with a different amino acid sequence than the normal protein. Any abnormal proteins bound for secretion from the cell are inserted into the plasma membrane (figure 9.8b), where they induce changes in metabolic pathways that result in hydroxyl radical formation. Thus aminoglycosides deliver a two-fold punch: protein synthesis is altered and oxygen radical production increases. It is therefore not surprising that these drugs are bactericidal, not static. **◀◀ Oxygen concentration (section 7.3); ▶▶ Proteins (appendix I)**

Tetracyclines

The **tetracyclines** are a family of antibiotics with a common four-ring structure to which a variety of side chains are attached (figure 9.9). Oxytetracycline and chlortetracycline are produced naturally by *Streptomyces* species, whereas other tetracyclines are semisynthetic. These antibiotics are similar to

the aminoglycosides in that they can combine with the 30S subunit of the ribosome, inhibiting protein synthesis. Their action is only bacteriostatic, though. Tetracyclines are broad-spectrum antibiotics that are active against most bacteria, including the intracellular pathogens rickettsias, chlamydiae, and mycoplasmas.

Macrolides

The **macrolide antibiotics** contain a ring structure consisting of 12 to 22 carbons called a lactone ring. The lactone ring is linked to one or more sugars (figure 9.10). Erythromycin binds to the 50S ribosomal subunit to inhibit bacterial protein synthesis. Erythromycin is a relatively broad-spectrum antibiotic effective against Gram-positive bacteria, mycoplasmas, and a few Gram-negative bacteria, but it is usually only bacteriostatic. It is used with patients who are allergic to penicillins and in the treatment of

(b)

Figure 9.8 Representative Aminoglycoside Antibiotics. (a) Identifying cyclohexane ring and amino sugar.

(b) Proposed aminoglycoside killing mechanism. Aminoglycoside (1) enters bacterium, causing mistranslation of bacterial proteins. (2) Mistranslated proteins translocate into periplasm and (3) integrate into the plasma membrane, causing (4) envelope stress that (5) upregulates hydroxyl radical formation.

MICRO INQUIRY How do these drugs inhibit protein synthesis?

Tetracycline (chlortetracycline, doxycycline)

Figure 9.9 Tetracyclines. Three members of the tetracycline family. Tetracycline lacks both of the groups that are shaded. Chlortetracycline (aureomycin) differs from tetracycline in having a chlorine atom (blue); doxycycline consists of tetracycline with an extra hydroxyl (light blue).

Figure 9.10 Erythromycin, a Macrolide Antibiotic.

Erythromycin is composed of a 14-member lactone ring (shaded), so named because it contains a lactone or cyclic ester group, that is connected to two sugars.

MICRO INQUIRY How is the mechanism by which macrolides block protein synthesis similar to that of the tetracyclines? How is it different?

whooping cough, diphtheria, diarrhea caused by *Campylobacter*, and pneumonia from *Legionella* or *Mycoplasma* infections. Clindamycin is effective against a variety of bacteria, including staphylococci and anaerobes such as *Bacteroides*. Azithromycin (Zithromax), which has surpassed erythromycin in use, is particularly effective against many bacteria, including the sexually transmitted *Chlamydia trachomatis*.

Chloramphenicol

Chloramphenicol was first produced from cultures of *Streptomyces venezuelae* but is now synthesized chemically. Like erythromycin, this antibiotic binds the 50S ribosomal subunit to inhibit bacterial protein synthesis. It has a very broad spectrum of activity but, unfortunately, is quite toxic. Consequently this antibiotic is used only in life-threatening situations when no other drug is adequate.

Metabolic Antagonists

Several valuable drugs act as **antimetabolites**: they antagonize, or block, the functioning of metabolic pathways. The chemical reactions of metabolic pathways are catalyzed by enzymes. Enzymes function by binding a molecule referred to as the enzyme substrate. Antimetabolites are structurally similar to the substrates of key enzymes and compete with the metabolites for the binding site of these enzymes. However, once bound to the enzyme, the antimetabolites are different enough to block enzyme activity and further progression of the pathway. By preventing metabolism, they are broad spectrum but bacteriostatic; their removal reestablishes the metabolic activity. ►► *Enzymes and ribozymes (section 10.6)*

Sulfonamides or Sulfa Drugs

Sulfonamides, or sulfa drugs, are structurally related to sulfanilamide, an analogue of *p*-aminobenzoic acid, or PABA (**figure 9.11**). PABA is an important component (cofactor) of many enzymes and is needed for folic acid (folate) synthesis. Folic acid is a precursor of purines and pyrimidines, the bases used in the construction of DNA, RNA, and other important cell constituents (e.g., ATP). When sulfanilamide or another sulfonamide enters a bacterial cell, it competes with PABA for the active site of an enzyme involved in folic acid synthesis, causing a decline in folate concentration (*see figure 10.18*). The resulting inhibition of purine and pyrimidine synthesis leads to cessation of protein synthesis and DNA replication. Sulfonamides

Figure 9.11 Sulfa Drugs. Both sulfanilamide and sulfamethoxazole compete with *p*-aminobenzoic acid to block folic acid synthesis.

MICRO INQUIRY Why do sulfa drugs have a high therapeutic index?

are selectively toxic for many bacteria and protozoa because these microbes manufacture their own folate and cannot effectively take up this cofactor, whereas humans do not synthesize folate; instead, we must obtain it in our diet. Sulfonamides thus have a high therapeutic index. However, the increasing resistance of many bacteria to sulfa drugs limits their effectiveness.

Trimethoprim

Trimethoprim is a synthetic antibiotic that also interferes with the production of folic acid. It does so by binding to dihydrofolate reductase (DHFR), the enzyme responsible for converting dihydrofolic acid to tetrahydrofolic acid, competing against the dihydrofolic acid substrate (figure 9.12). Trimethoprim is a

(a) Dihydrofolic acid (DFA)

(b) Dihydrofolate reductase

(c) Trimethoprim

Figure 9.12 Competitive Inhibition of Dihydrofolate Reductase (DHFR) by Trimethoprim. (a) Dihydrofolic acid (DFA) is the natural substrate for the DHFR enzyme of the folic acid pathway. (b) DHFR structure and its interaction with DFA (red), its natural substrate. Note the chemical structure and how it fits into the active site of the enzyme. (c) Trimethoprim mimics the structural orientation of the DFA and thus competes for the active site of the enzyme. This causes delayed or absent folic acid synthesis because the DFA cannot be converted to tetrahydrofolic acid when trimethoprim occupies the DHFR active site.

broad-spectrum antibiotic often used to treat respiratory and middle ear infections, urinary tract infections, and traveler's diarrhea. It is often combined with sulfa drugs to increase efficacy of treatment by blocking two key steps in the folic acid pathway. The inhibition of two successive steps in a single biochemical pathway means that less of each drug is needed in combination than when used alone. This is termed a synergistic drug interaction.

Nucleic Acid Synthesis Inhibition

The antibacterial drugs that inhibit nucleic acid synthesis function by inhibiting (1) DNA polymerase and topoisomerases or (2) RNA polymerase, to block replication or transcription, respectively. These drugs are not as selectively toxic as other antibiotics because bacteria and eukaryotes do not differ greatly with respect to nucleic acid synthesis. The most commonly used drugs in this category are the quinolones.

Quinolones

The **quinolones** are synthetic drugs that contain the 4-quinolone ring. They are increasingly used to treat a wide variety of infections. The first quinolone, nalidixic acid (figure 9.13), was synthesized in 1962. Since that time, generations of fluoroquinolones have been produced. Three of these—ciprofloxacin, norfloxacin, and ofloxacin—are currently used in the United States, and more fluoroquinolones are being synthesized and tested.

Quinolones act by inhibiting the bacterial topoisomerases DNA gyrase and topoisomerase II. DNA gyrase introduces negative twist in DNA and helps separate its strands. Inhibition of DNA gyrase disrupts DNA replication and repair, bacterial chromosome separation during division, and other processes involving DNA. Fluoroquinolones also inhibit topoisomerase II,

Figure 9.13 Quinolone Antimicrobial Agents. Ciprofloxacin and norfloxacin are newer-generation fluoroquinolones. The 4-quinolone ring in nalidixic acid has been numbered.

another enzyme that untangles DNA during replication. It is not surprising that quinolones are bactericidal. ►► *DNA replication in bacteria* (section 13.3)

The quinolones are broad-spectrum antibiotics. They are highly effective against enteric bacteria such as *E. coli* and *Klebsiella pneumoniae*. They can be used with *Haemophilus*, *Neisseria*, *P. aeruginosa*, and other Gram-negative pathogens. The quinolones also are active against Gram-positive bacteria such as *S. aureus*, *Streptococcus pyogenes*, and *Mycobacterium tuberculosis*. Thus they are used in treating a wide range of infections.

2. Why do penicillins and cephalosporins have a higher therapeutic index than most other antibiotics?
3. Would there be any advantage to administering a bacteriostatic agent along with penicillins? Any disadvantage?
4. What are antimetabolites? Why do you think these are effective against protozoan pathogens while the other drugs presented here generally are not?

9.5 Antifungal Drugs

After reading this section, you should be able to:

- Compare antifungal drug mechanisms of action
- Explain why there are far fewer antifungal agents than there are antibacterial agents

Treatment of fungal infections generally has been less successful than that of bacterial infections largely because as eukaryotes, fungal cells are much more similar to human cells than are bacterial cells. Many drugs that inhibit or kill fungi are therefore quite toxic for humans and thus have a low therapeutic index. In addition, most fungi have a detoxification system that modifies many antifungal agents, limiting drug effectiveness. Most antifungals are fungistatic only as long as repeated application maintains high levels of unmodified drug. Nonetheless, a few drugs are useful in treating many major fungal diseases. Effective antifungal agents frequently either extract fungal membrane sterols or prevent their synthesis. Similarly, because fungal cell walls contain chitin, the enzyme chitin synthase is the target for antifungals such as polyoxin D and nikkomycin.

Fungal infections are often subdivided into infections called superficial mycoses, subcutaneous mycoses, and systemic mycoses. Treatment for these types of disease is very different. Several drugs are used to treat superficial mycoses. Three drugs containing imidazole—miconazole, ketoconazole (figure 9.14), and clotrimazole—are broad-spectrum agents available as creams and solutions for the treatment of infections such as athlete's foot, and oral and vaginal candidiasis. They are thought to disrupt fungal membrane permeability and inhibit sterol synthesis. Nystatin (figure 9.14), a polyene

antibiotic from *Streptomyces*, is used to control *Candida* infections of the skin, vagina, or alimentary tract. It binds to sterols and damages the membrane, leading to fungal membrane leakage. Griseofulvin (figure 9.14), an antimycotic formed by *Penicillium*, is given orally to treat chronic superficial mycoses. It is thought to disrupt the mitotic spindle and inhibit cell division; it also may inhibit protein and nucleic acid synthesis. ►► *Human diseases caused by fungi and protists* (sections 40.2–40.6)

Systemic fungal infections are very difficult to control and can be fatal. Three drugs commonly used against systemic mycoses are amphotericin B, 5-flucytosine (figure 9.14), and fluconazole. Amphotericin B from *Streptomyces* spp. binds to the sterols in fungal membranes, disrupting membrane permeability and causing leakage of cell constituents. It is quite toxic to humans and used only for serious, life-threatening infections. The synthetic oral antimycotic agent 5-flucytosine (5-fluorocytosine) is effective against most systemic fungi, although drug resistance often develops rapidly (figure 9.14). The drug is converted to 5-fluorouracil by fungi, which is an analogue of uracil, one of the building blocks of RNA. During transcription, 5-fluorouracil is incorporated into RNA in place of uracil and disrupts RNA function. Fluconazole is used in the treatment of candidiasis, cryptococcal meningitis, and coccidioidal meningitis. It also disrupts fungal membrane sterols and ranges from fungistatic to fungicidal, depending on dose and organism. Because adverse effects of fluconazole are relatively uncommon, it is used prophylactically to prevent life-threatening fungal infections in AIDS patients and other individuals who are severely immunosuppressed. Posaconazole is a broad-spectrum, antifungal agent related to fluconazole (i.e., it is in the azole class of antifungals). It is approved for the prophylaxis and treatment of invasive fungal infections. Posaconazole is fungistatic against most pathogenic yeast species, including *Aspergillus*, *Candida*, *Cryptococcus*, and *Trichosporon*, and it has good coverage against species of *Aspergillus* and *Candida* that are resistant to other azole antifungal agents.

A life-threatening fungal infection of individuals with compromised immune systems is caused by *Pneumocystis jiroveci* (formerly *P. carinii*). Treatment of this disease is with atovaquone. Atovaquone is an analogue of ubiquinone, an integral component of the eukaryotic electron transport system. As an analogue of ubiquinone, atovaquone can act as a competitive inhibitor and thus suppress electron transport. The ultimate metabolic effects of electron transport blockade include inhibited or delayed synthesis of nucleic acids and ATP.

Subcutaneous mycoses are typically treated with combinations of drugs that would be used for superficial and systemic mycoses. The goal of this combination therapy is to provide less toxic drugs over longer time periods, with shorter term exposure to those that have greater toxic side effects. In this way, subcutaneous fungi are continuously targeted with antifungal drugs, while allowing patients respite from the side effects of the more toxic drugs. ►► *Human diseases caused by fungi and protists* (chapter 40)

9.6 Antiviral Drugs

After reading this section, you should be able to:

- Compare antiviral drug mechanisms of action
- Provide a rationale for combination drug therapy, using an anti-HIV model
- Explain why there are far fewer antiviral agents than there are antibacterial agents

Because viruses enter host cells and make use of host cell enzymes and constituents, it was long thought that a drug that blocked virus multiplication would be toxic for the host. However, the discovery of inhibitors of virus-specific enzymes and replication cycle processes has led to the development of antiviral drugs. Some important examples are shown in [figure 9.15](#).

◀◀ Viral multiplication (section 6.3)

Most antiviral drugs disrupt critical stages in a virus's multiplication cycle. Probably the most publicized antiviral agent is **Tamiflu** (generically, oseltamivir phosphate). Tamiflu ([figure 9.15](#)) inhibits the viral molecule neuraminidase, which is essential for release of newly synthesized influenza A virus particles from host cells. Thus Tamiflu received much attention during the 2009–2010 H1N1 influenza pandemic. While Tamiflu is not a cure for neuraminidase-expressing viruses, clinical trials show that patients who take Tamiflu within 48 hours of influenza infection are relieved of flu symptoms 1.3 days faster than patients who do not take Tamiflu. Unfortunately, prophylactic use has resulted in viral resistance to Tamiflu. It is important to recognize that Tamiflu is not a substitute for yearly flu vaccination and frequent hand washing. **Amantadine** ([figure 9.15](#)) and **rimantadine** can also be used to prevent influenza A illness. When given within the first 48 hours of infection, these drugs reduce the incidence of influenza by 50% to 70% in an exposed population. Amantadine blocks the penetration and uncoating of influenza virus particles. ▶▶ *Human diseases caused by viruses (section 38.1)*

Several drugs are commonly used to treat illnesses caused by viruses with DNA genomes. Adenine arabinoside (vidarabine) disrupts the activity of viral DNA polymerase and several other enzymes involved in DNA and RNA synthesis and function. It is given intravenously or applied as an ointment to treat herpes infections (e.g., cold sores and genital herpes). A third drug, acyclovir, is also used in the treatment of herpes infections. Upon phosphorylation, acyclovir also inhibits viral DNA polymerase. Unfortunately, acyclovir-resistant strains of herpes have developed. Effective acyclovir derivatives are now available. Valacyclovir is an orally administered prodrug form of acyclovir. Prodrugs are inactive until metabolized. Another kind of drug, foscarnet ([figure 9.15](#)),

also inhibits the virus's DNA polymerase, and is very effective at treating illnesses caused by herpes simplex viruses and cytomegalovirus. ▶▶ *Human diseases caused by viruses (section 38.3)*

Several broad-spectrum anti-DNA virus drugs have been developed. A good example is the drug HPMPC, also known as cidofovir ([figure 9.15](#)). It is effective against papovaviruses (warts), adenoviruses (respiratory diseases), herpesviruses (oral and genital sores), and poxviruses (chickenpox). The drug acts on the viral DNA polymerase as a competitive inhibitor. It is structurally similar to deoxycytosine triphosphate (dCTP), a substrate of DNA polymerase. Thus it blocks viral DNA synthesis. HPMPC has been used primarily against cytomegalovirus but also against herpes simplex and human papillomavirus infections.

Since the early days of human immunodeficiency virus (HIV) treatment, much effort has been focused on developing new drugs. These drugs target and interfere with critical steps in the viral replicative processes ([figure 9.16](#)). There are now four categories of drugs used in combination to manage HIV infection: (1) nucleoside reverse transcriptase inhibitors (NRTIs), which are nucleoside analogues that produce faulty viral DNA (e.g., **azidothymidine** or AZT); (2) nonnucleoside reverse transcriptase inhibitors (NNRTIs), which prevent HIV DNA synthesis by selectively binding to and inhibiting the reverse transcriptase enzyme; (3) protease inhibitors (PIs), which block the activity of the HIV protease that is needed for the production of all viral proteins; and (4) fusion inhibitors (FIs), a relatively new category of drugs that prevent HIV entry into cells ([figure 9.16](#)). Inhibition of reverse transcription, which catalyzes an early step in the multiplication cycle of the virus—the conversion of the virus's RNA genome into double-stranded DNA ([figure 9.16](#)), blocks viral DNA synthesis and halts HIV replication. Protease inhibitors are effective because HIV, like many RNA viruses, synthesizes polyproteins that must be cleaved into the individual proteins required for virus replication. Protease inhibitors mimic the peptide bond that is normally attacked by the protease. Three of the most used PIs are saquinavir, indinavir, and ritonavir ([figure 9.15](#)). Fusion inhibitors are particularly interesting as an effective blockade to viral entry into host cells, essentially preventing disease. ▶▶ *RNA viruses (section 27.4); Retroviruses (section 27.8)*

The most successful treatment approach to date in combating HIV/AIDS is to use drug combinations. Most effective is a cocktail of agents given at high dosages to prevent the development of drug resistance. For example, the combination of the two reverse transcriptase inhibitors AZT and 3TC, and the protease inhibitor ritonavir reduces HIV concentrations in plasma almost to zero. However, the treatment does not eliminate proviral HIV DNA that still resides in certain cells of the immune system (e.g., memory T cells) and possibly other cells. Thus with proper treatment, the virus often disappears from a patient's blood and drug-resistant strains do not seem to arise. But because HIV can remain dormant in memory T cells, it can survive drug cocktails and reactivate. Thus patients are not completely cured with drug treatment, requiring drug therapy for life. Unfortunately, side effects can be very severe,

Figure 9.15 Antiviral Drugs Target the Viral Replication Cycle. Drugs are categorized by mechanism of action. Their use is determined by type of viral disease, sensitivity of virus to the drug, and drug toxicity. Viral disease of the skin may permit use of a more toxic drug, for example, than viral disease of the liver.

and treatment is prohibitively expensive for those without medical insurance. Globally, the vast majority of HIV-positive individuals do not have access to effective combination therapy. Recent studies have led the CDC to recommend a pre-HIV exposure prophylaxis (prevention) strategy to men and women

who have sex with HIV-infected partners. The daily oral dose of two NRTIs was strongly correlated with reduced HIV transmission among uninfected individuals exposed to the virus through sexual contact. ►► *Acquired immunodeficiency syndrome (AIDS)* (section 38.3)

Infection begins with HIV fusion.
Fusion inhibitors block this step.

Once inside a host cell, HIV uncoats and its reverse transcriptase (RT) forces the host to make DNA from the viral RNA.
RT inhibitors block this step.

The viral DNA is transcribed and translated into a linear polypeptide that is cut to release viral proteins.
Protease inhibitors block this step.

Viral DNA is added to the host DNA by the action of a viral integrase.
Integrase inhibitors block this step.

Figure 9.16 Examples of How Anti-HIV Agents Block HIV Replication. Viral infection can be interrupted by correct use of drugs that target specific components of the HIV replicative process.

9.7 Antiprotozoan Drugs

After reading this section, you should be able to:

- Compare the mechanisms of action of antiprotozoan drugs
- Relate side effects and toxicity of antiprotozoan drugs to their mechanism of action
- Explain why there are far fewer antiprotozoan agents than there are antibacterial agents

As with other antimicrobial therapies, antiprotozoan drug development starts by identifying a unique target to which a drug can bind and thus prevent some vital function. However, because protozoa are eukaryotes, the potential for drug action on host cells and tissues is greater than it is when targeting bacteria. Most of the drugs used to treat protozoan infections have significant side effects; nonetheless, the side effects are usually acceptable when weighed against the parasitic burden.

The number of antiprotozoan drugs is relatively small, and the mechanism of action for most of these drugs is not completely understood. The drugs described here have potent antiprotozoan

action and appear to act on protozoan nucleic acid or some metabolic process.

Malaria, caused by any of five species of the genus *Plasmodium*, kills about a million people annually—most of them children. Drugs to treat and prevent malaria include everything from ancient Chinese remedies to quinine water. In fact, gin and tonics are said to have been the most popular drink among imperial British in South Asia due to its antimalarial activity. We now use more purified forms of **quinine drugs**, including chloroquine and qualaquin to treat malaria (**figure 9.17**). These drugs suppress protozoan reproduction and are effective in eradicating asexual stages of the protozoan's life cycle that occur in red blood cells. Several mechanisms of action have been reported. They can raise the internal pH, clump the hemoglobin waste product hemazoin (often called the plasmodial pigment), and intercalate into plasmodial DNA. Chloroquine also inhibits malarial heme polymerase, an enzyme that converts toxic heme metabolites into the nontoxic hemazoin. Inhibition of this enzyme leads to a buildup of toxic heme metabolites. Another drug, mefloquine, has been found to swell the *Plasmodium falciparum* food vacuoles, where it may act by forming toxic

Figure 9.17 Chloroquine, a Quinine Drug. Quinine drugs have a long history of use as antimalarial agents.

complexes that damage membranes and other plasmodial components. Primaquine is active against a dormant form of the protists (hypnozoites) that are found in the liver; it prevents relapses. Individuals who travel to areas where malaria is endemic typically receive chemoprophylactic treatment with chloroquine or other antimalarial agents. ►► *Malaria* (section 40.3)

Treatment of malaria has become a complex task, with specific drugs and therapies recommended according to (1) the endemic *Plasmodium* species, (2) drug sensitivity and resistance patterns, (3) drug cost, and (4) patient access to therapy. Because of these factors, a single drug therapy may be recommended in one area, while a different drug or even a combination therapy may be recommended in another. As mentioned, many factors impact treatment decisions, including patient compliance. Intermittent drug use is a strong selective pressure for drug resistance. Thus, treatment regimens may also rely on patient adherence to the drug dosing schedule. In general, the World Health Organization recommends a combination of a quinine drug and a derivative of **artemisinin**. Having its origins as a treatment in traditional Chinese medicine, artemisinin is a chemical found in the sweet wormwood plant (*Artemisia annua*). A semisynthetic artemisinin derivative used in combination therapies is an effective treatment of malaria and a truly cost-effective treatment. The mechanism of artemisinin action is not well understood; it appears to form reactive oxygen intermediates inside *Plasmodium*-infected red blood cells, leading to altered hemoglobin catabolism and plasmodium electron transport chain damage. ►► *Oxygen concentration* (section 7.3)

There are many other diseases caused by protozoa, as discussed in chapter 40. Amoebic dysentery is usually treated with **metronidazole**. Anaerobic organisms, such as the causative agent *Entamoeba*, readily reduce it to the active metabolite within the cytoplasm. A number of antibiotics that inhibit bacterial protein synthesis are also used to treat protozoan infection. These include the aminoglycosides clindamycin and paromomycin. Although aminoglycosides do not bind to eukaryotic ribosomes, these polycationic molecules have a high affinity for nucleic acids and RNA in particular. Different aminoglycoside antibiotics bind to different sites on RNAs. RNA binding interferes with the normal expression and function of the RNA, resulting in cell death.

The antifungal atovaquone (p. 201) is used to treat toxoplasmosis, caused by *Toxoplasma gondii*. Toxoplasmosis is a life-threatening infection in immunocompromised individuals and can cause severe birth defects in human fetuses. Atovaquone interferes with eukaryotic electron transport to kill the protozoan parasite. Pyrimethamine and dapsone are also used to treat *Toxoplasma* infections and are thought to act in the same way as trimethoprim—interfering with folic acid synthesis by inhibition of dihydrofolate reductase. Another drug that interferes with electron transport is nitazoxanide, which is used to treat cryptosporidiosis, a food- and waterborne disease. ►► *Toxoplasmosis* (section 40.5); *Cryptosporidiosis* (section 40.5)

Retrieve, Infer, Apply

1. Suggest why drugs that inhibit bacterial protein synthesis are also effective against some protists.
2. Why is malaria, like tuberculosis, now treated with several drugs simultaneously?
3. What special considerations must be taken into account when treating infections caused by protozoan parasites?

9.8 Factors Influencing Antimicrobial Drug Effectiveness

After reading this section, you should be able to:

- Predict the effects of (1) delivery route, (2) metabolism, and (3) local concentration on the effectiveness of an antimicrobial drug
- Correlate the sensitivity of a microorganism to an antimicrobial agent with microbial growth in the presence of that agent
- Identify practices that lead to antimicrobial drug resistance and suggest countermeasures

Drug Effectiveness

It is crucial to recognize that effective drug therapy is not a simple matter. Drugs can be administered in several different ways, and they do not always spread rapidly throughout the body or immediately kill all invading pathogens. A complex array of factors influences the effectiveness of antimicrobial drugs.

First, the drug must actually be able to reach the site of infection. Understanding the factors that control drug activity, stability, and metabolism in vivo are essential in drug formulation. For example, the mode of administration plays an important role. A drug such as penicillin G is not suitable for oral administration because it is relatively unstable in stomach acid. Some antibiotics—for example, gentamicin and other aminoglycosides—are not well absorbed from the intestinal tract and must be injected intramuscularly or given intravenously. Other antibiotics (neomycin, bacitracin) are so toxic that they can only be applied topically to skin lesions. Nonoral routes of administration are called **parenteral routes**. Even when an agent is administered properly, it may be excluded from the site of infection. For example, blood clots, necrotic tissue, or biofilms can protect bacteria

from a drug, either because body fluids containing the agent may not easily reach the pathogens or because the agent is absorbed by materials surrounding them.

Second, the pathogen must be susceptible to the drug. Bacteria in biofilms or abscesses may be replicating very slowly and are therefore resistant to chemotherapy because many agents affect pathogens only if they are actively growing and dividing. A pathogen, even though growing, may simply not be susceptible to a particular agent. To control resistance, drug cocktails can be used to treat some infections. A notable example of this is the use of clavulanic acid (to inactivate penicillinase) combined with ampicillin to treat penicillin-resistant bacteria.

Third, the chemotherapeutic agent must reach levels in the body that exceed the pathogen's MIC value if it is going to be effective. The concentration reached will depend on the amount of drug administered, the route of administration and speed of uptake, and the rate at which the drug is cleared or eliminated from the body. It makes sense that a drug will remain at high concentrations longer if it is absorbed over an extended period and excreted slowly.

Finally, chemotherapy has been rendered less effective and much more complex by the spread of drug-resistance genes and prevention of drug access by biofilm components. ►► *Origin and transmission of drug resistance (section 16.9)*

Overcoming Drug Resistance

As we discuss in chapter 16, bacteria are very adept at spreading resistance genes around, both within a population and to other members of a microbial community. However, what keeps the resistance genes in a population and contributes to the generation of drug-resistant bacterial strains is exposure to the drug. Clearly, it is important that physicians be able to treat infectious disease in their patients. The problem is that drugs are being overused, misused, and in many cases abused. Put simply, the more drugs are used, the more likely it is that bacteria will become resistant to them. That raises the question: Is there a way to overcome drug resistance?

Several strategies can be employed to discourage the emergence of drug resistance. The drug can be given in a high enough concentration to destroy susceptible microbes and most spontaneous mutants that might arise during treatment. Sometimes two or even three different drugs can be administered simultaneously with the hope that each drug will prevent the emergence of resistance to the other. This approach is used in treating tuberculosis, HIV, and malaria, for example. When treating tuberculosis (TB), several drugs are administered simultaneously (e.g., isoniazid [INH] plus rifampin, ethambutol, and pyrazinamide). These drugs are administered for 6 to 9 months as a way of decreasing the possibility that the bacterium develops drug resistance. If a patient fails to take prescribed antibiotics as directed (e.g., does not complete the course of treatment), resistant mutants survive and flourish because of their competitive advantage over nonresistant strains. Preventing the growth of such mutants is the rationale behind “directly observed therapy” (DOT). During DOT, a health care worker observes each TB patient take each antibiotic

dose, thereby ensuring full antibiotic regimen compliance. The use of DOT increased from 21% in 1993 to 57% in 2005, the latest year with available data, effectively contributing to the substantial 50% decline in reported TB cases in the United States between 1993 and 2006. Unfortunately, the number of worldwide TB cases doubled over that same time period. ►► *Human diseases caused by bacteria (section 39.1)*

Other strategies used to prevent drug resistance include the strict control on use of chemotherapeutic drugs, particularly broad-spectrum drugs, which should be used only when absolutely necessary. If possible, the pathogen should be identified, drug sensitivity tests performed, and the proper narrow-spectrum drug employed. Patient compliance is just as important because completing a full course of antimicrobial therapy often prevents full mutation to resistant phenotypes.

Despite efforts to control the emergence and spread of drug resistance, the situation continues to worsen. Thus an urgent need exists for new antibiotics that microorganisms have never encountered. Pharmaceutical and biotechnology companies collect and analyze samples from around the world in a search for completely new antimicrobial agents. Both culture-based and metagenomics approaches are used (see figure 18.21). Structure-based or rational drug design is another option. If the three-dimensional structure of a susceptible target molecule such as an enzyme essential to microbial function is known, computer programs can be used to design drugs that precisely fit the target molecule. These drugs might be able to bind to the target and disrupt its function sufficiently to destroy the pathogen. Pharmaceutical companies are using these approaches to develop drugs for the treatment of AIDS, cancer, septicemia caused by lipopolysaccharide, and the common cold. Information derived from the sequencing and analysis of pathogen genomes is also useful in identifying new targets for antimicrobial drugs. For example, genomics studies are providing data for research on inhibitors of both aminoacyl-tRNA synthetases and the enzyme that removes the formyl group from the N-terminal methionine during bacterial protein synthesis. The drug susceptibility of enzymes required for fatty acid synthesis is also being analyzed. A most interesting response to the current crisis is the renewed interest in an idea first proposed early in the twentieth century by Felix d’Herelle, one of the discoverers of bacterial viruses (bacteriophages). d’Herelle proposed that bacteriophages could be used to treat bacterial diseases. Although most microbiologists did not pursue his proposal actively due to technical difficulties and the advent of antibiotics, Russian scientists developed the medical use of bacteriophages. Currently Russian physicians use bacteriophages to treat many bacterial infections. Bandages are saturated with phage solutions, phage mixtures are administered orally, and phage preparations are given intravenously to treat *Staphylococcus* infections. Several American companies are actively conducting research on phage therapy and preparing to carry out clinical trials. ►► *Viruses and other acellular infectious agents (chapter 6); ►► Microbial genomics (chapter 18); ►► Biotechnology and industrial microbiology (chapter 42)*

Retrieve, Infer, Apply

1. What factors do you think must be considered when treating an infection present in a biofilm on a medical implant (e.g., an artificial hip) versus a skin infection caused by the same microbe?

2. What is parenteral administration of a drug? Why is it used?
3. What are the primary medical practices that result in antimicrobial drug resistance? How can these be overcome?

Key Concepts

9.1 The Development of Chemotherapy

- The modern era of chemotherapy began with Paul Ehrlich's work on drugs against African sleeping sickness and syphilis.
- Other early pioneers were Gerhard Domagk, Alexander Fleming, Howard Florey, Ernst Chain, Norman Heatley, and Selman Waksman.

9.2 General Characteristics of Antimicrobial Drugs

- An effective chemotherapeutic agent must have selective toxicity. A drug with great selective toxicity has a high therapeutic index and usually disrupts a structure or process unique to the pathogen. It has fewer side effects.
- Antibiotics can be classified in terms of the range of target microorganisms (narrow spectrum versus broad spectrum); their source (natural, semisynthetic, or synthetic); and their general effect (static versus cidal) (**table 9.1**).

9.3 Determining the Level of Antimicrobial Activity

- Antibiotic effectiveness can be estimated through the determination of the minimal inhibitory concentration and the minimal lethal concentration with dilution susceptibility tests.
- Tests such as the Kirby-Bauer test (a disk diffusion test) and the Etest® are often used to estimate a pathogen's susceptibility to drugs quickly (**figures 9.2–9.4**).

9.4 Antibacterial Drugs

- Members of the penicillin family contain a β -lactam ring and disrupt bacterial cell wall synthesis, resulting in cell lysis (**figure 9.5**). Some, such as penicillin G, are usually administered by injection and are most effective against Gram-positive bacteria. Others can be given orally (penicillin V), are broad spectrum (ampicillin, carbenicillin), or are usually penicillinase-resistant (methicillin).
- Cephalosporins are similar to penicillins but can be given to patients with penicillin allergies (**figure 9.6**).
- Vancomycin is a glycopeptide antibiotic that inhibits transpeptidation during peptidoglycan synthesis (**figure 9.7**). It is used against drug-resistant staphylococci, enterococci, and clostridia.
- Aminoglycoside antibiotics such as streptomycin and gentamicin bind to the small ribosomal subunit, inhibit protein synthesis, and are bactericidal (**figure 9.8**).

- Tetracyclines are broad-spectrum antibiotics having a four-ring nucleus with attached groups (**figure 9.9**). They bind to the small ribosomal subunit and inhibit protein synthesis.
- Erythromycin is a bacteriostatic macrolide antibiotic that binds to the large ribosomal subunit and inhibits protein synthesis (**figure 9.10**).
- Chloramphenicol is a broad-spectrum, bacteriostatic antibiotic that inhibits protein synthesis. It is quite toxic and used only for very serious infections.
- Sulfonamides or sulfa drugs resemble *p*-aminobenzoic acid and competitively inhibit folic acid synthesis (**figure 9.11**).
- Trimethoprim is a synthetic antibiotic that inhibits dihydrofolate reductase, which is required by organisms in the manufacture of folic acid (**figure 9.12**).
- Quinolones are a family of bactericidal synthetic drugs that inhibit DNA gyrase and thus inhibit DNA replication (**figure 9.13**).

9.5 Antifungal Drugs

- Because fungi are more similar to human cells than bacteria, antifungal drugs generally have lower therapeutic indexes than antibacterial agents and produce more side effects.
- Superficial mycoses can be treated with miconazole, ketoconazole, clotrimazole, tolinaftate, nystatin, and griseofulvin (**figure 9.14**). Amphotericin B, 5-flucytosine, and fluconazole are used for systemic mycoses.

9.6 Antiviral Drugs

- Antiviral drugs interfere with critical stages in the virus life cycle (amantadine, rimantadine, ritonavir) or inhibit the synthesis of virus-specific nucleic acids (zidovudine, adenine arabinoside, acyclovir) (**figure 9.15**).
- Drug combinations (cocktails) appear to be more effective than monotherapies.

9.7 Antiprotozoan Drugs

- The mechanisms of action of most drugs used to treat protozoan infection are unknown.
- Some antiprotozoan drugs interfere with critical steps in nucleic acid synthesis, protein synthesis, electron transport, or folic acid synthesis.

9.8 Factors Influencing Antimicrobial Drug Effectiveness

- A variety of factors can greatly influence the effectiveness of antimicrobial drugs during use. These include route, effective concentration, and pathogen sensitivity.

- Drug resistance can often limit drug effectiveness. However, it can be overcome through the judicious use of antimicrobial agents (decreasing selective pressure), use of drug cocktails (attacking more than one microbial structure or function), and use of specific, narrow-spectrum drugs to target infecting microbes.

Compare, Hypothesize, Invent

1. What advantage might soil bacteria and fungi gain from the synthesis of antibiotics?
2. Some advocate stockpiling the drug Tamiflu in the event of an influenza pandemic. Others point out that wealthy, Western nations would have an unfair advantage because developing nations (where the pandemic is most likely to start) would not have access to this expensive antiviral. Furthermore, some fear that indiscriminate use of the drug would promote the evolution of resistant flu strains. Given these caveats, do you think developed nations should stockpile Tamiflu for the protection and treatment of their citizens? Explain your answer.
3. You are a pediatrician treating a child with an upper respiratory infection that is clearly caused by a virus. The child's mother insists that you prescribe antibiotics—she's not leaving without them! How do you convince the child's mother that antibiotics will do more harm than good?
4. Antibiotics that target bacterial molecules not previously exploited are desperately needed. One such target is the

protein FtsZ. The small molecule 3-methoxybenzamide (3-MBA) is known to inhibit FtsZ in *Bacillus subtilis* but is not bacteriocidal. Nonetheless, researchers reasoned that 3-MBA offered a good starting point for the synthesis of a molecule that might be a potential drug candidate. Over 500 3-MBA analogues were synthesized and screened; one called PA190723 was extremely potent in its capacity to bind FtsZ and inhibit bacterial growth. In fact, when used in a mouse model, PA190723 was bacteriocidal against methicillin- and multidrug-resistant *Staphylococcus aureus*.

What makes FtsZ a good drug target (see chapters 3 and 7)? What preliminary information about 3-MBA would be helpful if you were designing the 3-MBA analogues? As these researchers move forward with clinical (human) testing, what other parameters and outcomes must be assessed besides the bacteriocidal activity of PA190723?

Introduction to Metabolism

Flushed Away

For one day, count the number of times you flush the toilet in your home. Is your toilet a low-volume toilet that sends 1.6 gallons or less out of your house with each flush? Or is it an older, water-greedy toilet? Did you ever wonder where the wastes you flush away go?

If you live in a city, your wastes travel through a labyrinth of pipes that carry them to a wastewater treatment plant. Now do some math: multiply the number of gallons you flushed away by the number of people in your town. That's how much wastewater is sent each day to your town's wastewater treatment plant. If you live in a large city, the amount of wastewater generated is astronomical: in New York City it's about 1.3 billion gallons per day!

The cost of treating wastewater so that it is safe to release into the environment is also astronomical. New York City spends an estimated \$400 million each year. Thus wastewater treatment is a big item in any city's budget. But can these wastes be used to decrease the cost of treatment or, better yet, generate funds for municipalities? The answer to that question is yes, and it is the metabolic diversity of microbes that makes it possible.

As we describe in chapter 43, wastewater treatment plants are home to a complex microbial community. Working together, these microbes decrease the organic matter in wastewater and generate several by-products. One of the most important is methane, a product of degradation of organic matter under anoxic conditions. For many years, wastewater treatment facilities simply burned the methane as it was produced. Increasingly, wastewater treatment plants are using the methane to heat their buildings, and some municipalities, such as New York City, are exploring the possibility of selling methane to natural gas providers, which then would supply it to homes for heating.

Another by-product of wastewater treatment is sludge, the solid material composed of undigested material and biomass created as the organic material in wastewater is removed. Many towns truck the sludge

Each day, toilets send billions of gallons of wastewater to sewage treatment plants. The treatment of wastewater is a significant cost to municipalities.

to landfills. However, many landfills are at or nearing capacity and will no longer accept solid waste. Increasingly cities are selling sludge to farmers and ranchers to use as a soil amendment. Some are exploring the use of sludge for paving roads and as building materials.

The treatment of wastewater is not the only example of how humans exploit the metabolic prowess of microbes. Microbes generate numerous metabolites that humans have found desirable. As we describe in chapter 41, ethanol is important in the production of beer, ale, and wine. Propionic acid flavors Swiss cheese. Carbon dioxide leavens bread, and antibiotics save the lives of humans every day.

The impact of microbial metabolites goes beyond their use in industry and food production. It is now recognized that the microbes living in and on the human body contribute compounds that are needed for human metabolism. Indeed, it is thought that the metabolic capabilities of both the human normal microbiota and their human hosts are highly integrated as the result of coevolution. ►► *Microbiology of food (chapter 41); Biotechnology and industrial microbiology (chapter 42); Human-microbe interactions (section 32.2)*

The importance of microbial metabolism is evidenced in less obvious but equally significant ways. Microbes are not visible to us, but they constitute the largest component of biomass on Earth and therefore contribute to the cycling of elements in ecosystems. The nitrogen cycle is of particular note. Four of the eight transformations of nitrogen illustrated in **figure 10.1** are done only by microbes, and microbes contribute to the remaining four. ►► *Biogeochemical cycling (section 28.1)*

Clearly, microbial metabolism is extremely important to the well-being of humans, and much of the study of microbes has focused on this aspect of their biology. Chapters 10 through 12 focus on the metabolic processes that conserve the energy supplied by an organism's energy source and how that energy is used to synthesize the building blocks from which an organism is constructed. In this chapter, we lay the foundation for that discussion.

Figure 10.1 Contributions of Microbes to the Nitrogen Cycle. This is a simplified representation of the nitrogen cycle. A more complete cycle is presented in chapter 28.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Distinguish metabolism, catabolism, and anabolism
- ✓ Describe the structure of bacterial and archaeal cell envelopes (sections 3.3–3.5 and 4.2)
- ✓ Describe mitochondrial structure and function (section 5.6)

10.1 Metabolism: Important Principles and Concepts

After reading this section, you should be able to:

- List the features common to all types of metabolism
- Describe the three types of work carried out by cells
- State the relationship between cellular work and energy
- Paraphrase the first and second laws of thermodynamics
- Use the equation for free energy change and the equation that links standard free energy change to a reaction's equilibrium constant and explain their importance
- Infer from a standard free energy change whether a reaction is exergonic or endergonic

It would be nice to think that microbes existed for the benefit of humans and that their metabolisms evolved for us to exploit, but of course this is not the case. Rather, they use their vast repertoire of chemical reactions to survive and reproduce, just as all organisms do. Thus metabolism is central to all life. The forces of evolution have shaped the metabolic process used by organisms for billions of years. Despite the diversity of chemical reactions that have evolved, there are several aspects of metabolism that are

common to all organisms. Here we list the common features, noting where they are discussed in this chapter.

- **Life obeys the laws of thermodynamics** (this section). Therefore to maintain their structural complexity, organisms must obtain energy from their environment.
- **The energy cells obtain from their environment is most often conserved as a molecule called ATP** (section 10.2). ATP is used to supply the energy needed for certain chemical reactions to proceed.
- **Oxidation-reduction (redox) reactions play a critical role in energy conservation** (section 10.3). Many of these redox reactions occur in electron transport chains (section 10.4).
- **The chemical reactions that occur in cells are organized into pathways.** Thus the product of one reaction is the substrate for the next reaction in the pathway (section 10.5).
- **Each reaction of a pathway is catalyzed by an enzyme or a ribozyme.** Enzymes and ribozymes are critical to all life as they speed up the reactions that enable life to exist (section 10.6).
- **The functioning of biochemical pathways is regulated** so that their products are made at the correct time (section 10.7).

Cellular Work and Energy Transfers

Examine the common features of metabolism just described. It should be clear that cells must do work in order to survive and reproduce. Cells carry out three major types of work. **Chemical work** involves the synthesis of complex biological molecules from much simpler precursors (i.e., anabolism); energy is needed to increase the molecular complexity of a cell. **Transport work** requires energy to take up nutrients, eliminate wastes, and maintain ion balances. Energy input is needed because molecules and ions often must be transported across cell membranes against an electrochemical gradient. The third type of work is **mechanical work**. Energy is required for cell motility and the movement of structures within cells, such as partitioning chromosomes during cell division.

As just indicated, cells need energy to do work. Indeed, **energy** may be defined most simply as the capacity to do work. This is because all physical and chemical processes are the result of the application or movement of energy. Organisms obtain the energy they need from an energy source present in their environment. They convert the energy it provides into a useful form. The most commonly used form of cellular energy is the nucleoside triphosphate ATP. In addition, other nucleoside triphosphates and other high-energy molecules are required for specific processes.

To understand how energy is conserved in ATP and how ATP is used to do cellular work, some knowledge of the basic principles of thermodynamics is required. The science of **thermodynamics** analyzes energy changes in a collection of matter (e.g., a cell or a plant) called a system. All other matter in the universe is called the surroundings. Thermodynamics focuses on the energy differences between the initial state and the final state of a system. It is not concerned with the rate of the process. For instance, if a pan of water is heated to boiling, only the condition of the water at the start and at boiling is important in thermodynamics, not how fast it is heated.

Laws of Thermodynamics

Two important laws of thermodynamics are critical to understanding energy transfers. The **first law of thermodynamics** says that energy can be neither created nor destroyed. The total energy in the universe remains constant, although it can be redistributed, as it is during the many energy exchanges that occur during chemical reactions.

For example, heat is given off by exothermic reactions and absorbed during endothermic reactions. However, the first law alone cannot explain why heat is released by one chemical reaction and absorbed by another. Explanations for this require the

second law of thermodynamics and a condition of matter called entropy. **Entropy** is a measure of the randomness or disorder of a system. The greater the disorder of a system, the greater its entropy. The second law states that physical and chemical processes proceed in such a way that the randomness or disorder of the universe (the system and its surroundings) increases. However, even though the entropy of the universe increases, the entropy of any given system within the universe can increase, decrease, or remain unchanged.

Two types of energy units are employed to specify the amount of energy used in or evolving from a particular process. A **calorie** (cal) is the amount of heat energy needed to raise 1 gram of water from 14.5 to 15.5°C. The amount of energy also may be expressed in terms of **joules** (J), the units of work capable of being done. One cal of heat is equivalent to 4.1840 J of work. One thousand calories, or a kilocalorie (kcal), is enough energy to boil 1.9 milliliters of water. A kilojoule is enough energy to boil about 0.44 milliliters of water or enable a person weighing 70 kilograms to climb 35 steps.

Free Energy and Chemical Reactions

The first and second laws of thermodynamics can be combined in a useful equation, relating the changes in energy that can occur in chemical reactions and other processes.

$$\Delta G = \Delta H - T \Delta S$$

ΔG is the change in free energy, ΔH is the change in enthalpy, T is the temperature in Kelvin ($^{\circ}\text{C} + 273$), and ΔS is the change in entropy occurring during the reaction. The change in **enthalpy** is the change in heat content. Cellular reactions occur under conditions of constant pressure and volume. Thus the change in enthalpy is about the same as the change in total energy during the reaction. The **free energy change** is the amount of energy in a system (or cell) available to do useful work at constant temperature and pressure. Therefore the change in entropy (ΔS) is a measure of the proportion of the total energy change that the system cannot use in performing work. Free energy and entropy

changes do not depend on how the system gets from start to finish. A reaction will occur spontaneously—that is, without any external cause—if the free energy of the system decreases during the reaction or, in other words, if ΔG is negative. It follows from the equation that a reaction with a large positive change in entropy will normally tend to have a negative ΔG value and therefore occur spontaneously. A decrease in entropy will tend to make ΔG more positive and the reaction less favorable.

It is helpful to think of the relationship between entropy (ΔS) and change in free energy (ΔG) in terms that are more concrete. Consider the Greek myth of Sisyphus, king of Corinth. For his assorted crimes against the gods, he was condemned to roll a large boulder to the top of a steep hill for all eternity. This represents a very negative change in entropy—a boulder poised at the top of a hill is neither random nor disordered—and this activity (reaction) has a very positive ΔG . That is to say, Sisyphus had to put a lot of energy into the system. Unfortunately for Sisyphus, as soon as the boulder was at the top of the hill, it spontaneously rolled back down the hill. This represents a positive change in entropy and a negative ΔG . Sisyphus did not need to put energy into the system. He could simply stand at the top of the hill and watch the reaction proceed.

The change in free energy has a definite, concrete relationship to the direction of chemical reactions. Consider this simple reaction.

If molecules A and B are mixed, they will combine to form the products C and D. Eventually C and D will become concentrated enough to combine and produce A and B at the same rate as C and D are formed. The reaction is now at **equilibrium**: the rates in both directions are equal and no further net change occurs in the concentrations of reactants and products. This situation is described by the **equilibrium constant** (K_{eq}), relating the equilibrium concentrations of products and substrates to one another.

$$K_{\text{eq}} = \frac{[C][D]}{[A][B]}$$

If the equilibrium constant is greater than one, the products are in greater concentration than the reactants at equilibrium; that is, the reaction tends to go to completion as written.

The equilibrium constant of a reaction is directly related to its change in free energy. When the free energy change for a process is determined at carefully defined standard conditions of concentration, pressure, pH, and temperature, it is called the **standard free energy change** (ΔG°). If the pH is set at 7.0 (which is close to the pH of living cells), the standard free energy change is indicated by the symbol $\Delta G^{\circ'}$. The change in standard free energy may be thought of as the maximum amount of energy available from the system for useful work under standard conditions. Using $\Delta G^{\circ'}$ values allows comparisons of reactions without considering variations in ΔG due to differences in environmental conditions. The relationship between $\Delta G^{\circ'}$ and K_{eq} is given by this equation.

$$\Delta G^{\circ'} = -2.303RT \cdot \log K_{\text{eq}}$$

R is the gas constant (1.9872 cal/mole-degree or 8.3145 J/mole-degree), and T is the absolute temperature. Inspection of this

Exergonic reactions ΔG° is negative.**Endergonic reactions** ΔG° is positive.

Figure 10.2 The Relationship of ΔG° to the Equilibrium of Reactions. Note the differences between exergonic and endergonic reactions.

MICRO INQUIRY Which reaction would release heat? Explain your answer.

equation shows that when ΔG° is negative, the equilibrium constant is greater than one and the reaction goes to completion as written. It is said to be an **exergonic reaction** (figure 10.2). In an **endergonic reaction**, ΔG° is positive and the equilibrium constant is less than one. That is, the reaction is not favorable, and little product will be formed at equilibrium under standard conditions. Keep in mind that the ΔG° value shows only where the reaction lies at equilibrium, not how fast the reaction reaches equilibrium.

Retrieve, Infer, Apply

1. What kinds of work are carried out in a cell? Suppose a bacterium was doing the following: synthesizing peptidoglycan, rotating its flagellum and swimming, and secreting siderophores. What type of work is the bacterium doing in each case?
2. What is thermodynamics? Summarize the first and second laws of thermodynamics.
3. Define entropy and enthalpy. Do living cells increase entropy within themselves? Do they increase entropy in the environment?
4. Define free energy. What are exergonic and endergonic reactions?
5. Suppose that a chemical reaction had a large negative ΔG° value. Is the reaction endergonic or exergonic? What would this indicate about its equilibrium constant? If displaced from equilibrium, would the reaction proceed rapidly to completion? Would much or little free energy be made available?

10.2 ATP: The Major Energy Currency of Cells

After reading this section, you should be able to:

- Draw a simple schematic that illustrates the structure of ATP
- Describe ATP's role as a coupling agent that links exergonic and endergonic reactions
- Compare ATP's phosphate transfer potential to that of glucose 6-phosphate and phosphoenolpyruvate (PEP) and relate this to ATP's function in cells
- Describe the energy cycle observed in all organisms
- Describe the metabolic functions of three nucleoside triphosphates (other than ATP)

Energy is released from a cell's energy source in exergonic reactions (i.e., those reactions with a negative ΔG). Rather than wasting this energy, much of it is trapped in a practical form that allows its transfer to the cellular systems doing work. These systems carry out endergonic reactions (e.g., anabolism), and the energy captured by the cell is used to drive these reactions to completion. In living organisms, the most commonly used practical form of energy is **adenosine 5'-triphosphate (ATP; figure 10.3)**. In a sense, cells carry out certain processes so that they can “earn” ATP and

(b)

Figure 10.3 Adenosine Triphosphate. (a) Structure of ATP, ADP, and AMP. The two red bonds (—) are more easily broken and release considerable energy that can be used in endergonic reactions. The pyrimidine ring atoms have been numbered, as have the carbon atoms in ribose. (b) A stick-and-ball model of ATP.

Figure 10.4 ATP as a Coupling Agent. ATP is formed by exergonic reactions and then used to drive endergonic reactions.

carry out other processes in which they “spend” their ATP. Thus ATP is often referred to as the cell’s energy currency. In the cell’s economy, ATP serves as the link between exergonic reactions and endergonic reactions (figure 10.4).

What makes ATP suited for its role as energy currency? ATP is a high-energy molecule. That is, it is hydrolyzed almost completely to the products **adenosine diphosphate (ADP)** and **orthophosphate (P_i)**, with a strongly exergonic ΔG° of -7.3 kcal/mole (-30.5 kJ/mole).

The energy released is used to power endergonic reactions (figure 10.4).

The very negative ΔG° of hydrolysis of ATP is related to another important characteristic of ATP: its ability to transfer a phosphoryl group to another molecule. ATP is said to have a **high phosphate transfer potential** because it readily donates a phosphoryl group to other molecules. Note in table 10.1 that there are other phosphorylated compounds found in cells. These molecules are generated during catabolism of organic molecules such as glucose. Some of these molecules have even higher phosphate transfer potentials than ATP. The fact that ATP does

not have the highest phosphate transfer potential means that it can easily be made by cells from ADP, using molecules such as phosphoenolpyruvate (PEP) as the source of the phosphoryl group. This mechanism for making ATP is called **substrate-level phosphorylation**. ▶▶ *From glucose to pyruvate (section 11.4)*

ATP, ADP, and P_i form an energy cycle. As seen in figure 10.5, the energy released from an energy source is used to synthesize ATP from ADP and P_i. When ATP is hydrolyzed, the energy released drives endergonic processes such as anabolism, transport, and mechanical work. The mechanisms for synthesizing ATP are described in more detail in chapter 11.

ATP is the major energy currency for cells, but it is not the only energy currency. Other nucleoside triphosphates (NTPs) have major roles in metabolism. Guanosine 5′-triphosphate (GTP) supplies some of the energy used during protein synthesis. Cytidine 5′-triphosphate (CTP) is used during lipid synthesis, and uridine 5′-triphosphate (UTP) is used for the synthesis of peptidoglycan and other polysaccharides. ▶▶ *Translation in bacteria (section 13.7); Lipid synthesis (section 12.7); Synthesis of carbohydrates (section 12.4)*

Figure 10.5 The Cell’s Energy Cycle. ATP is formed from energy made available during aerobic respiration, anaerobic respiration, fermentation, chemolithotrophy, and phototrophy. Its breakdown to ADP and phosphate (P_i) makes chemical, transport, and mechanical work possible.

| Table 10.1 Phosphate Transfer Potential of Common Phosphorylated Compounds ¹ | | |
|---|--|------------------------------|
| Phosphorylated Molecule | ΔG° of Hydrolytic Removal of Phosphate (KJ/mol) | Phosphate Transfer Potential |
| High-Energy Phosphorylated Compounds | | |
| Phosphoenolpyruvate ² | −61.9 | 61.9 |
| 1, 3-bisphosphoglycerate ² | −49.3 | 49.3 |
| ATP (hydrolysis to AMP) | −45.6 | 45.6 |
| ATP (hydrolysis to ADP) | −30.5 | 30.5 |
| Low-Energy Phosphorylated Compounds | | |
| Glucose 6-phosphate | −13.8 | 13.8 |
| Glycerol 1-phosphate | −9.2 | 9.2 |

¹ Phosphate transfer potential is defined as the negative of the standard free energy change (ΔG°) for the hydrolytic removal of phosphate from the phosphorylated molecule.
² Phosphoenolpyruvate and 1,3-bisphosphoglycerate are generated during the catabolism of organic molecules such as glucose.

2. Describe the energy cycle and ATP's role in it. What characteristics of ATP make it suitable for this role?

10.3 Redox Reactions: Reactions of Central Importance in Metabolism

After reading this section, you should be able to:

- Describe a redox reaction, noting the role of the two half reactions and identifying the electron donor, electron acceptor, and conjugate redox pairs of the reaction
- Relate the standard reduction potential of a conjugate redox pair to its tendency to act as an electron-donating half reaction
- State the equation that links standard free energy change to the difference in standard reduction potentials of the two half reactions of a redox reaction
- Predict which molecule will act as an electron donor, which molecule will act as an electron acceptor, and the relative amount of energy released by a redox reaction, using the standard reduction potentials of the reaction's conjugate redox pairs

Free energy changes are related to the equilibria of all chemical reactions, including the equilibria of oxidation-reduction reactions. The release of energy from an energy source normally involves oxidation-reduction reactions. **Oxidation-reduction (redox) reactions** are those in which electrons move from an **electron donor** to an **electron acceptor**.¹ As electrons move from the donor to acceptor, the donor becomes less energy rich and the acceptor becomes more energy rich. Thus electrons can be thought of as packets of energy. The more electrons a molecule has and is able to donate in a redox reaction, the more energy rich the molecule is. This explains why molecules such as glucose, which can donate up to 24 electrons in redox reactions, are such excellent sources of energy.

Each redox reaction consists of two half reactions. One half reaction functions as the electron-donating half reaction (i.e., an oxidation reaction), and the other functions as the electron-accepting half reaction (i.e., the reduction). By convention, half reactions are written as reductions. Thus each half reaction consists of a molecule that can accept electrons (on the left side of the chemical equation), the number (n) of electrons (e^-) it accepts, and the molecule it becomes after accepting the electrons. The latter is placed on the right side of the chemical equation and is referred to as a donor, because it has electrons it can give up. The acceptor and donor of a half reaction are referred to as a **conjugate redox pair**.

The equilibrium constant for a redox half reaction is called the **standard reduction potential** (E'_0) and is a measure of the tendency of the donor of a half reaction to lose electrons. By convention, the standard reduction potentials for half reactions, such as those in **table 10.2**, are determined at pH 7 and are represented by E'_0 . Standard reduction potentials are measured in volts, a unit of electrical potential or electromotive force. Therefore conjugate redox pairs are a potential source of energy.

The reduction potential has a concrete meaning. Conjugate redox pairs with more negative reduction potentials will spontaneously donate electrons to pairs with more positive potentials and greater affinity for electrons. Thus electrons tend to move from donors at the top of the list in table 10.2 to acceptors at the bottom because the latter have more positive potentials. This may

Table 10.2 Selected Biologically Important Half Reactions

| Half Reaction | E'_0 (Volts) ¹ |
|---|-----------------------------|
| $2H^+ + 2e^- \rightarrow H_2$ | -0.42 |

| $\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$ | 0.82 |

¹ E'_0 is the standard reduction potential at pH 7.0.

² The value for $FAD/FADH_2$ applies to the free cofactor because it can vary considerably when bound to an apoenzyme.

³ The value for free Fe, not Fe complexed with proteins (e.g., cytochromes).

¹ In redox reactions, the electron donor is often called the reducing agent or reductant because it is donating electrons to the acceptor and thus reducing it. The electron acceptor is called the oxidizing agent or oxidant because it is removing electrons from the donor and oxidizing it.

be expressed visually in the form of an electron tower in which the most negative reduction potentials are at the top (figure 10.6). Electrons “fall down” the tower from donors higher in the tower (i.e., those having more negative potentials) to acceptors lower in the tower (i.e., those having more positive potentials).

Consider the case of the electron acceptor **nicotinamide adenine dinucleotide (NAD⁺)**. The NAD⁺/NADH conjugate redox pair has a very negative E'_0 , and NADH can therefore give electrons to many acceptors, including O₂.

Because the reduction potential of NAD⁺/NADH is more negative than that of $\frac{1}{2}\text{O}_2/\text{H}_2\text{O}$, electrons flow from NADH (the donor) to O₂ (the acceptor), as shown in figure 10.6. The redox reaction is shown here.

Figure 10.6 Electron Movement and Reduction Potentials.

Electrons spontaneously move from donors higher on the tower (more negative potentials) to acceptors lower on the tower (more positive potentials). That is, the donor is always higher on the tower than the acceptor. For example, NADH will donate electrons to oxygen and form water in the process. Some typical donors and acceptors are shown on the left, and their reduction potentials are given in brackets.

MICRO INQUIRY Why would energy be required to move electrons “up” the tower, from water to nitrate, for example?

The relatively negative E'_0 of the NAD⁺/NADH pair also means that the pair stores more potential energy than redox pairs with less negative (or more positive) E'_0 values. It follows that when electrons move from a donor to an acceptor with a more positive redox potential, free energy is released. The $\Delta G'^0$ of the reaction is directly related to the magnitude of the difference between the reduction potentials of the two couples ($\Delta E'_0$). The larger the $\Delta E'_0$, the greater the amount of free energy made available, as is evident from the equation

$$\Delta G'^0 = -nF \cdot \Delta E'_0$$

in which n is the number of electrons transferred, F is the Faraday constant (23,062 cal/mole-volt; 96,480 J/mole-volt), and $\Delta E'_0$ is the E'_0 of the acceptor minus the E'_0 of the donor. For every 0.1 volt change in $\Delta E'_0$, there is a corresponding 4.6 kcal (19.3 kJ) change in $\Delta G'^0$ when a two-electron transfer takes place. This is similar to the relationship of $\Delta G'^0$ and K_{eq} in other chemical reactions: the larger the equilibrium constant, the greater the $\Delta G'^0$. The difference in reduction potentials between NAD⁺/NADH and $\frac{1}{2}\text{O}_2/\text{H}_2\text{O}$ is 1.14 volts, a large $\Delta E'_0$ value. When electrons move from NADH to O₂, a large amount of free energy is made available and can be used to synthesize ATP and do other work.

How NAD⁺ Works

10.4 Electron Transport Chains: Sets of Sequential Redox Reactions

After reading this section, you should be able to:

- List the molecules that are commonly found in electron transport chains (ETCs) and indicate if they transfer electrons and protons or just electrons
- Arrange electron carriers in an ETC using their standard reduction potentials
- Indicate the location of ETCs in bacterial, archaeal, and eukaryotic cells

We have focused our attention on the reduction of O₂ by NADH because NADH plays a central role in the metabolism of many organisms. For instance, glucose is a common organic energy source. As glucose is catabolized, it is oxidized. Many of the electrons released from glucose are accepted by NAD⁺, reducing it to NADH, which transfers the electrons to O₂. However, it does not do so directly. Instead, the electrons are transferred to O₂ via a series of electron carriers that are organized into a system called an **electron transport chain (ETC)**. An ETC is similar to a bucket brigade. Each carrier represents a person receiving a pail of water (electrons) that are destined for the fire (terminal electron acceptor). The pail of water is passed down the line, just as electrons are passed from carrier to carrier. As soon as one person hands off a pail of water to the person after him in the line, he can receive a new bucket from the person before him in the line. Likewise, as electrons flow through the ETC, each carrier is sequentially reduced (given the pail full of water) and then

Figure 10.7 Electron Transport Chains. Electron transport chains (ETCs) are associated with membranes. Electrons flow from the electron carrier having the most negative reduction potential to the carrier having the most positive reduction potential. During respiratory processes (e.g., aerobic respiration), an exogenous molecule such as oxygen serves as the terminal electron acceptor. (a) The mitochondrial ETC. (b) A typical bacterial ETC.

MICRO INQUIRY Refer to figure 10.6 and determine the E'_0 for NAD^+/NADH and coenzyme Q/ CoQH_2 . Suggest a plausible E'_0 value for FMN.

reoxidized (passes the pail on to the next person in the brigade), and is ready to accept more electrons as catabolism continues.

The first electron carrier in an ETC has the most negative E'_0 , each successive carrier is slightly less negative (figure 10.7). Thus electrons are transferred spontaneously from one carrier to the next. The carriers direct the electrons to the terminal electron acceptor (in this case, O_2). This protects the cells from random, nonproductive reductions of other molecules in the cell. The use of several carriers in a chain also releases energy from an energy source such as glucose in a controlled manner so that more can be conserved and used to form ATP.

Electron transport chains are associated with or are in the plasma membranes and intracytoplasmic membranes of bacterial and archaeal cells (figure 10.7). In eukaryotes they are localized to the internal membranes of mitochondria and chloroplasts. They are important to almost all types of energy-conserving processes, as discussed in chapter 11.

The electron carriers associated with ETCs differ in terms of their chemical nature and the way they carry electrons. NADH and its chemical relative **nicotinamide adenine dinucleotide phosphate (NADPH)**, which donate electrons to ETCs, contain a nicotinamide ring (figure 10.8). This ring accepts two electrons and one proton from a donor (e.g., an intermediate formed during the catabolism of glucose), and a second proton is released. **Flavin adenine dinucleotide (FAD)** and **flavin mononucleotide (FMN)** bear two electrons and two protons on the complex ring system shown in figure 10.9. Proteins bearing FAD and FMN are often called flavoproteins. **Coenzyme Q (CoQ)** or **ubiquinone** is a quinone that transports two electrons and two protons (figure 10.10). **Cytochromes** and several other carriers use iron atoms to transport one electron at a time. In cytochromes, the iron atoms are part of a heme group or other similar iron-porphyrin rings (figure 10.11). There are several different cytochromes, each consisting of a protein and an iron-porphyrin ring.

Figure 10.8 The Structure and Function of NAD. (a) The structure of NAD⁺ and NADP⁺. NADP⁺ differs from NAD⁺ in having an extra phosphate on one of its ribose sugar units. (b) NAD⁺ can accept two electrons and one proton from a reduced substrate (S). In this example, the electrons and proton are supplied by the hydrogen atoms of the reduced substrate; recall that each hydrogen atom consists of one proton and one electron. (c) Stick-and-ball model of NAD⁺.

Figure 10.9 The Structure and Function of FAD. The vitamin riboflavin is composed of the isoalloxazine ring and its attached ribose sugar. FMN is riboflavin phosphate. The portion of the ring directly involved in oxidation-reduction reactions is in color.

Figure 10.10 The Structure and Function of Coenzyme Q (Ubiquinone). The length of the side chain varies among organisms from n = 6 to n = 10.

Figure 10.11 The Structure of Heme. Heme is composed of a porphyrin ring and an attached iron atom. It is the nonprotein component of many cytochromes. The iron atom alternatively accepts and releases an electron.

Figure 10.12 An Iron-Sulfur Protein. The protein portion of the molecule is represented by the green ribbon. The sulfur atoms (orange) are contributed by cysteine residues (yellow) in the protein. The iron atoms (gray) are associated with the sulfur to form an iron-sulfur cluster. The iron atoms are responsible for electron transfer, transferring one electron at a time.

Some iron-containing electron-carrying proteins lack a heme group and are called **nonheme iron proteins**. They are often referred to as **iron-sulfur (Fe-S) proteins** because the iron is associated with sulfur atoms (**figure 10.12**). **Ferredoxin** is an Fe-S protein active in photosynthesis-related electron transport. Like cytochromes, Fe-S proteins carry only one electron at a time. The differences in the number of electrons and protons transported by electron carriers are of great importance to the operation of ETCs, and we discuss them further in chapter 11.

Proton Pump

1. How is the direction of electron flow between conjugate redox pairs related to the standard reduction potential and the release of free energy?
2. When electrons flow from the NAD^+/NADH conjugate redox pair to the $\frac{1}{2}\text{O}_2/\text{H}_2\text{O}$ redox pair, does the reaction begin with NAD^+ or with NADH ? What is produced— O_2 or H_2O ?
3. Which among the following would be the best electron donor? Which would be the worst? Ubiquinone/ubiquinol, NAD^+/NADH , FAD/FADH_2 , $\text{NO}_3^-/\text{NO}_2^-$. Explain your answers.
4. In general terms, how is ΔG° related to $\Delta E'_0$? What is the $\Delta E'_0$ when electrons flow from the NAD^+/NADH redox pair to the $\text{Fe}^{3+}/\text{Fe}^{2+}$ redox pair? How does this compare to the $\Delta E'_0$ when electrons flow from the $\text{Fe}^{3+}/\text{Fe}^{2+}$ conjugate redox pair to the $\frac{1}{2}\text{O}_2/\text{H}_2\text{O}$ pair? Which will yield the largest amount of free energy to the cell?
5. Name and briefly describe the major electron carriers found in cells. Why is NADH a good electron donor? Why is ferredoxin an even better electron donor?

10.5 Biochemical Pathways

After reading this section, you should be able to:

- Describe the components of a biochemical pathway and how they are organized

Organisms carry out a myriad of chemical reactions, and the products of these reactions are called **metabolites**. The reactions are organized into **biochemical pathways**, which can take various forms. Some are linear (**figure 10.13a**). In linear pathways, the first molecule in the pathway is often termed the starting molecule or the substrate of the pathway. The last molecule is called the end product. Those metabolites in between are pathway intermediates. As seen in **figure 10.13b**, some linear pathways are branched and can yield more than one product. Biochemical pathways can also be cycles (**figure 10.13c**). In this case, all molecules in the pathway can be thought of as intermediates. For the cycle to continue running, there must be inputs into it. In both types of pathways, each reaction is represented by an arrow and is catalyzed by an enzyme or ribozyme, as discussed in section 10.6.

Biochemical pathways are often illustrated as though they exist in isolation of each other. Unfortunately, this is very misleading (especially to students). In reality, biochemical pathways are connected and form a complex network (**figure 10.13d**). Thus, an intermediate of a pathway may be diverted from one pathway to another pathway. This is important to recognize because biochemical pathways are dynamic. As long as the starting molecules or inputs of the pathway are available and some end product is needed, these molecules will flow into and out of the many pathways that function in cells. Microbiologists are often concerned with metabolite flux. **Metabolite flux** is the rate of turnover of a metabolite; that is, the rate at which a metabolite is formed and then used. Metabolite flux can be used as a measure of pathway activity and to understand metabolic networks.

Figure 10.13 Chemical Reactions Carried Out by Cells Are Organized into Biochemical Pathways. Biochemical pathways take two main forms: linear and cyclic. (a) Molecules in the linear forms are distinguished based on their placement in the pathway. The first molecule (A) is the starting molecule (substrate) of the pathway. Those in the middle of the pathway are called intermediates (molecules B, C, and D). The last molecule of the pathway (E) is the product of the pathway. (b) Some linear biochemical pathways are branched and thus have more than one end product (molecules Q and T). (c) The molecules present in biochemical cycles are intermediates of the pathway (molecules V, W, X, Y, and Z). Biochemical cycles also generate products (molecule S); however, to keep the cycle running, there must be inputs into the cycle (molecules U and T). (d) Metabolic pathways are interconnected and form a complex network. In this representation of a metabolic network, each ball represents a metabolite formed by reactions in the network. Each line represents the enzyme-catalyzed reaction that converts one metabolite into another.

10.6 Enzymes and Ribozymes

After reading this section, you should be able to:

- State the function and chemical makeup of enzymes
- Distinguish apoenzyme from holoenzyme and prosthetic group from coenzyme
- Draw a diagram that shows the effect of an enzyme on the activation energy of a chemical reaction
- Describe the effects of substrate concentration, pH, and temperature on enzyme activity
- Differentiate competitive and noncompetitive inhibitors of enzymes
- Discuss the importance of the discovery of ribozymes
- Compare and contrast ribozymes and enzymes
- List two examples of ribozymes and the reactions they catalyze

As we discussed in section 10.1, an exergonic reaction is one with a negative ΔG° and an equilibrium constant greater than one. An exergonic reaction proceeds to completion in the direction written (i.e., toward the right of the equation). Nevertheless, reactants for an exergonic reaction often can be combined with no obvious result. For instance, if a polysaccharide such as starch is mixed in water, the hydrolysis of the starch into its component monosaccharides (glucose) is exergonic and will occur spontaneously; that is, it will occur on its own, given enough time. However, the time needed is very long. Even if an organic chemist carried out this reaction in 6 moles/liter (M) HCl and at 100°C, it would still take several hours to go to completion. A cell, on the other hand, can accomplish the same reaction at neutral pH, at a much lower temperature, and in just fractions of a second. Cells can do this because they manufacture biological catalysts that speed up

chemical reactions. Most of these catalysts are proteins called enzymes. Other catalysts are RNA molecules termed ribozymes. Enzymes and ribozymes are critically important to cells, since most biological reactions occur very slowly without them. Indeed, enzymes and ribozymes make life possible.

Enzyme Structure

Enzymes are protein catalysts that have great specificity for the reaction catalyzed, the molecules acted on, and the products they yield. A **catalyst** is a substance that increases the rate of a chemical reaction without being permanently altered itself. The reacting molecules are called **substrates**, and the substances formed are the **products**. Enzymes may be placed in one of six general classes and usually are named in terms of the substrates they act on and the type of reaction catalyzed (table 10.3).

►► Proteins (appendix I)

Many enzymes are composed only of proteins. However, some are composed of two parts: a protein component called the **apoenzyme** and a nonprotein component called a **cofactor**. Cofactors include metal ions and a variety of organic molecules. The complete enzyme consisting of the apoenzyme and its cofactor is called the **holoenzyme**. If the cofactor is firmly attached to the apoenzyme, it is a **prosthetic group**. If the cofactor is loosely attached and can dissociate from the apoenzyme after products have been formed, it is called a **coenzyme**. Many vitamins required by humans serve as coenzymes or as their precursors (e.g., riboflavin is incorporated into FAD). Coenzymes often carry one of the products of a chemical reaction to another enzyme or transfer chemical groups from one substrate to another (figure 10.14).

How Enzymes Speed Up Reactions

It is important to keep in mind that enzymes increase the rates of reactions but do not alter their equilibrium constants. If a reaction is endergonic, the presence of an enzyme will not shift its

Figure 10.14 Coenzymes as Carriers.

Table 10.3 Enzyme Classification

| Type of Enzyme | Reaction Catalyzed by Enzyme | Example of Reaction |
|----------------|--|--|
| Oxidoreductase | Oxidation-reduction reactions | Lactate dehydrogenase: $\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{lactate} + \text{NAD}^+$ |
| Transferase | Reactions involving the transfer of chemical groups between molecules | Aspartate carbamoyltransferase: $\text{Aspartate} + \text{carbamoylphosphate} \rightleftharpoons \text{carbamoylaspartate} + \text{phosphate}$ |
| Hydrolase | Hydrolysis of molecules | Glucose 6-phosphatase: $\text{Glucose 6-phosphate} + \text{H}_2\text{O} \rightarrow \text{glucose} + \text{P}_i^1$ |
| Lyase | Breaking of C—C, C—O, C—N and other bonds by a means other than hydrolysis | Fumarase: $\text{L-malate} \rightleftharpoons \text{fumarate} + \text{H}_2\text{O}$ |
| Isomerase | Reactions involving isomerizations | Alanine racemase: $\text{L-alanine} \rightleftharpoons \text{D-alanine}$ |
| Ligase | Joining of two molecules using ATP (or the energy of other nucleoside triphosphates) | Glutamine synthetase: $\text{Glutamate} + \text{NH}_3 + \text{ATP} \rightarrow \text{glutamine} + \text{ADP} + \text{P}_i$ |

¹ P_i is inorganic phosphate.

equilibrium so that more products are formed. Enzymes simply speed up the rate at which a reaction proceeds toward its final equilibrium. 🌀 *How Enzymes Work*

How do enzymes catalyze reactions? Some understanding of the mechanism can be gained by considering the course of a simple exergonic chemical reaction.

When molecules A and B approach each other to react, they form a transition-state complex, which resembles both the substrates and the products (**figure 10.15**). **Activation energy** is required to bring the reacting molecules together in the correct way to reach the transition state. The transition-state complex can then resolve to yield the products C and D. The difference in free energy level between reactants and products is $\Delta G^{\circ'}$. Thus

Figure 10.15 Enzymes Lower the Energy of Activation. This figure traces the course of a chemical reaction in which A and B are converted to C and D. The transition-state complex is represented by AB^{\ddagger} , and the activation energy required to reach it, by E_a . The red line represents the course of the reaction in the presence of an enzyme. Note that the activation energy is much lower in the enzyme-catalyzed reaction.

the equilibrium in our example lies toward the products because $\Delta G^{\circ'}$ is negative (i.e., the products are at a lower energy level than the substrates).

As seen in figure 10.15, A and B will not be converted to C and D if they are not supplied with an amount of energy equivalent to the activation energy. Enzymes accelerate reactions by lowering the activation energy; therefore more substrate molecules will have sufficient energy to come together and form products. Even though the equilibrium constant (or $\Delta G^{\circ'}$) is unchanged, equilibrium is reached more rapidly in the presence of an enzyme because of this decrease in activation energy.

Researchers have worked hard to discover how enzymes lower the activation energy of reactions. Enzymes bring substrates together at a specific location in the enzyme called the **active** or **catalytic site** to form an enzyme-substrate complex. How the enzyme and substrate interact still has not been fully elucidated. However, the induced fit model describes the interaction for many enzymes. In the induced fit model, the enzyme changes shape when it binds the substrate so that the active site surrounds and precisely fits the substrate. This mechanism is used by hexokinase, as illustrated in **figure 10.16**. The formation of an enzyme-substrate complex can lower the activation energy in many ways. For example, by bringing the substrates together at the active site, the enzyme is, in effect, concentrating them and speeding up the reaction. An enzyme does not simply concentrate its substrates, however. It also binds them so that they are correctly oriented with respect to each other. Such an orientation lowers the amount of energy that the substrates require to reach the transition state. These and other catalytic site activities speed up a reaction by hundreds of thousands of times.

Substrate Concentration and Enzyme Activity

Enzyme activity varies in response to substrate concentration. At very low substrate concentrations, an enzyme makes product slowly because it seldom contacts a substrate molecule. If more substrate molecules are present, an enzyme binds substrate more often, and the velocity of the reaction (usually expressed in terms of the rate of product formation) is greater than at a

Figure 10.16 The Induced Fit Model of Enzyme Function. Shown is the reaction between glucose and ATP catalyzed by the enzyme hexokinase.

lower substrate concentration. Thus the rate of an enzyme-catalyzed reaction increases with substrate concentration (figure 10.17). Eventually further increases in substrate concentration do not result in a greater reaction velocity because the available enzyme molecules are binding substrate and converting it to product as rapidly as possible. That is, the enzyme is saturated with substrate and operating at maximal velocity (V_{\max}). The resulting substrate concentration curve is a hyperbola (figure 10.17).

The substrate concentrations in cells are often low. Therefore it is useful to know the substrate concentration an enzyme needs to function adequately. Usually the **Michaelis constant** (K_m), the substrate concentration required for the enzyme to achieve half-maximal velocity, is used as a measure of the apparent affinity of an enzyme for its substrate. The lower the K_m value, the lower the substrate concentration at which an enzyme catalyzes its reaction. Enzymes with a low K_m value are said to have a high affinity for their substrates. Since the concentrations of substrates in cells are often low, enzymes with lower K_m values are able to function better.

Enzyme Denaturation

Enzyme activity is changed not only by substrate concentration but also by alterations in pH and temperature. Each enzyme functions most rapidly at a specific pH optimum. When the pH

deviates too greatly from an enzyme's optimum, activity slows and the enzyme may be damaged. Enzymes likewise have temperature optima for maximum activity. If the temperature rises too much above the optimum, an enzyme's structure will be disrupted and its activity lost. This phenomenon is known as **denaturation**. The pH and temperature optima of a microorganism's enzymes often reflect the pH and temperature of its habitat. Not surprisingly, bacteria and archaea that grow best at high temperatures often have enzymes with high temperature optima and great heat stability. ◀◀ *Influences of environmental factors on growth (section 7.3)*

Enzyme Inhibition

Microorganisms can be poisoned by a variety of chemicals (e.g., cyanide), and many of the most potent poisons are enzyme inhibitors. A **competitive inhibitor** directly competes with the substrate at an enzyme's catalytic site and prevents the enzyme from forming product (figure 10.18). Competitive inhibitors usually resemble normal substrates, but they cannot be converted to products.

Competitive inhibitors are important in the treatment of many microbial diseases. Sulfa drugs such as sulfanilamide (figure 10.18b) resemble *p*-aminobenzoate (PABA), a molecule used in the formation of the coenzyme folic acid. Sulfa drugs compete with PABA for the catalytic site of an enzyme involved in folic acid synthesis. This blocks the production of folic acid and inhibits the growth of organisms that require its synthesis. Humans are not harmed because they do not synthesize folic acid but rather obtain it in their diet. ◀◀ *Metabolic antagonists (section 9.4)*

Noncompetitive inhibitors affect enzyme activity by binding to the enzyme at some location other than the active site. This alters the enzyme's shape, rendering it inactive or less active. These inhibitors are called noncompetitive because they do not directly compete with the substrate. Heavy metals such as mercury frequently are noncompetitive inhibitors of enzymes.

Figure 10.17 The Effect of Substrate Concentration on Enzyme Activity. Enzyme activity increases as substrate concentration increases until a maximum velocity is reached (V_{\max}). The resulting curve is described by the Michaelis-Menten equation, which was derived by biochemists Leonor Michaelis (1875–1949) and Maud Menten (1879–1960). It relates reaction velocity (v) to substrate concentration (S) using V_{\max} and the Michaelis constant (K_m).

MICRO INQUIRY Will an enzyme with a relatively high K_m have a high or low affinity for its substrate? Explain.

Ribozymes: Catalytic RNA Molecules

Biologists once thought that all cellular reactions were catalyzed by proteins. However, in the early 1980s Thomas Cech and Sidney Altman discovered that some RNA molecules also can catalyze reactions. Catalytic RNA molecules are called **ribozymes**. One important ribozyme is located in ribosomes and is responsible for catalyzing peptide bond formation between amino acid residues during protein synthesis. However, the best-studied ribozymes catalyze self-splicing, in which they cut themselves and then join segments of themselves back together (table 10.4). Just as with enzymes, the shape of a ribozyme is essential to catalytic efficiency. Ribozymes even have Michaelis-Menten kinetics (figure 10.17). One particularly interesting ribozyme is a self-splicing ribozyme produced by hepatitis delta virus. It is unusual in that it can fold into two shapes with quite different catalytic activities: the regular RNA cleavage activity and an RNA ligation reaction.

▶▶ *Translation in bacteria (section 13.5)*

Figure 10.18 Competitive Inhibition of Enzyme Activity. (a) A competitive inhibitor is usually similar in shape to the normal substrate of the enzyme and therefore can bind the active site of the enzyme. This prevents the substrate from binding, and the reaction is blocked. (b) Structure of sulfanilamide, a structural analogue of PABA. PABA is the substrate of an enzyme involved in folic acid biosynthesis. When sulfanilamide binds the enzyme, activity of the enzyme is inhibited and synthesis of folic acid is stopped.

MICRO INQUIRY Based on this figure, explain the notion of a minimum inhibitory concentration of sulfanilamide.

Table 10.4 Examples of Self-Splicing Ribozymes

| Function | Where observed |
|--|---|
| Splicing of pre-rRNA | <i>Tetrahymena</i> spp. |
| Splicing of mitochondrial rRNA and mRNA | Numerous fungi |
| Splicing of chloroplast tRNA, rRNA, and mRNA | Plants and algae |
| Splicing of viral mRNA | Viruses (e.g., T4, hepatitis delta virus) |

Retrieve, Infer, Apply

1. What is an apoenzyme? A holoenzyme? What are the two types of cofactors? What roles do cofactors play in enzyme function?
2. Illustrate the effect enzymes have on the activation energy of the reactions they catalyze. What is a transition state complex? Use your drawing to explain why enzymes do not change the equilibria of the reactions they catalyze.
3. How does enzyme activity change with substrate concentration? How does the Michaelis constant (K_m) relate to enzyme function?
4. What special properties might an enzyme isolated from a psychrophilic bacterium have? Will enzymes need to lower the activation energy more or less in thermophiles or psychrophiles?
5. What are competitive and noncompetitive inhibitors, and how do they inhibit enzymes?
6. How are enzymes and ribozymes similar? How do they differ?

10.7 Regulation of Metabolism

After reading this section, you should be able to:

- List the three methods cells use to regulate metabolism
- Describe metabolic channeling and one example of how it is accomplished; predict whether it is an important regulatory mechanism in bacterial, archaeal, and eukaryotic cells
- Distinguish allosteric regulation and covalent modification
- Describe the structure of an allosteric enzyme
- Create a concept map that illustrates how positive allosteric and negative allosteric effectors regulate the activity of an enzyme
- List the three chemical groups commonly used to covalently modify an enzyme and its activity
- Explain how feedback inhibition is used to control the functioning of biosynthetic pathways
- Predict which enzymes of a biochemical pathway are likely to be regulated by either allosteric control or covalent modification
- Develop a model illustrating how feedback inhibition can be used to regulate a multiply branched biosynthetic pathway

Microorganisms must regulate their metabolism to conserve raw materials and energy, and to maintain a balance among various cell components. Microbes often live in environments where the nutrients, energy sources, and physical conditions change rapidly. Therefore microbes must continuously monitor internal and external conditions, and respond accordingly. This involves activating or inactivating metabolic pathways as

needed. Metabolic pathways can be regulated in three major ways: (1) metabolic channeling, (2) regulation of the synthesis of a particular enzyme (often referred to as regulation of gene expression), and (3) direct stimulation or inhibition of the activity of critical enzymes, referred to as posttranslational regulation.

Metabolic Channeling

Metabolic channeling influences pathway activity by localizing metabolites and enzymes into different parts of a cell. One of the most common metabolic channeling mechanisms is **compartmentation**, the differential distribution of enzymes and metabolites among separate cell structures or organelles. Compartmentation is particularly important in eukaryotic microorganisms with their many membrane-bound organelles. For example, fatty acid catabolism is located within the mitochondrion, whereas fatty acid synthesis occurs in the cytosol. The periplasm in Gram-negative bacteria can also be considered an example of compartmentation. Compartmentation makes possible the simultaneous but separate operation and regulation of similar pathways. Furthermore, pathway activities can be coordinated through regulation of the transport of metabolites and coenzymes between cell compartments.

Regulation of Gene Expression

In the second regulatory mechanism—regulation of the synthesis of a particular enzyme—transcription and translation rates are altered to control the amount of an enzyme present in the cell. Regulation of gene expression is relatively slow, but it saves the cell considerable energy and raw materials. Cells have evolved numerous mechanisms for regulating gene expression. We save the discussion of these mechanisms for chapters 14 and 15. ►► *Transcription in bacteria* (section 13.5); *Translation in bacteria* (section 13.7); *Regulation of bacterial cellular processes* (chapter 14); *Regulation of cellular processes* (section 15.5)

Posttranslational Regulation of Enzyme Activity

In contrast to regulation of gene expression, the direct stimulation or inhibition of the activity of critical enzymes rapidly alters pathway activity. It is often called **posttranslational regulation** because it occurs after the enzyme has been synthesized. A number of posttranslational regulatory mechanisms are known. Some are irreversible; for instance, cleavage of a protein can either activate or inhibit its activity. Others, such as allosteric regulation and covalent modification, are reversible.

Allosteric Regulation

Most regulatory enzymes are **allosteric enzymes**. The activity of an allosteric enzyme is altered by a small molecule known as an **allosteric effector**. The effector binds reversibly by noncovalent forces to a **regulatory site** separate from the catalytic site and causes a change in the shape (conformation) of the enzyme (**figure 10.19**). The activity of the catalytic site is altered as a

result. A positive effector increases enzyme activity, whereas a negative effector decreases activity (i.e., inhibits the enzyme). These changes in activity often result from alterations in the apparent affinity of the enzyme for its substrate, but changes in maximum velocity also can occur.

Covalent Modification of Enzymes

Regulatory enzymes also can be switched on and off by **reversible covalent modification**. Usually this occurs through the addition and removal of a particular chemical group, typically a phosphoryl, methyl, or adenylyl group.

One of the most intensively studied regulatory enzymes is *Escherichia coli*'s glutamine synthetase, an enzyme involved in nitrogen assimilation. It is a large, complex enzyme consisting of

Allosteric enzymes have two important sites: the catalytic site and the regulatory site. Substrate binds to the catalytic site; an allosteric effector binds to the regulatory site.

Binding of the allosteric effector to the regulatory site causes a change in the catalytic site. In this example, the catalytic site is changed such that substrate can now bind.

Figure 10.19 Allosteric Regulation. The structure and function of an allosteric enzyme.

MICRO INQUIRY Is this allosteric effector a positive or negative effector? Is this true of all allosteric effectors?

Figure 10.20 Regulation of Glutamine Synthetase Activity by Covalent Modification. Glutamine synthetase consists of 12 subunits. Six subunits form a ring, and one ring (darker color) is above the other (lighter color). Not all of the lower ring subunits are shown. Each subunit can be adenylylated. Only the adenylyl groups on the upper ring are shown. As the number of adenylyl groups increases, the activity of the enzyme decreases.

12 subunits, each of which can be covalently modified by an adenylic acid residue (figure 10.20). When an adenylic acid residue is attached to all of its 12 subunits, glutamine synthetase is not very active. Removal of AMP groups produces more active deadenylylated glutamine synthetase, and glutamine is formed.

►► Nitrogen assimilation (section 12.5)

Using covalent modification for the regulation of enzyme activity has some advantages. These interconvertible enzymes often are also allosteric. For instance, glutamine synthetase also is regulated allosterically. Because each form can respond differently to allosteric effectors, systems of covalently modified enzymes are able to respond to more stimuli in varied and sophisticated ways. Regulation can also be exerted on the enzymes that catalyze the covalent modifications, which adds a second level of regulation to the system.

Feedback Inhibition

The rate of many metabolic pathways is adjusted through control of a pacemaker enzyme, one that catalyzes the slowest or rate-limiting reaction in the pathway. Because other reactions proceed more rapidly than the pacemaker reaction, changes in the activity of this enzyme directly alter the speed with which a pathway operates. Usually the first reaction in a pathway is catalyzed by a pacemaker enzyme. The end product of the pathway often inhibits this regulatory enzyme, a process known as **feedback inhibition** or **end product inhibition**. Feedback inhibition ensures balanced production of a pathway end product. If the end product becomes too concentrated, it inhibits the regulatory enzyme and slows its own synthesis. As the concentration of the end product decreases, pathway activity again increases and more product is formed. In this way, feedback inhibition automatically matches end product supply with the demand.  *A Biochemical Pathway, Feedback Inhibition of Biochemical Pathways*

Frequently a biosynthetic pathway branches to form more than one end product. In such a situation, the synthesis of all end

products must be coordinated precisely. It would not do to have one end product present in excess while another is lacking. Branching biosynthetic pathways usually achieve a balance among end products by using regulatory enzymes at branch points (figure 10.21). If an end product is present in excess, it often inhibits the first enzyme on the branch leading to its formation, in this way regulating its own formation without affecting the synthesis of other products. In figure 10.21, notice that both products also inhibit the initial enzyme in the pathway. An excess of one product slows the flow of carbon into the whole pathway and also inhibits the appropriate branch-point enzyme. Because less carbon is required when only one branch is functioning, feedback inhibition of the initial pacemaker enzyme helps match the supply with the demand in branching pathways. The regulation of multiple branched pathways is often made even more sophisticated by the presence of **isoenzymes** (**isozymes**), different forms of an enzyme that catalyze the same reaction. The initial pacemaker step may be catalyzed by several isoenzymes, each under separate control. In this case, an excess of a single end product reduces pathway activity but does not completely block pathway function because some isoenzymes are still active.

Figure 10.21 Feedback Inhibition. Feedback inhibition in a branching pathway with two end products. The branch-point enzymes, those catalyzing the conversion of intermediate E to F and G, are regulated by feedback inhibition. Products P and Q also inhibit the initial reaction in the pathway. A colored line with a minus sign at one end indicates that an end product, P or Q, is inhibiting the enzyme catalyzing the step next to the minus.

MICRO INQUIRY What would happen to product formation if P and Q inhibited the formation of intermediate E independently of one another?

Retrieve, Infer, Apply

1. Briefly describe the three ways a metabolic pathway may be regulated.
2. Define the terms metabolic channeling and compartmentation. How are they involved in the regulation of metabolism?
3. Define allosteric enzyme and allosteric effector.
4. How can regulatory enzymes be influenced by reversible covalent modification? What group is used for this purpose with glutamine synthetase, and which form of this enzyme is active?
5. What is a pacemaker enzyme? Feedback inhibition? How does feedback inhibition automatically adjust the concentration of a pathway end product?
6. What is the significance of the fact that regulatory enzymes often are located at pathway branch points? What are isoenzymes, and why are they important in pathway regulation?

Key Concepts

10.1 Metabolism: Important Principles and Concepts

- Despite the tremendous metabolic diversity observed in the microbial world, there are common features to all types of metabolisms. These are (1) life obeys the laws of thermodynamics, (2) ATP is the major form of energy currency for cells, (3) redox reactions are important in energy-conserving processes, (4) cellular chemical reactions are organized into biochemical pathways, (5) cellular chemical reactions are catalyzed by enzymes or ribozymes, and (6) the functioning of biochemical pathways is regulated.
- Living cells carry out three major kinds of work: chemical work of biosynthesis, transport work, and mechanical work. Energy is required to do cellular work and can be defined as the capacity to do work.
- Thermodynamics is the field that analyzes energy changes in systems such as cells. The first law of thermodynamics states that energy is neither created nor destroyed. The second law of thermodynamics states that changes occur in such a way that the randomness or disorder of the universe increases to the maximum possible. That is, entropy always increases during spontaneous processes.
- The first and second laws of thermodynamics can be combined to determine the amount of energy made available for useful work.

$$\Delta G = \Delta H - T \cdot \Delta S$$

In this equation the change in free energy (ΔG) is the energy made available for useful work, the change in enthalpy (ΔH) is the change in heat content, and the change in entropy is ΔS .

- The standard free energy change ($\Delta G^{\circ'}$) for a chemical reaction is directly related to the equilibrium constant.
- In exergonic reactions, $\Delta G^{\circ'}$ is negative and the equilibrium constant is greater than one; the reaction goes to completion as written. Endergonic reactions have a positive $\Delta G^{\circ'}$ and an equilibrium constant less than one (figure 10.2).

10.2 ATP: The Major Energy Currency of Cells

- ATP is a high-energy molecule that transports energy in a useful form from one reaction or location in a cell to another (figure 10.3).
- ATP is readily synthesized from ADP and P_i using energy released from exergonic reactions; when hydrolyzed back to ADP and P_i , it releases the energy, which is used to drive endergonic reactions. This cycling of ATP with ADP and P_i is called the cell's energy cycle (figure 10.5).

10.3 Redox Reactions: Reactions of Central Importance in Metabolism

- In oxidation-reduction (redox) reactions, electrons move from an electron donor to an electron acceptor. Each redox reaction consists of two half reactions: one is the electron-donating half reaction; the other is the electron-accepting half reaction.
- Each half reaction of a redox reaction consists of a molecule that can accept electrons and one that can donate electrons. These two molecules are called a conjugate redox pair.
- The standard reduction potential measures the tendency of the donor of a conjugate redox pair to give up electrons.
- Conjugate redox pairs with more negative reduction potentials donate electrons to those with more positive potentials, and energy is made available during the transfer (figure 10.6 and table 10.2).

10.4 Electron Transport Chains: Sets of Sequential Redox Reactions

- Many metabolic processes use a series of electron carriers to transport electrons from the primary electron donor (e.g., an organism's energy source) to a final electron acceptor (e.g., oxygen). A series of electron carriers is called an electron transport chain (ETC). ETCs are associated with or located in membranes (figure 10.7).
- Some of the most important electron carriers in cells are NAD, NADP, FAD, FMN, coenzyme Q, cytochromes, and the nonheme iron (Fe-S) proteins (figures 10.8–10.12). They differ in several ways, including how many electrons and protons they transfer.

10.5 Biochemical Pathways

- The chemical reactions carried out by cells are organized to form biochemical pathways. The intermediates and products of the pathways are called metabolites (**figure 10.13**).
- Metabolic pathways are interconnected such that the intermediates and end product of one pathway may be the starting molecules of others (**figure 10.13d**). Metabolite flux refers to the turnover of metabolites as they are used in various biochemical pathways.

10.6 Enzymes and Ribozymes

- Enzymes are protein catalysts that catalyze specific reactions.
- Many enzymes consist of a protein component, the apoenzyme, and a cofactor. Cofactors may be metals or organic molecules. Some cofactors are prosthetic groups, which are tightly bound to the apoenzyme. Other cofactors are loosely bound and are called coenzymes.
- Enzymes and ribozymes speed chemical reactions by binding substrates at their active sites and lowering the activation energy (**figures 10.15 and 10.16**).
- The rate of an enzyme- or ribozyme-catalyzed reaction increases with substrate concentration at low substrate levels and reaches a plateau (the maximum velocity) at saturating substrate concentrations. The Michaelis constant is the substrate concentration that the enzyme or ribozyme requires to achieve half maximal velocity (**figure 10.17**).
- Enzymes have pH and temperature optima for activity. Their activity can be slowed by competitive and noncompetitive inhibitors (**figure 10.18**).

- Some ribozymes alter either their own structure or that of other RNAs. An important ribozyme is located in the ribosome, where it links amino acids together during protein synthesis.

10.7 Regulation of Metabolism

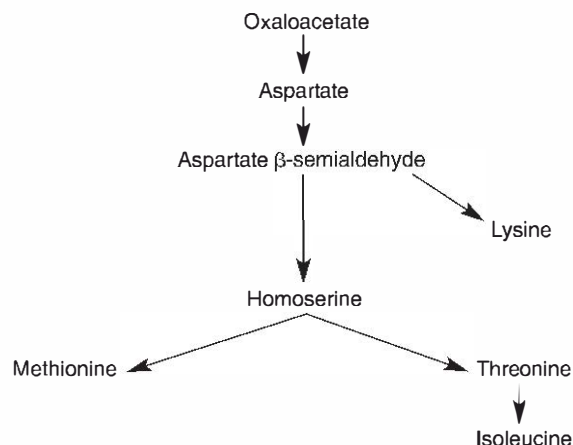

- The regulation of metabolism keeps cell components in proper balance and conserves metabolic energy and material. There are three major approaches to regulating metabolism: metabolic channeling, regulation of gene expression, and posttranslational regulation of enzyme activity.
- Metabolic channeling localizes metabolites and enzymes in different parts of the cell and influences pathway activity. A common channeling mechanism is compartmentation.
- Regulation of gene expression is brought about by controlling the rate of transcription and translation. This is discussed in chapters 14 and 15.
- Posttranslational regulation is the direct control of enzyme activity. There are two major types of reversible posttranslational regulation: allosteric control and covalent modification. In allosteric control, certain enzymes in a pathway are regulatory enzymes to which an allosteric effector binds noncovalently to a regulatory site separate from the catalytic site. This causes a conformational change in the enzyme and alters its activity (**figure 10.19**). In covalent modification, enzyme activity is regulated by reversible attachment of a chemical group, such as a phosphoryl, methyl, or adenylyl group (**figure 10.20**).
- The first enzyme in a pathway and enzymes at branch points often are subject to feedback inhibition by one or more end products. Excess end product slows its own synthesis (**figure 10.21**).

Compare, Hypothesize, Invent

1. Examine the structures of macromolecules in appendix I. Which type has the most electrons to donate? Suggest why carbohydrates are usually the primary source of energy for bacteria that use organic molecules as energy sources?
2. Most enzymes do not operate at their biochemical optima inside cells. Suggest why this is the case.
3. Examine the branched pathway shown here for the synthesis of the amino acids aspartate, methionine, lysine, threonine, and isoleucine.

Scenario 1: The microbe is cultured in a medium containing aspartate and lysine but lacking methionine, threonine, and isoleucine.

Scenario 2: The microbe is cultured in a medium containing a rich supply of all five amino acids.

For each of these two scenarios, answer the following questions:

- a. Which portion(s) of the pathway would need to be shut down in this situation?
 - b. How might allosteric control be used to accomplish this?
4. Chlamydia are pathogenic bacteria that must be grown within a eukaryotic host cell. They rely on the host cell for many nutrients, including nucleotides, lipids, and amino acids. It is thus no surprise that when grown in coculture with a host depleted of any of these metabolites, chlamydial growth declines. However, investigators were surprised to find that high levels of certain amino acids also inhibit chlamydial growth. Further investigation found that the amino acids leucine, isoleucine, methionine, and

phenylalanine could retard growth, but this effect could be reversed if valine was added at the same time. The authors discovered that the amino acid transporter BrnQ was blocked by the four growth inhibitory amino acids.

Develop a model whereby BrnQ transports valine and the observed growth inhibition is due to competitive inhibition by high levels of these four amino acids. Your model should take into account the similarity between valine, leucine, and isoleucine (*see appendix I*) and the fact that BrnQ transports methionine under normal conditions.

Catabolism: Energy Release and Conservation

The Richest Hill On Earth

The history of Butte, Montana, is a colorful one filled with interesting characters, great tragedies, and the amazing resilience of its people. The city has gone through boom-and-bust cycles related to its location—it sits on a mountain rich in copper and other metals. From the 1860s until 1982, mining shaped life in Butte. It began with underground mining, which was accompanied by one of the worst mining disasters in U.S. history. In 1917 the Granite Mountain fire took the lives of 168 miners.

The advent of open-pit mining of the mountain in 1955 raised the hope that earlier mining tragedies would be averted. That hope came to fruition. Over the next 20 years, the strip mine devoured the side of the mountain and parts of the city, creating the Berkeley Pit, a deep hole a mile and a half across. In the process, it yielded over 1 billion tons of copper, gold, lead, and other metals, and was a boon to Butte's economy.

As the mine operated, groundwater and runoff entered the pit, requiring that the water be continuously pumped out. When the mine closed in 1982, the pumps were shut down and water began to accumulate. Now the north edge of Butte borders on the Berkeley Pit Lake, a lake containing water contaminated with toxic metals and a pH of about 2.5. The danger of the water was tragically demonstrated in 1995 when 342 migrating snow geese died after landing in the lake.

But the Berkeley Pit Lake is not devoid of life. In 1998 a search for microbial life in the lake began. The study, led by Montana Tech University scientist Grant Mitman, led to the discovery of algae, fungi, and bacteria living in the lake. This led scientists to suggest that microbes might be used to bioremediate (clean up) the water. Later studies by Don and Andrea Stierle of the University of Montana-Missoula led to the discovery of microbes that produce interesting chemicals that may be useful for treating cancer, migraines, and other illnesses. Thus, the Berkeley Pit Lake may be able to restore the title of “the richest hill on Earth” to the Butte area due to the metabolic activity of its resident microbes.

A photograph of the Berkeley Pit taken in 2006 by an astronaut on the International Space Station. At that time, the water was more than 900 feet deep.

The story of the Berkeley Pit clearly demonstrates that microbes are the most successful organisms on Earth as witnessed by their growth under almost every conceivable condition. In large part, their success results from the diversity of their fueling reactions—those reactions that convert energy from an organism's energy source into ATP, provide reducing power, and generate precursor metabolites. The fueling reactions are the focus of this chapter.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Distinguish metabolism, catabolism, and anabolism
- ✓ Discuss the function of ATP and how that function is related to its phosphate transfer potential (section 10.2)
- ✓ Relate the standard reduction potential of a conjugate redox pair to its tendency to act as an electron-donating half reaction (section 10.3)
- ✓ List the molecules that are commonly found in electron transport chains (ETCs) and indicate if they transfer electrons and protons or just electrons (section 10.4)
- ✓ Describe the organization of cellular chemical reactions into interconnected biochemical pathways (section 10.5)
- ✓ State the function of enzymes and ribozymes in cellular chemical reactions (section 10.6)

11.1 Metabolic Diversity and Nutritional Types

After reading this section, you should be able to:

- Use the terms that describe a microbe's carbon source, energy source, and electron source
- State the carbon, energy, and electron sources of photolithoautotrophs, photoorganoheterotrophs, chemolithoautotrophs, chemolithoheterotrophs, and chemoorganoheterotrophs
- Describe the products of the fueling reactions
- Discuss the metabolic flexibility of microorganisms

As we discuss in chapter 10, all organisms require an energy source to maintain their order and complexity. Furthermore, the importance of redox reactions in cellular metabolism dictates that organisms must also have an electron source. Finally, life on Earth is carbon-based. Thus all organisms must obtain carbon from their environments to synthesize the organic molecules they need to survive. The central importance of energy, electrons, and carbon has led biologists to describe organisms in terms of how these requirements are met. The terms devised can be combined to characterize an organism's nutritional type. The energy, electrons, and carbon that an organism obtains from its environment are used in chemical reactions that are referred to as fueling reactions. The nutritional types and fueling reactions are the focus of this section. In addition, we explore how the fueling reactions relate to other metabolic processes carried out by microbes.

Nutritional Types

For each requirement—energy, electrons, and carbon—a dichotomy exists for how an organism fulfills that need. Only two sources of energy are available to organisms: light and certain chemical molecules. **Phototrophs** use light as their energy source (**table 11.1**); **chemotrophs** obtain energy from the oxidation of chemical compounds (either organic or inorganic). Likewise, organisms have only two sources for electrons. **Lithotrophs** (i.e., “rock-eaters”) use reduced inorganic substances as their electron source, whereas **organotrophs** extract electrons from reduced organic compounds. Finally, organisms may be **heterotrophs**—organisms that use reduced, preformed organic molecules as their carbon source for growth, or they may be **autotrophs**—organisms that use carbon dioxide (CO₂) as their sole or principal source of carbon.

By combining the roots of these terms, most organisms can be placed in one of five nutritional types based on their primary sources of carbon, energy, and electrons (**table 11.2**). The majority

of microorganisms thus far studied are either photolithoautotrophic, chemolithoautotrophic, or chemoorganoheterotrophic. **Photolithoautotrophs** (often called simply **photoautotrophs**) use light energy and have CO₂ as their carbon source. Photosynthetic protists and cyanobacteria employ water as the electron donor and release oxygen. Other photolithoautotrophs, such as the purple sulfur bacteria and the green sulfur bacteria, cannot oxidize water but extract electrons from inorganic donors such as hydrogen, hydrogen sulfide, and elemental sulfur. **Chemolithoautotrophs** oxidize reduced inorganic compounds such as iron-, nitrogen-, or sulfur-containing molecules to derive both energy and electrons for biosynthesis, using carbon dioxide as the carbon source. Chemolithoautotrophs contribute greatly to the chemical transformations of elements (e.g., the conversion of ammonia to nitrate or sulfur to sulfate) that continually occur in ecosystems. Photoautotrophs and chemolithoautotrophs also are important primary producers in ecosystems. That is, they fix

Table 11.1 Sources of Carbon, Energy, and Electrons

| Carbon Sources | |
|------------------|--|
| Autotrophs | CO ₂ sole or principal biosynthetic carbon source |
| Heterotrophs | Reduced, preformed, organic molecules from other organisms |
| Energy Sources | |
| Phototrophs | Light |
| Chemotrophs | Oxidation of organic or inorganic compounds |
| Electron Sources | |
| Lithotrophs | Reduced inorganic molecules |
| Organotrophs | Organic molecules |

Table 11.2 Major Nutritional Types of Microorganisms

| Nutritional Type | Carbon Source | Energy Source | Electron Source | Representative Microorganisms |
|------------------------|-----------------|---|--|---|
| Photolithoautotroph | CO ₂ | Light | Inorganic e ⁻ donor | Purple and green sulfur bacteria, cyanobacteria, diatoms |
| Photoorganoheterotroph | Organic carbon | Light | Organic e ⁻ donor | Purple nonsulfur bacteria, green nonsulfur bacteria |
| Chemolithoautotroph | CO ₂ | Inorganic chemicals | Inorganic e ⁻ donor | Sulfur-oxidizing bacteria, hydrogen-oxidizing bacteria, methanogens, nitrifying bacteria, iron-oxidizing bacteria |
| Chemolithoheterotroph | Organic carbon | Inorganic chemicals | Inorganic e ⁻ donor | Some sulfur-oxidizing bacteria (e.g., <i>Beggiatoa</i>) |
| Chemoorganoheterotroph | Organic carbon | Organic chemicals, often same as C source | Organic e ⁻ donor, often same as C source | Most nonphotosynthetic microbes, including most pathogens, fungi, and many protists and archaea |

CO₂, making reduced organic molecules that sustain the chemoorganoheterotrophs that share their habitats. ►► *Nitrifying bacteria* (section 22.1); *Phototrophic bacteria* (section 21.4); *Purple sulfur bacteria* (section 22.3)

Chemoorganoheterotrophs (sometimes called **chemoheterotrophs** or chemoorganotrophs) use the reduced organic compounds made by autotrophs as sources of energy, electrons, and carbon. Frequently the same organic nutrient will satisfy all these requirements. Chemoorganotrophs contribute to biogeochemical cycles, such as the carbon cycle and nitrogen cycle, in which elements are converted into different forms. In addition, they are of considerable practical importance. Many chemoorganotrophs are used industrially to make foods (e.g., yogurt, pickles, cheese), medical products (e.g., antibiotics), and beverages (e.g., beer and wine). Nearly all pathogenic microorganisms are chemoorganoheterotrophs.

►► *Biogeochemical cycling* (section 28.1)

The other nutritional types have fewer known microorganisms but are very important ecologically. Some phototrophic bacteria (e.g., purple nonsulfur and green bacteria) use organic matter as their electron donor and carbon source. These **photoorganoheterotrophs** are common inhabitants of polluted lakes and streams. **Chemolithoheterotrophs** use reduced inorganic molecules as their energy and electron source but derive their carbon from organic sources. Like chemolithoautotrophs, they contribute to numerous biogeochemical cycles.

►► *Purple nonsulfur bacteria* (section 22.1)

Although we have sorted microbes into a particular nutritional type, microbes are not always so easily categorized. Some show great metabolic flexibility and alter their metabolism in response to environmental changes. For example, many purple nonsulfur bacteria act as photoorganoheterotrophs in the absence of oxygen but oxidize organic molecules and function chemoorganotrophically at normal oxygen levels (see figure 22.4). When oxygen is low, phototrophic and chemoorganotrophic metabolism may function simultaneously. This allows the bacterium to gain energy from both light and organic molecules, and still supply the carbon it needs for biosynthesis. Some of these bacteria also can grow as photolithoautotrophs with molecular hydrogen as an electron donor. This sort of flexibility gives these microbes a distinct advantage if environmental conditions frequently change.

Fueling Reactions

Despite the diversity of energy, electron, and carbon sources used by organisms, all are used to generate three main products: **ATP**, the primary molecule used to conserve the energy supplied by an energy source; **reducing power**, molecules that serve as a ready supply of electrons for a variety of chemical reactions; and **precursor metabolites**, small organic molecules that provide the carbon skeletons needed for biosynthesis of important chemical

Figure 11.1 The Fueling Reactions and Their Role in Metabolism. Organisms use their fueling reactions to convert their carbon, energy, and electron sources into precursor metabolites, ATP, and, reducing power, respectively. In autotrophs, the precursor metabolites arise from CO₂-fixation and related pathways, which are discussed in chapter 12. In heterotrophs, the precursor metabolites arise from reactions of the central metabolic pathways (see figure 12.2). ATP and reducing power are used in anabolic reactions that convert precursor metabolites into monomers and other building blocks. Monomers are used to generate macromolecules such as proteins, which are assembled into various cell structures.

building blocks (monomers) such as amino acids (figure 11.1). The processes that supply these products are called **fueling reactions**. With the exception of CO₂-fixation, the fueling reactions are part of catabolism. As seen in figure 11.1, the generation of monomers using the products of the fueling reactions paves the way for anabolic reactions that synthesize macromolecules (e.g., polymers such as proteins). The macromolecules are used to construct cellular structures such as ribosomes and flagella.

Retrieve, Infer, Apply

1. Discuss the ways in which organisms are classified based on their requirements for energy, carbon, and electrons.
2. Describe the nutritional requirements of the major nutritional groups and give some microbial examples of each.
3. Compare photolithoautotrophy with chemolithoautotrophy. Do you think it is possible for an ecosystem to exist solely on the organic carbon generated by chemolithotrophy (i.e., without any contribution by photosynthetic organisms)? Explain your reasoning.
4. What are the three major products generated by the fueling reactions? Summarize how they are used in anabolic processes.

11.2 Chemoorganotrophic Fueling Processes

After reading this section, you should be able to:

- List the three types of chemoorganotrophic metabolisms
- List the pathways of major importance to chemoorganotrophs and explain their importance
- Propose an explanation that accounts for the existence of amphibolic pathways

When chemoorganotrophs oxidize an organic energy source, the electrons released are accepted by electron carriers such as NAD^+ and FAD . When these reduced electron carriers (e.g., NADH , FADH_2) in turn donate the electrons to an electron transport chain, the metabolic process is called **respiration** and may be divided into two different types (figure 11.2). In aerobic respiration, the final electron acceptor is oxygen, whereas the terminal acceptor in anaerobic respiration is a different oxidized molecule such as NO_3^- , SO_4^{2-} , CO_2 , Fe^{3+} , or SeO_4^{2-} . Organic acceptors such as fumarate and humic acids also may be used. As just noted, respiration involves the activity of an electron transport chain. As electrons pass through the chain to the final electron acceptor, a type of potential energy called the proton motive force (PMF) is generated and used to synthesize ATP from ADP and phosphate (P_i). In contrast, **fermentation** (Latin *fermentare*, to cause to rise) uses an electron acceptor that is endogenous (from within the cell)

and does not involve an electron transport chain. The endogenous electron acceptor is usually an intermediate (e.g., pyruvate) of the catabolic pathway used to degrade and oxidize the organic energy source. During fermentation, ATP is synthesized almost exclusively by substrate-level phosphorylation, a process in which a phosphate is transferred to ADP from a high-energy molecule (e.g., phosphoenolpyruvate) generated by catabolism of the energy source.

By convention, aerobic respiration, anaerobic respiration, and fermentation are usually described with glucose as the energy source. This is done for several reasons. One is that glucose is used by many chemoorganotrophs as an energy source. But perhaps more important is the way catabolic pathways are organized. Most chemoorganotrophs can use a wide variety of organic molecules as energy sources (figure 11.3). They are degraded by pathways that either generate glucose or intermediates of the pathways used in glucose catabolism. Thus nutrient molecules are funneled

into ever fewer metabolic intermediates. Indeed, a common pathway often degrades many similar molecules (e.g., several different sugars). The existence of a few metabolic pathways that each degrade many nutrients greatly increases metabolic efficiency by avoiding the need for a large number of less metabolically flexible pathways.

The diversity of organic molecules used as energy sources by chemoorganotrophic microbes contributes to their ecology. They are found in habitats rich in organic molecules, particularly those molecules they can use as energy sources. For instance, lactose catabolizers are common in the intestinal tracts of mammals, where they may have a ready supply of this sugar. Clostridia and other soil bacteria that use amino acids as energy sources are important decomposers of proteins in protein-rich habitats. One-carbon molecules such as methane can also be catabolized by microbes, some doing so aerobically, others anaerobically. Furthermore, some bacteria such as the soil-dwelling pseudomonads are able to degrade unusual and often complex organic molecules, including pesticides, polystyrene, polychlorinated biphenyls (PCBs), and even the phenolic resins used as glue in the production of plywood and fiberboard. These microbes are useful in bioremediation.

►► Biodegradation and bioremediation (section 43.4)

The catabolic pathways of greatest importance to chemoorganotrophs are the glycolytic pathways (section 11.4) and the tricarboxylic acid (TCA) cycle (section 11.5). They are important not only for their role in catabolism but also for their roles in anabolism. They supply material needed for biosynthesis, including precursor metabolites and reducing power. Furthermore, some enzymes of these pathways are reversible and can function either catabolically or anabolically. ►► Precursor metabolites (section 12.2)

Pathways with enzymes that function both catabolically and anabolically are often called **amphibolic**

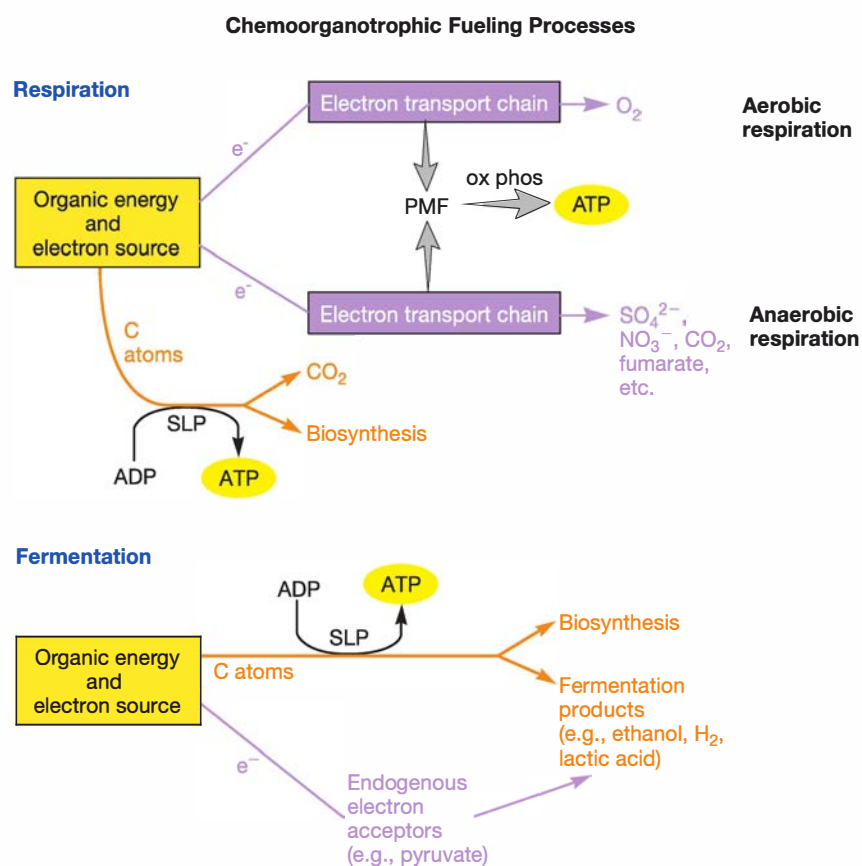

Figure 11.2 Chemoorganotrophic Fueling Processes. Organic molecules serve as energy and electron sources for all three fueling processes used by chemoorganotrophs. In aerobic respiration and anaerobic respiration, the electrons pass through an electron transport chain. This generates a proton motive force (PMF), which is used to synthesize most of the cellular ATP by a mechanism called oxidative phosphorylation (ox phos); a small amount of ATP is made by a process called substrate-level phosphorylation (SLP). In aerobic respiration, O_2 is the terminal electron acceptor, whereas in anaerobic respiration, exogenous molecules other than O_2 serve as electron acceptors. During fermentation, endogenous organic molecules act as electron acceptors, electron transport chains do not function, and most organisms synthesize ATP only by substrate-level phosphorylation.

Figure 11.3 Pathways Used by Chemoorganotrophs to Catabolize Organic Energy Sources. Notice that these pathways funnel metabolites into the glycolytic pathways and the tricarboxylic acid cycle, thus increasing metabolic efficiency and flexibility.

pathways (Greek *amphi*, on both sides). For instance, many of the enzymes of the Embden-Meyerhof pathway (a glycolytic pathway) are freely reversible. They function catabolically during glycolysis but anabolically during gluconeogenesis, a pathway that generates glucose from pyruvate and other small molecules (figure 11.4). Other reactions in glycolysis are not reversible. During glycolysis, an enzyme catalyzes the reaction in a catabolic direction, and during gluconeogenesis, a different enzyme catalyzes the reverse, anabolic reaction. Thus, although glycolysis and gluconeogenesis share many enzymes, they are two distinct pathways.

In the following sections, we explore the metabolism of chemoorganotrophs in more detail. The discussion begins with aerobic respiration and introduces the glycolytic pathways, TCA cycle, and other important processes. Many of these also occur during anaerobic respiration. Thus in many cases, anaerobic respiration differs from aerobic respiration mainly in terms of the terminal electron acceptor. Fermentation is quite distinct from respiration. It involves only a subset of the reactions that function during respiration and only partially catabolizes the energy source. However, it is widely used by microbes and has

Figure 11.4 An Amphibolic Pathway. The Embden-Meyerhof pathway is an example of an amphibolic pathway. Many reactions of this pathway are catalyzed by enzymes that function in glycolysis and in an anabolic pathway called gluconeogenesis. Gluconeogenesis reverses the glycolytic process and allows cells to synthesize glucose from smaller molecules such as pyruvate. Note that some glycolytic reactions are catalyzed by enzymes unique to that pathway. Likewise, some gluconeogenic reactions are catalyzed by enzymes unique to gluconeogenesis. Therefore, although they share several enzymes, the two pathways are distinct.

1. Give examples of the types of electron acceptors used by fermentation and respiration. What is the difference between aerobic respiration and anaerobic respiration?
2. Why is it to a cell's advantage to catabolize diverse organic energy sources by funneling them into a few common pathways?
3. What are amphibolic pathways? Why are they important?

11.3 Aerobic Respiration

After reading this section, you should be able to:

- Describe in general terms what happens to a molecule of glucose during aerobic respiration
- List the end products made during aerobic respiration
- Identify the process that generates the most ATP during aerobic respiration

Aerobic respiration is a process that can completely catabolize a reduced organic energy source to CO_2 using the glycolytic pathways and TCA cycle with O_2 as the terminal electron acceptor for an electron transport chain (figure 11.2). We focus in this section and the following three sections on the aerobic respiration of glucose. The catabolism of glucose begins with one or more pathways that yield pyruvate (section 11.4). These pathways also produce NADH, FADH_2 , or both. Next the partially oxidized carbon is fed into the TCA cycle and oxidized completely to CO_2 with the production of some GTP or ATP, NADH, and FADH_2 (section 11.5). The NADH and FADH_2 formed by glycolysis and the TCA cycle are oxidized by an electron transport chain, using O_2 as the terminal electron acceptor (section 11.6). It is the activity of the electron transport chain that conserves most of the energy used to make ATP during aerobic respiration.

11.4 From Glucose to Pyruvate

After reading this section, you should be able to:

- List the three major pathways that catabolize glucose to pyruvate
- Describe substrate-level phosphorylation
- Diagram the major changes made to glucose as it is catabolized by the Embden-Meyerhof, Entner-Doudoroff, and pentose phosphate pathways
- Identify those reactions of the Embden-Meyerhof, Entner-Doudoroff, and pentose phosphate pathways that consume ATP, produce ATP and NAD(P)H, generate precursor metabolites, or are redox reactions
- Calculate the yields of ATP and NAD(P)H by the Embden-Meyerhof, Entner-Doudoroff, and pentose phosphate pathways
- Summarize the function of the Embden-Meyerhof, Entner-Doudoroff, and pentose phosphate pathways
- Draw a simple diagram that shows the connection between the Entner-Doudoroff pathway and the Embden-Meyerhof pathway and the connection between the pentose phosphate pathway and the Embden-Meyerhof pathway
- Create a table that shows which types of organisms use each of the glycolytic pathways

Microorganisms employ several metabolic pathways to catabolize glucose to pyruvate, including (1) the Embden-Meyerhof

pathway, (2) the Entner-Doudoroff pathway, and (3) the pentose phosphate pathway. We refer to these pathways collectively as **glycolytic pathways** or as **glycolysis** (Greek *glyco*, sweet, and *lysis*, a loosening). However, in some texts, the term glycolysis refers only to the Embden-Meyerhof pathway. For the sake of simplicity, the detailed structures of some metabolic intermediates are not used in pathway diagrams. However, these can be found in appendix II.

Embden-Meyerhof Pathway: The Most Common Route to Pyruvate

The **Embden-Meyerhof pathway** is undoubtedly the most common pathway for glucose degradation to pyruvate. It is found in all major groups of microorganisms, as well as in plants and animals, and functions in the presence or absence of O_2 . As noted earlier, it is an important amphibolic pathway and provides several precursor metabolites, NADH, and ATP for the cell. Reactions of the Embden-Meyerhof pathway occur in the cytoplasm.

The pathway may be divided into two parts (figure 11.5 and appendix II). In the initial 6-carbon phase, ATP is used to phosphorylate glucose twice, yielding fructose 1,6-bisphosphate. This preliminary phase “primes the pump” by adding phosphates to each end of the sugar. In essence, the organism invests some of its ATP so that more can be made later in the pathway.

The 3-carbon, energy-conserving phase begins when fructose 1,6-bisphosphate is cleaved into two halves, each with a phosphate. One of the products, dihydroxyacetone phosphate, is immediately converted to glyceraldehyde 3-phosphate. This yields two molecules of glyceraldehyde 3-phosphate, which are then catabolized to pyruvate in a five-step process. Because dihydroxyacetone phosphate can be easily converted to glyceraldehyde 3-phosphate, both halves of fructose 1,6-bisphosphate are used in the 3-carbon phase.

NADH and ATP are produced in the 3-carbon phase of the pathway. NADH is formed when glyceraldehyde 3-phosphate is oxidized with NAD^+ as the electron acceptor, and a phosphate is simultaneously incorporated to give a high-energy molecule called 1,3-bisphosphoglycerate. This reaction sets the stage for ATP production. The phosphate on the first carbon of 1,3-bisphosphoglycerate is donated to ADP to produce ATP. This is an example of **substrate-level phosphorylation** because ADP phosphorylation is coupled with the exergonic hydrolysis of a high-energy molecule having a higher phosphate transfer potential than ATP (see table 10.1). A second ATP is made by substrate-level phosphorylation when the phosphate on phosphoenolpyruvate (the last intermediate of the pathway) is donated to ADP. This reaction also yields pyruvate, the final product of the pathway.  ATP (section 10.2);  How NAD^+ Works

The yields of ATP and NADH by the Embden-Meyerhof pathway may be calculated. In the 6-carbon phase, two ATP are used to form fructose 1,6-bisphosphate. For each glyceraldehyde

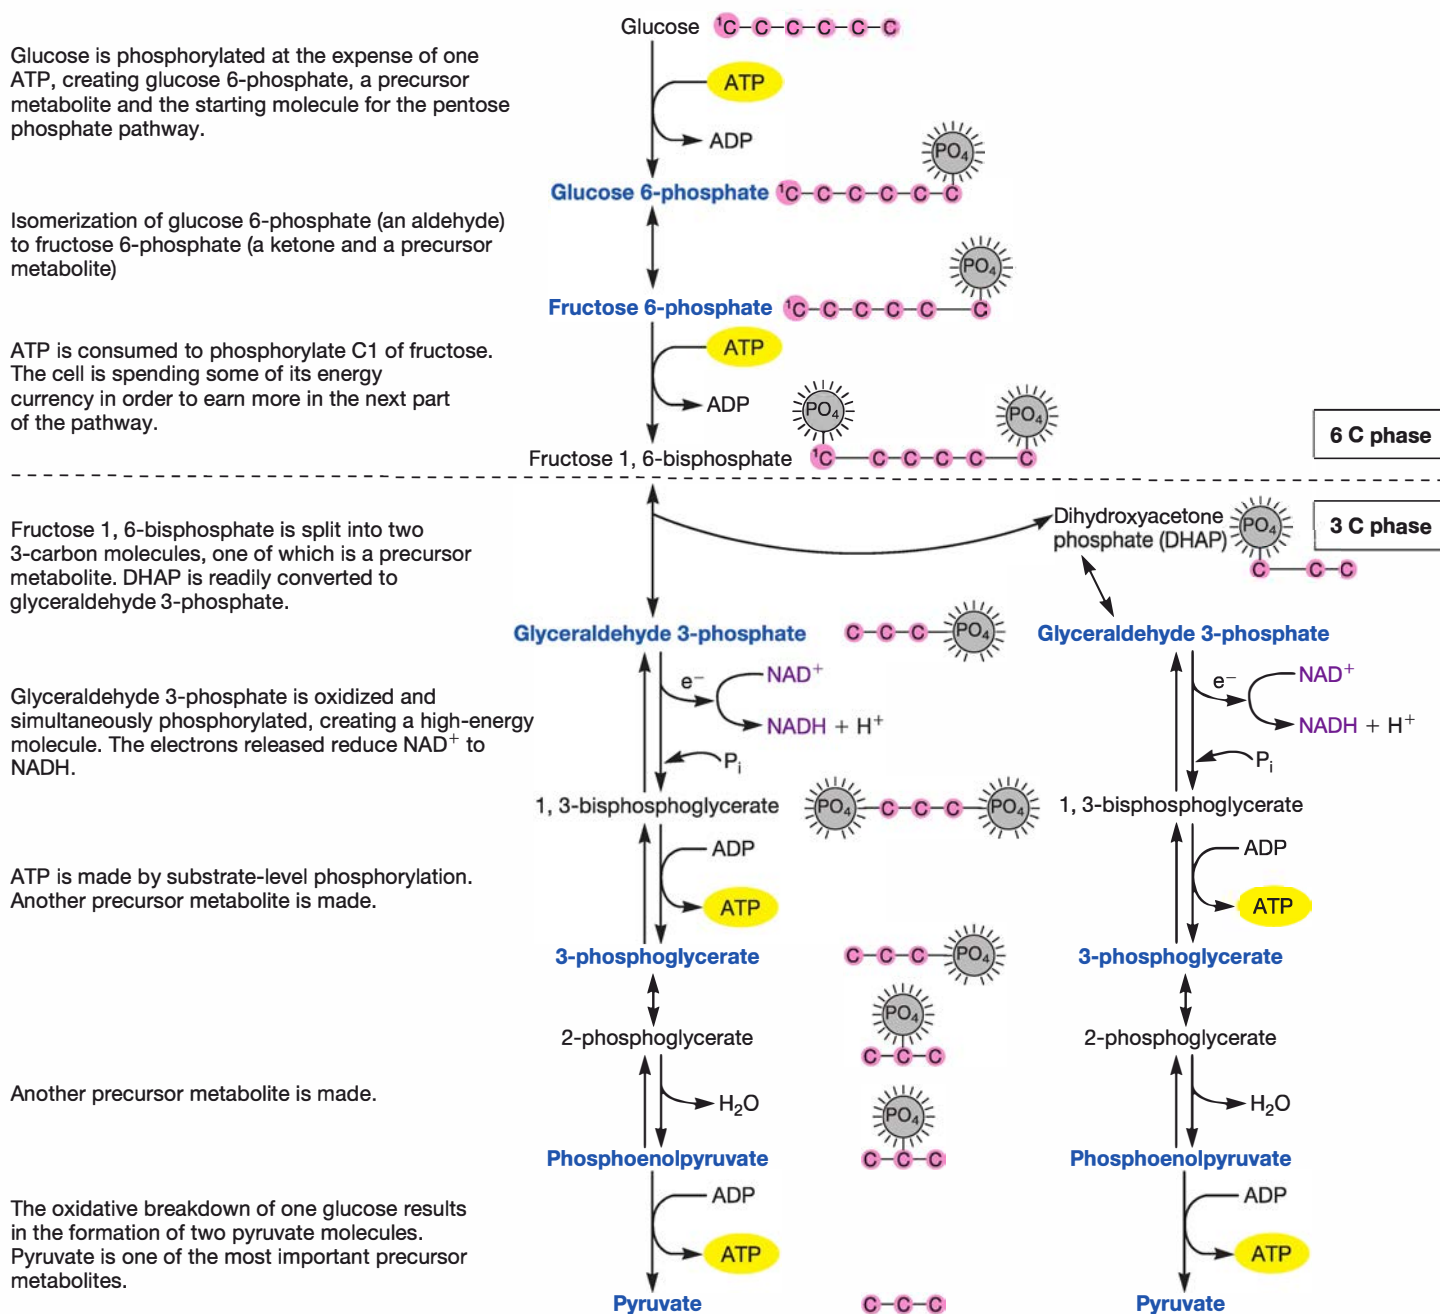

Figure 11.5 Embden-Meyerhof Pathway. This is one of three pathways used to catabolize glucose to pyruvate, and it can function during aerobic respiration, anaerobic respiration, and fermentation. When used during respiration, the electrons accepted by NAD^+ are transferred to an electron transport chain and are ultimately accepted by an exogenous electron acceptor. When used during fermentation, the electrons accepted by NAD^+ are donated to an endogenous electron acceptor (e.g., pyruvate). The Embden-Meyerhof pathway also generates several precursor metabolites (shown in blue).

MICRO INQUIRY Which reactions are examples of substrate-level phosphorylation?

3-phosphate transformed into pyruvate, one NADH and two ATP are formed. Because two glyceraldehyde 3-phosphates arise from a single glucose (one by way of dihydroxyacetone phosphate), the 3-carbon phase generates four ATP and two NADH per glucose. Subtraction of the ATP used in the 6-carbon phase from that produced by substrate-level phosphorylation in the 3-carbon phase gives a net yield of two ATP per glucose.

Thus the catabolism of glucose to pyruvate can be represented by this equation.

The NADH is used during aerobic respiration to transport electrons to an electron transport chain. **How Glycolysis Works**

Entner-Doudoroff Pathway

Although the Embden-Meyerhof pathway is the most common route for the conversion of 6-carbon sugars (hexoses) to pyruvate, the **Entner-Doudoroff pathway** is used by some soil bacteria (e.g., *Pseudomonas*, *Rhizobium*, *Azotobacter*, and *Agrobacterium* spp.) and a few other Gram-negative bacteria. To date, very few Gram-positive bacteria have been found to use this pathway, with the intestinal bacterium *Enterococcus faecalis* being a rare exception. It is not used by eukaryotes.

The Entner-Doudoroff pathway essentially replaces the first phase of the Embden-Meyerhof pathway, yielding pyruvate and glyceraldehyde 3-phosphate, rather than two molecules of glyceraldehyde 3-phosphate. A key intermediate of the pathway is 2-keto-3-deoxy-6-phosphogluconate (KDPG), which is formed from glucose by three reactions that consume one ATP and produce one NADPH (figure 11.6 and appendix II). KDPG is then cleaved to pyruvate and glyceraldehyde 3-phosphate. Bacteria that use this pathway also have the enzymes that function in the second phase of the Embden-Meyerhof pathway. These enzymes may be used to catabolize the glyceraldehyde 3-phosphate to form a second pyruvate molecule. If this occurs, then two ATP and one NADH are formed. Thus the catabolism of one glucose molecule to two pyruvates by way of the Entner-Doudoroff pathway coupled with the second half of the Embden-Meyerhof

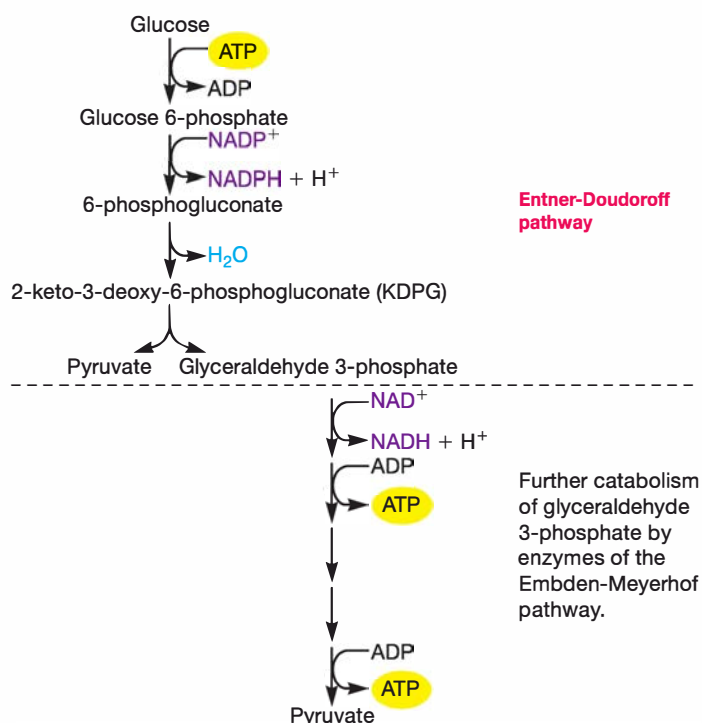

Figure 11.6 The Entner-Doudoroff Pathway.

MICRO INQUIRY For what kinds of reactions is NADPH used?

pathway has a net yield of one ATP, one NADH, and one NADPH. During aerobic respiration, the NADH is used to transport electrons to an electron transport chain (ETC); the NADPH is used as reducing power for anabolic reactions.

Pentose Phosphate Pathway: A Major Producer of Reducing Power for Anabolic Reactions

The **pentose phosphate**, or **hexose monophosphate**, pathway may be used at the same time as either the Embden-Meyerhof or the Entner-Doudoroff pathways. It can operate either aerobically or anaerobically and is important in both biosynthesis and catabolism. It is used by all organisms because of its role in providing reducing power and important precursor metabolites.

The pentose phosphate pathway begins with the oxidation of glucose 6-phosphate to 6-phosphogluconate followed by the oxidation of 6-phosphogluconate to the 5-carbon sugar (i.e., pentose sugar) ribulose 5-phosphate and CO₂ (figure 11.7 and appendix II). NADPH is produced during these oxidations. Ribulose 5-phosphate is then converted to a mixture of 3- to 7-carbon sugar phosphates. Two enzymes play a central role in these transformations: (1) transketolase catalyzes the transfer of 2-carbon groups, and (2) transaldolase transfers a 3-carbon group from sedoheptulose 7-phosphate (a 7-carbon molecule) to glyceraldehyde 3-phosphate (a 3-carbon molecule). The overall result is that three glucose 6-phosphates are converted to two fructose 6-phosphates, glyceraldehyde 3-phosphate, and three CO₂ molecules, as shown in this equation.

These intermediates are used in two ways. Fructose 6-phosphate can be changed back to glucose 6-phosphate while glyceraldehyde 3-phosphate is converted to pyruvate by enzymes of the Embden-Meyerhof pathway. Alternatively two glyceraldehyde 3-phosphates may combine to form fructose 1,6-bisphosphate, which is eventually converted back into glucose 6-phosphate. This results in the complete degradation of glucose 6-phosphate to CO₂ and the production of a great deal of NADPH.

The pentose phosphate pathway is an important amphibolic pathway because: (1) NADPH produced by the pathway serves as a source of electrons for the reduction of molecules during biosynthesis. Indeed, the pentose phosphate pathway is the major source of reducing power for cells, yielding two NADPH molecules for each glucose metabolized to pyruvate in this way. (2) The pathway produces two important precursor metabolites: erythrose 4-phosphate and ribose 5-phosphate. Erythrose 4-phosphate is used to synthesize aromatic amino acids and vitamin B₆ (pyridoxal); ribose 5-phosphate is a major component of nucleic acids. Furthermore, when a microorganism is growing on a 5-carbon sugar, the pathway can function biosynthetically to supply hexose

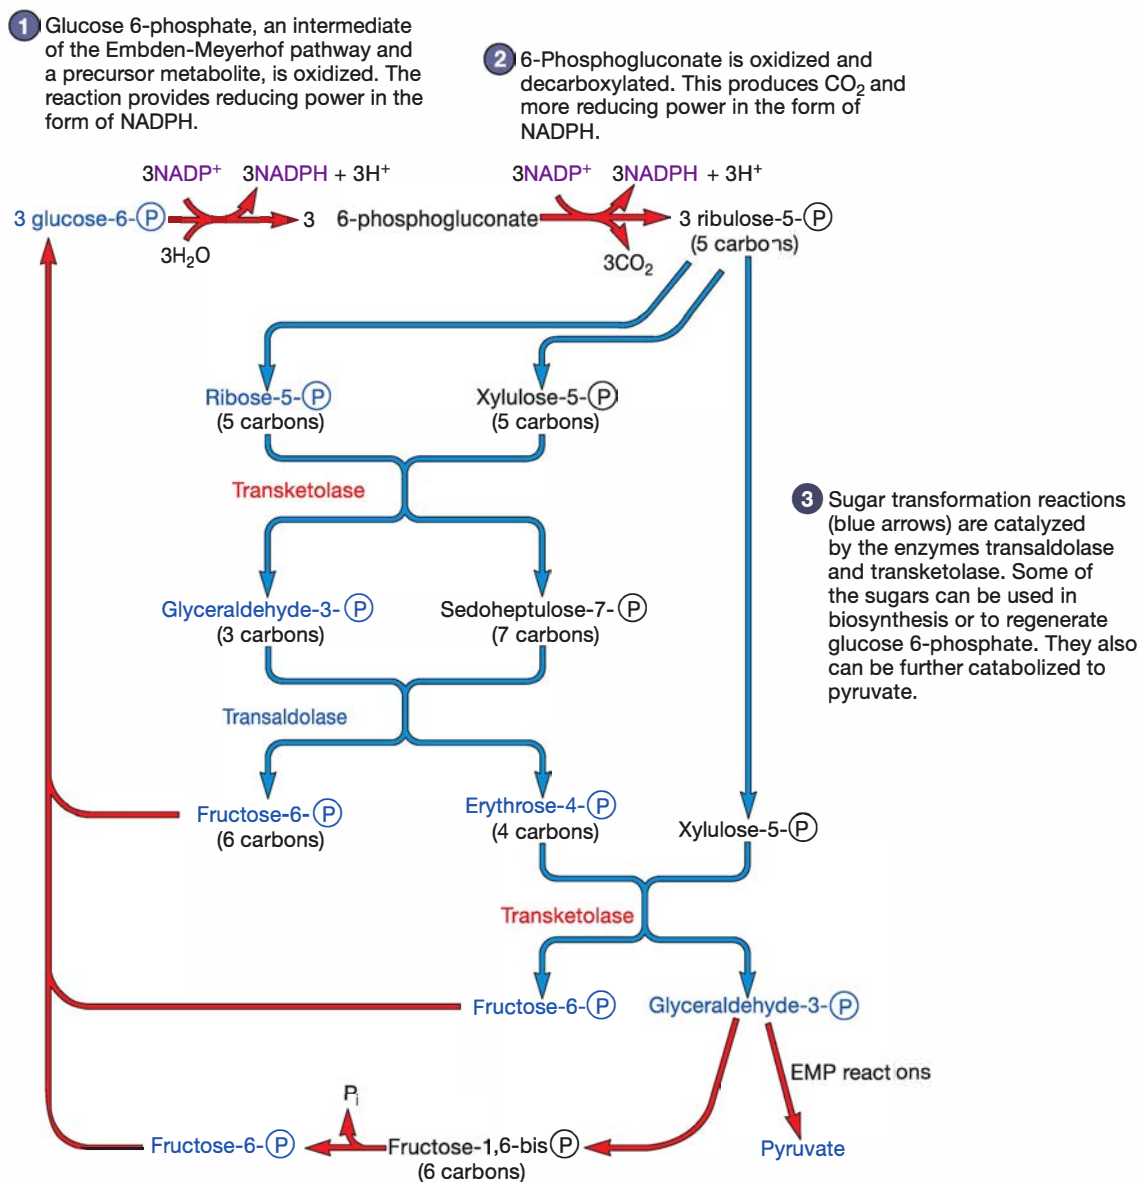

Figure 11.7 The Pentose Phosphate Pathway. The catabolism of three glucose 6-phosphate molecules to two fructose 6-phosphates, a glyceraldehyde 3-phosphate, and three CO₂ molecules is traced. Note that the pentose phosphate pathway generates several intermediates that are also intermediates of the Embden-Meyerhof pathway (EMP). These intermediates can be fed into the EMP with two results: (1) continued degradation to pyruvate or (2) regeneration of glucose 6-phosphate by gluconeogenesis. The pentose phosphate pathway also plays a major role in producing reducing power (NADPH) and several precursor metabolites (shown in blue) for biosynthesis. The sugar transformations are indicated with blue arrows.

MICRO INQUIRY For what macromolecule is ribose 5-phosphate a precursor?

sugars (e.g., glucose needed for peptidoglycan synthesis). (3) Intermediates in the pathway may be used to produce ATP. For instance, glyceraldehyde 3-phosphate can enter the 3-carbon phase of the Embden-Meyerhof pathway. As it is degraded to pyruvate, two ATP are formed by substrate-level phosphorylation. **►►** *Synthesis of amino acids (section 12.5); Synthesis of purines, pyrimidines, and nucleotides (section 12.6)*

11.5 Tricarboxylic Acid Cycle

After reading this section, you should be able to:

- State the alternate names for the tricarboxylic acid (TCA) cycle
- Diagram the major changes made to pyruvate as it is catabolized by the TCA cycle
- Identify those reactions of the TCA cycle that produce ATP (or GTP) and NAD(P)H, generate precursor metabolites, or are redox reactions
- Calculate the yields of ATP (or GTP), NAD(P)H, and FADH₂ by the TCA cycle
- Summarize the function of the TCA cycle
- Diagram the connections between the various glycolytic pathways and the TCA cycle
- Locate the TCA cycle enzymes in bacterial, archaeal, and eukaryotic cells

In the glycolytic pathways, glucose is oxidized to pyruvate. During aerobic respiration, the catabolic process continues by oxidizing pyruvate to three CO₂. The first step of this process employs a multienzyme system called the pyruvate dehydrogenase complex. It oxidizes and cleaves pyruvate to form one CO₂ and the 2-carbon molecule **acetyl-coenzyme A (acetyl-CoA)** (figure 11.8). Acetyl-CoA is energy rich because hydrolysis of the bond that links acetic acid to coenzyme A (a thioester bond) has a large negative change in free energy, just as hydrolysis of the bond in many phosphate-containing molecules does. As shown in figure 11.3, carbohydrates as well as fatty acids and amino acids can be converted to acetyl-CoA (section 11.9).

Acetyl-CoA then enters the **tricarboxylic acid (TCA) cycle**, which is also called the **citric acid cycle** or the **Krebs cycle** (figure 11.8 and *appendix II*). In the first reaction, acetyl-CoA is condensed with (i.e., added to) the 4-carbon intermediate oxaloacetate to form citrate, a molecule with six carbons. Citrate is rearranged to give isocitrate, a more readily oxidized alcohol. Isocitrate is subsequently oxidized and decarboxylated twice to yield α -ketoglutarate (five carbons) and then succinyl-CoA (four carbons), another high-energy molecule containing a thioester bond. At this point, two NADH molecules have been formed and two carbons lost from the cycle as CO₂. The cycle continues when succinyl-CoA is converted to succinate. This involves hydrolysis of the thioester bond in succinyl-CoA and using the large amount of energy released to form either one ATP or one GTP by substrate-level phosphorylation. GTP is also a high-energy molecule, and it is functionally equivalent to ATP. It is used in protein synthesis and to make other nucleoside triphosphates, including ATP. Two oxidation steps follow, yielding one FADH₂ and one NADH. The last oxidation step regenerates oxaloacetate, and as long as there is a supply of acetyl-CoA, the cycle can repeat itself. Inspection of figure 11.8 shows that the TCA cycle generates two CO₂ molecules, three NADH molecules, one FADH₂, and either one ATP or GTP for each acetyl-CoA molecule oxidized. 🌀 *How the Krebs Cycle Works*

TCA cycle enzymes are widely distributed among microorganisms. In bacteria and archaea, they are located in the

cytoplasm. In eukaryotes, they are found in the mitochondrial matrix. The complete cycle appears to be functional in many aerobic bacteria, free-living protists, and fungi. This is not surprising because the cycle plays an important role in energy conservation by producing numerous NADH and FADH₂ (section 11.6). Even those microorganisms that lack the complete TCA cycle usually have most of its enzymes, because the TCA cycle is also a key source of precursor metabolites for use in biosynthesis.

Retrieve, Infer, Apply

1. Identify the substrate and products of the TCA cycle. Describe its organization in general terms. What are its major functions?
2. What chemical intermediate links pyruvate to the TCA cycle?
3. How many times must the TCA cycle be performed to oxidize one molecule of glucose completely to six molecules of CO₂? Why?
4. In what eukaryotic organelle is the TCA cycle found? Where is the cycle located in bacterial and archaeal cells?
5. Why is it desirable for a microbe with the Embden-Meyerhof pathway and the TCA cycle also to have the pentose phosphate pathway?

11.6 Electron Transport and Oxidative Phosphorylation

After reading this section, you should be able to:

- Compare and contrast the mitochondrial electron transport chain (ETC) and bacterial ETCs
- Describe the chemiosmotic hypothesis
- Correlate length of an ETC and the carriers in it with the magnitude of the proton motive force (PMF) it generates
- Explain how ATP synthase uses PMF to generate ATP
- Draw a simple diagram that shows the connections between the glycolytic pathways, TCA cycle, ETC, and ATP synthesis
- List the ways the PMF is used by bacterial cells in addition to ATP synthesis
- Calculate the maximum possible ATP yields when glucose is completely catabolized to six molecules of CO₂ during aerobic respiration

During the oxidation of glucose to six CO₂ molecules by glycolysis and the TCA cycle, as many as four ATP molecules are generated by substrate-level phosphorylation. Thus at this point, the work done by the cell has yielded relatively little ATP. However, in oxidizing glucose, the cell has also generated numerous molecules of NADH and FADH₂. Both of these molecules have a relatively negative E_0' and can be used to conserve energy. In fact, most of the ATP generated during respiration comes from the energy conserved when these electron carriers are oxidized by an electron transport chain. We examine the mitochondrial electron transport chain first because it has been well studied and because it functions in fungi and many protists. We then turn to bacterial chains and a discussion of ATP synthesis.

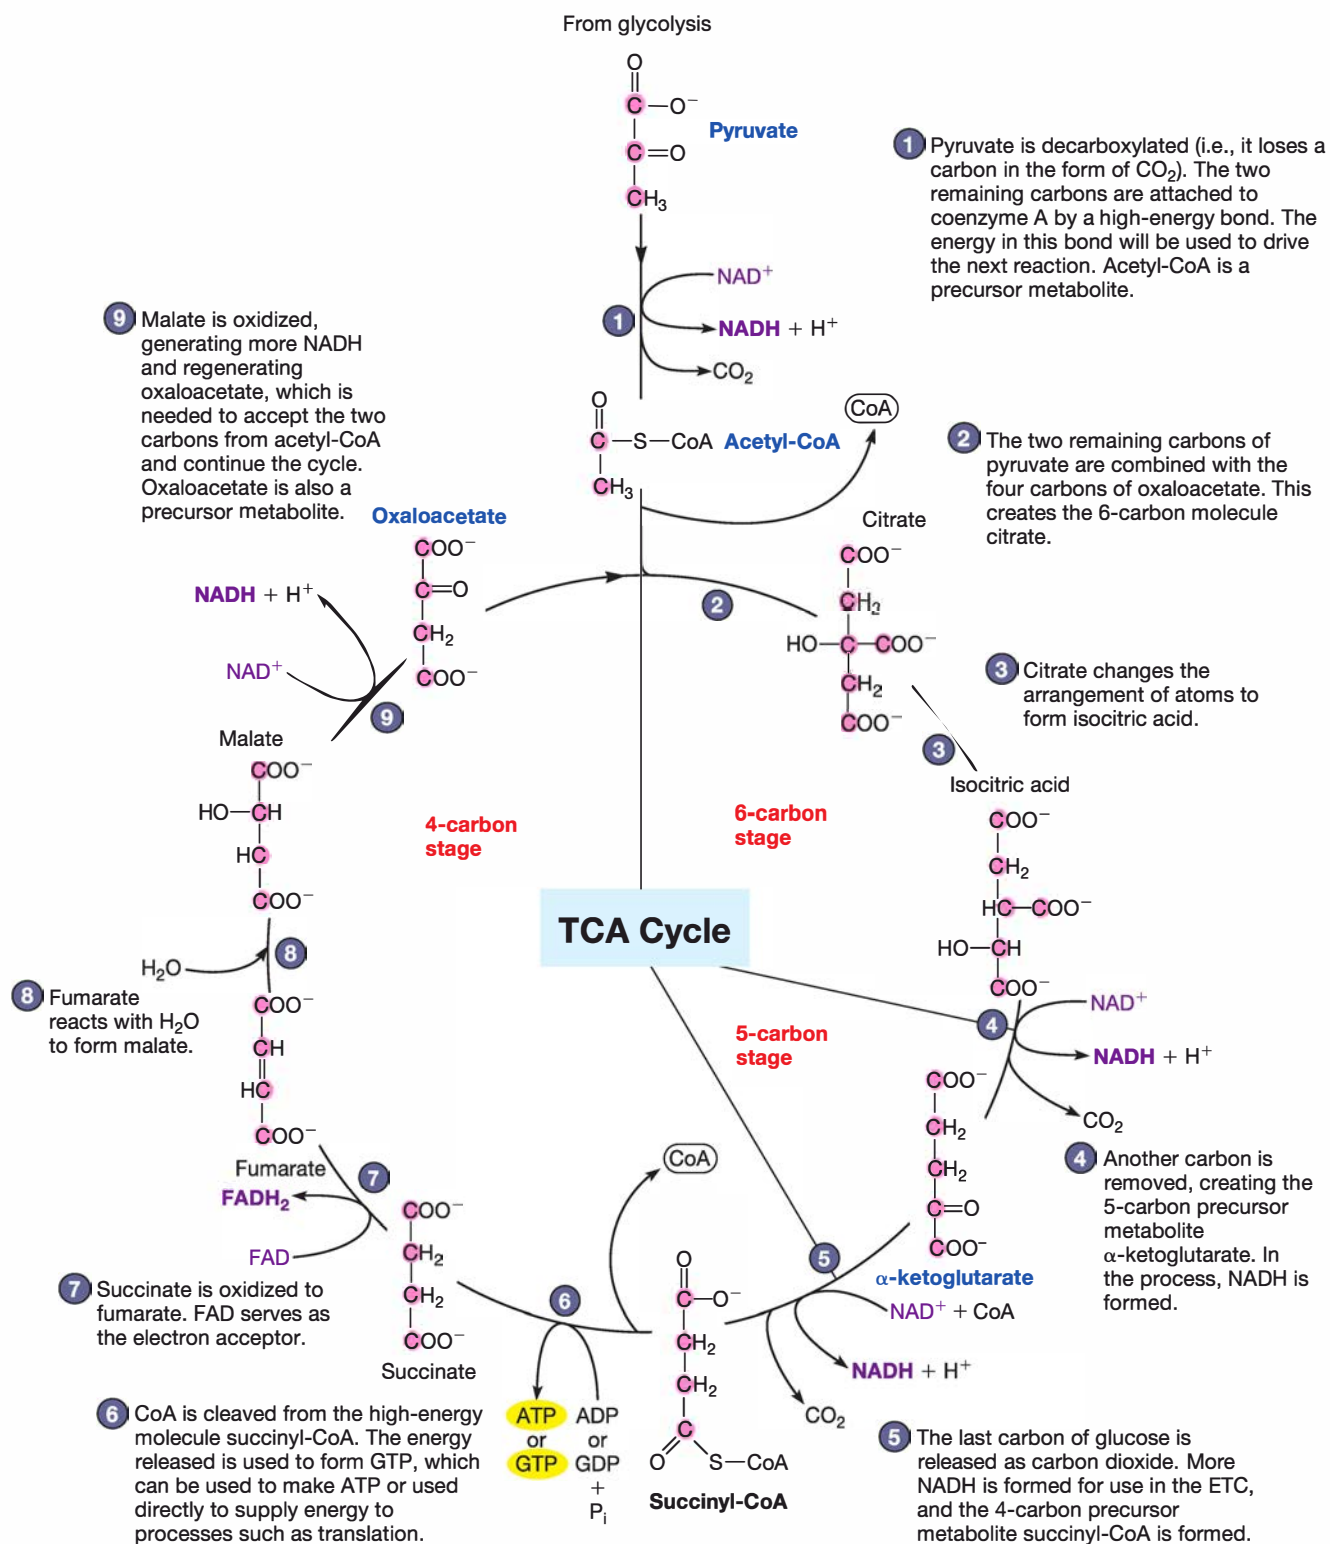

Figure 11.8 The Tricarboxylic Acid Cycle. The TCA cycle is linked to glycolysis by a connecting reaction catalyzed by the pyruvate dehydrogenase complex. The reaction decarboxylates pyruvate (removes a carboxyl group as CO_2) and generates acetyl-CoA. The cycle may be divided into three stages based on the size of its intermediates. The three stages are separated from one another by two decarboxylation reactions. Precursor metabolites are shown in blue. NADH and FADH_2 are shown in purple; they can transfer electrons to the electron transport chain (ETC).

MICRO INQUIRY What reaction provides the energy to fuel the condensation (joining) of the 4-carbon oxaloacetate with the 2-carbon acetyl-CoA to form citrate?

Electron Transport Chains

The mitochondrial **electron transport chain (ETC)** is composed of a series of electron carriers that operate together to transfer electrons from donors, such as NADH and FADH₂, to O₂ (figure 11.9). The electrons flow from carriers with more negative reduction potentials to those with more positive potentials and eventually combine with O₂ and H⁺ to form water. Each carrier is in turn reduced and then reoxidized. Thus the carriers are constantly recycled as electron transport through the chain occurs. The pattern of electron flow is exactly the same as seen in the electron tower that is described in chapter 10 and reproduced here (figure 11.10). The electrons move down this potential gradient much like water flowing down a series of rapids. The difference in reduction potentials between O₂ and NADH is large, about 1.14 volts, which makes possible the release of a great deal of energy. However, the ETC breaks up the overall energy release into small steps, facilitating energy conservation. The energy released is sufficient for ATP production. Thus much as the energy from waterfalls can be harnessed by waterwheels and used to generate electricity, so too is the flow of electrons through an ETC harnessed to make ATP.

In eukaryotes, the ETC carriers reside within the inner membrane of the mitochondrion where they are arranged into four complexes, each capable of transporting electrons part of

the way to O₂ (figure 11.11). Coenzyme Q and cytochrome *c* connect the complexes with each other. As electrons move through the ETC, protons are moved across the inner membrane, forming a proton gradient.

Although some bacterial and archaeal ETCs resemble the mitochondrial chain, they are frequently very different. First, bacterial and archaeal ETCs are located primarily within the plasma membrane. Furthermore, some Gram-negative bacteria have ETC carriers in the periplasmic space and even the outer membrane (see figure 22.28). Bacterial and archaeal ETCs also can be composed of different electron carriers and may be branched. That is, electrons may enter the chain at several points and leave through several terminal oxidases. Bacterial and archaeal ETCs also may be shorter, resulting in the release of less energy (and the transport of fewer protons across the membrane). Although microbial ETCs differ in details of construction, they operate using the same fundamental principles.

Electron Transport System and ATP Synthesis

The ETC of *Paracoccus denitrificans* and *Escherichia coli* will serve as examples of bacterial chains. *P. denitrificans* is a Gram-negative, soil bacterium that is a facultative anaerobe and is extremely versatile metabolically. Under oxic conditions, it carries out aerobic respiration using the ETC shown in figure 11.12. This chain is very similar to the mitochondrial

Figure 11.9 The Reduction Potentials of Carriers in the Mitochondrial Electron Transport Chain. In mitochondria, the electron carriers are organized into four complexes that are linked by coenzyme Q (CoQ) and cytochrome *c* (Cyt *c*). Electrons flow from NADH and succinate down the reduction potential gradient to oxygen.

Figure 11.10 The Electron Tower. Electrons move spontaneously from donors with more negative reduction potentials to acceptors with more positive reduction potentials.

Figure 11.11 Creation of a Proton Gradient by the Mitochondrial Electron Transport Chain and Its Use in Synthesis of ATP. Electron carriers in the mitochondrial ETC are organized into four complexes. As electrons move along the ETC, protons are transported across the membrane creating a proton gradient. Proton release occurs when electrons are transferred from carriers, such as FMN and coenzyme Q (Q), that carry both electrons and protons to components such as nonheme iron proteins (FeS) and cytochromes (Cyt) that transport only electrons. Complex IV pumps protons across the membrane as electrons pass from cytochrome *a* to oxygen. The number of protons moved across the membrane at each site per pair of electrons transported is still somewhat uncertain; the current consensus is that at least 10 protons must move outward during NADH oxidation. One molecule of ATP is synthesized and released from the enzyme ATP synthase for every three protons that cross the membrane by passing through it.

Figure 11.12 *Paracoccus denitrificans* Electron Transport Chain Used During Aerobic Respiration. *P. denitrificans* can respire both aerobically and anaerobically (figure 11.18). The aerobic ETC resembles a mitochondrial ETC and uses oxygen as the terminal electron acceptor. This metabolically versatile bacterium can also use methanol and methylamine as electron donors. They donate electrons to the chain at the level of cytochrome *c*. Locations of proton movement are shown, but the number of protons involved has not been indicated. Abbreviations used: Flavoprotein (FP), methanol dehydrogenase (MD).

MICRO INQUIRY How does the number of H^+ moved across the membrane as a result of NADH oxidation compare with the number of H^+ moved following methanol oxidation?

chain. NADH generated by the oxidation of organic substrates (during glycolysis and the TCA cycle) is oxidized to NAD^+ by the first component in the ETC, membrane-bound NADH dehydrogenase. The electrons from NADH are transferred to carriers with progressively more positive reduction potentials. As electrons move through the carriers, protons are moved across the plasma membrane to the periplasmic space, rather than to an intermembrane space, as seen in the mitochondrion (compare figures 11.11 and 11.12). The metabolic diversity of the bacterium is also demonstrated in figure 11.12. When the microbe is growing on an energy source such as glucose, electrons are transferred to the ETC by NADH, as just described. However, *P. denitrificans* also can use 1-carbon molecules such as methanol as a source of energy. In this case, NADH is not involved, and electrons are donated directly to the chain from the 1-carbon compound at the level of cytochrome *c*.

A simplified view of the *E. coli* chain is shown in figure 11.13. This chain differs from the mitochondrial chain in part because it contains a different array of cytochromes. Furthermore, the *E. coli* ETC has two branches that operate under different oxygen levels. When oxygen is readily available, the cytochrome *bo* branch is used (lower half of figure 11.13). When oxygen is less plentiful, the cytochrome *bd* branch is used because it has a higher affinity for oxygen (upper half of figure 11.13). However, it is less efficient than the *bo* branch because the *bd* branch moves fewer protons into the periplasmic space.  *Electron Transport Systems and Formation of ATP*

Oxidative Phosphorylation

Oxidative phosphorylation is the process by which ATP is synthesized as the result of electron transport driven by the oxidation of a chemical energy source. The mechanism by which oxidative phosphorylation takes place has been studied intensively for years and is best explained by the **chemiosmotic hypothesis**, which was formulated by British biochemist Peter Mitchell. According to the chemiosmotic hypothesis, mitochondrial ETCs are organized so that protons move across the inner membrane from the mitochondrial matrix to the intermembrane space as electrons are transported down the chain (figure 11.11). In bacteria and archaea, the protons usually are moved across the plasma membrane from the cytoplasm to the periplasmic space (figures 11.12 and 11.13).

The movement of protons across the membrane is not completely understood. However, in some cases, the protons are actively pumped across the membrane (e.g., by complex IV of the mitochondrial chain; figure 11.11). In other cases, translocation of protons results from the juxtaposition of carriers that accept both electrons and protons with carriers that accept only electrons. For instance, coenzyme Q accepts two electrons and two protons but delivers only two electrons to complex III of the mitochondrial chain. This transfer of electrons is complicated by the fact that cytochrome *b* and the FeS protein of complex III accept only one electron at a time and do not accept protons. This difference in protons and electrons

Figure 11.13 The Electron Transport Chain of *E. coli*. NADH transfers electrons from an organic energy and electron source to the electron transport chain. Ubiquinone-8 (Q) connects the NADH dehydrogenase with two terminal oxidase systems. The upper branch operates when the bacterium is in stationary phase and there is little oxygen. At least five cytochromes are involved: *b*₅₅₈, *b*₅₉₅, *b*₅₆₂, *d*, and *o*. The lower branch functions when *E. coli* is growing rapidly with good aeration.

carried sets the stage for a phenomenon called the **Q cycle** that ultimately moves four protons across the membrane (figure 11.14). The Q cycle involves the sequential oxidation of two reduced coenzyme Q molecules (QH₂), the transfer of two of the four electrons released by these oxidations to one molecule of the oxidized form of coenzyme Q (located nearby in the membrane) via the cytochrome *b* located in complex III, and the transfer of the remaining two electrons to the FeS protein of complex III.

The result of proton expulsion during electron transport is the formation of a concentration gradient of protons (ΔpH ; chemical potential energy) and a charge gradient ($\Delta \Psi$; electrical potential energy). Thus as long as the membrane is intact,

Figure 11.14 The Q Cycle. This simplified illustration shows the major events in the Q cycle.

the mitochondrial matrix is more alkaline and more negative than the intermembrane space. Likewise with bacterial and archaeal cells, the cytoplasm is more alkaline and more negative than the periplasmic space. The combined chemical and electrical potential differences make up the **proton motive force (PMF)**. The PMF is used to perform work when protons flow back across the membrane, down the concentration and charge gradients, and into the mitochondrial matrix (or the cytoplasm of bacterial and archaeal cells). This flow is exergonic and is often used to phosphorylate ADP to ATP. The PMF is also used by many secondary active transport systems to move nutrients into the cell and to rotate the bacterial flagellar motor. Thus the PMF plays a central role in a cell's physiology (**figure 11.15**).

◀ **Uptake of nutrients (section 3.3); Bacterial flagella (section 3.7)**

Figure 11.15 The Central Role of Proton Motive Force. Active transport is not always driven by PMF.

The use of PMF for ATP synthesis is catalyzed by **ATP synthase**. The best-studied ATP synthases are the F_1F_0 ATP synthases found in mitochondria, chloroplasts, and bacteria. They are also known as F_1F_0 ATPases because they can catalyze ATP hydrolysis. The mitochondrial F_1 component appears as a spherical structure attached to the mitochondrial inner membrane surface by a stalk (**figure 11.16**). The F_0 component is embedded in the membrane. ATP synthase is on the inner surface of the plasma membrane in bacterial cells. F_0 participates in proton movement across the membrane. F_1 is a large complex in which three α subunits alternate with three β subunits. The catalytic sites for ATP synthesis are located on the β subunits. At the center of F_1 is the γ subunit. The γ subunit extends through F_1 and interacts with F_0 .

It is now known that ATP synthase functions like a rotary engine, much like the rotary motor of bacterial flagella. It is thought that the flow of protons down the proton gradient through the F_0 subunit causes F_0 and the γ subunit to rotate. As the γ subunit rotates rapidly within the F_1 (much like a car's crankshaft), conformation changes occur in the β subunits (**figure 11.16b**). One conformation change (β_E to β_{HC}) allows entry of ADP and P_i into the catalytic site. Another conformation change (β_{HC} to β_{DP}) loosely binds ADP and P_i in the catalytic site. ATP is synthesized when the β_{DP} conformation is changed to the β_{TP} conformation, and ATP is released when β_{TP} changes to the β_E conformation, to start the synthesis cycle anew.

ATP Yield During Aerobic Respiration

It is possible to estimate the number of ATP molecules synthesized per NADH or $FADH_2$ oxidized by an ETC. During aerobic respiration, a pair of electrons from NADH and $FADH_2$ is donated to the ETC and ultimately used to reduce an atom of oxygen to H_2O .

Figure 11.16 ATP Synthase Structure and Function. (a) The major structural features of ATP synthase deduced from X-ray crystallography and other studies. **F₁** is a spherical structure composed largely of alternating α and β subunits; the three active sites are on the β subunits. The γ subunit extends through the center of the sphere and can rotate. The stalk (γ and ϵ subunits) connects the sphere to **F₀**, the membrane embedded complex that serves as a proton channel. **F₀** contains one a subunit, two b subunits, and nine to 12 c subunits. The stator arm is composed of subunit a , two b subunits, and the δ subunit; it is embedded in the membrane and attached to **F₁**. A ring of c subunits in **F₀** is connected to the stalk and may act as a rotor (inset) and move past the a subunit of the stator. As the c subunit ring turns, it rotates the shaft (γ and ϵ subunits). The inset is an atomic force micrograph of the **F₀** rotor. (b) The binding change mechanism is a widely accepted model of ATP synthesis. This simplified drawing of the model shows the three catalytic β subunits and the γ subunit, which is located at the center of the **F₁** complex. As the γ subunit rotates, it causes conformational changes in each subunit. The β_E (empty) conformation is an open conformation, which does not bind nucleotides. When the γ subunit rotates, β_E is converted to the β_{HC} (half closed) conformation. P_i and ADP can enter the catalytic site when it is in this conformation. The next rotation by the γ subunit is critical because it brings about three significant conformational changes: (1) β_{HC} to β_{DP} (ADP bound), (2) β_{DP} to β_{TP} (ATP bound), and (3) β_{TP} to β_E . Change from β_{DP} to β_{TP} is accompanied by the formation of ATP; change from β_{TP} to β_E allows for release of ATP from ATP synthase.

The energy released drives the synthesis of ATP. Prior to the acceptance of the chemiosmotic hypothesis, the concept of the phosphorus to oxygen (P/O) ratio was used as a measure of the number of ATP molecules (phosphorus) generated per oxygen (O) reduced as NADH and FADH₂ were oxidized. With the acceptance of the chemiosmotic hypothesis, it was recognized that the important measurement was the number of protons transported across the membrane by NADH oxidation and the number of protons consumed during the synthesis of ATP. Despite this change, the expression of the amount of ATP synthesized as the result of the

oxidation of NADH is still often referred to as the P/O ratio. The best estimates of the number of protons moved across the membrane due to NADH oxidation is 10; six electrons are thought to be transferred when FADH₂ oxidation initiates electron flow to oxygen. It is currently thought that four protons are consumed during ATP synthesis; three are used by ATP synthase and one is used for transport of ATP, ADP, and P_i . Thus the P/O ratio is estimated to be 2.5 for NADH and 1.5 for FADH₂.

Given this information, the maximum ATP yield of aerobic respiration in a eukaryote can be calculated (figure 11.17).

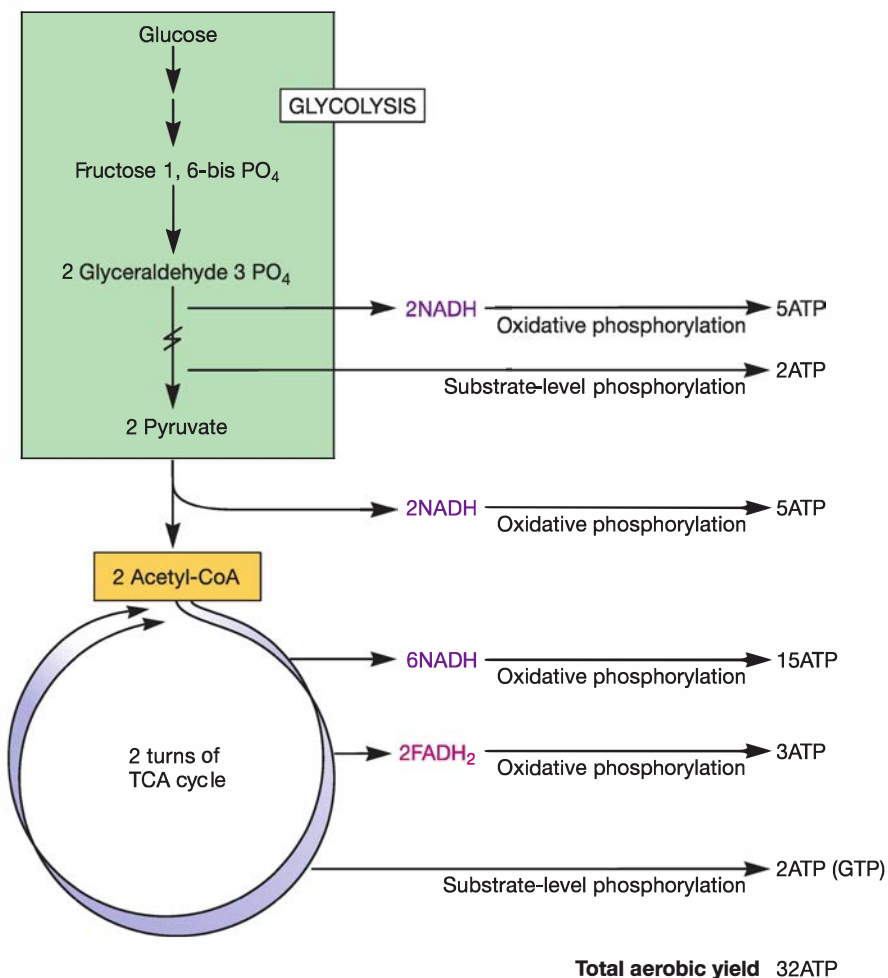

Figure 11.17 Maximum Theoretic ATP Yield from Aerobic Respiration. To attain the theoretic maximum yield of ATP, one must assume a P/O ratio of 2.5 for the oxidation of NADH and 1.5 for FADH₂.

Substrate-level phosphorylation yields at most two ATP molecules per glucose converted to pyruvate (figures 11.5 and 11.7). Two ATP are generated by substrate-level phosphorylation during the two turns of the TCA cycle needed to oxidize two acetyl-CoA molecules (figure 11.8). Thus during aerobic respiration of glucose, at most four ATP molecules are made by substrate-level phosphorylation. Most of the ATP made during aerobic respiration is generated by oxidative phosphorylation. Up to 10 NADH (2 from glycolysis, 2 from pyruvate conversion to acetyl-CoA, and 6 from the TCA cycle) and 2 FADH₂ (from the TCA cycle) are generated when glucose is oxidized completely to 6 CO₂. Assuming a P/O ratio of 2.5 for NADH oxidation and 1.5 for FADH₂ oxidation, the 10 NADH could theoretically drive the synthesis of 25 ATP, while oxidation of the 2 FADH₂ molecules would add another 3 ATP for a maximum of 28 ATP generated via oxidative phosphorylation. Thus oxidative phosphorylation accounts for seven times more ATP than does substrate-level phosphorylation. The maximum total yield of ATP during aerobic respiration by eukaryotes is 32 ATP.

Bacterial ETCs are often shorter and therefore transport fewer protons across the plasma membrane. Thus their ETCs have lower P/O ratios than eukaryotic chains, and their ATP yields are smaller. For example, *E. coli*, with its truncated ETC, has a P/O ratio around 1.3 when using the cytochrome *bo* path at high oxygen levels and a ratio of only about 0.67 when employing the cytochrome *bd* branch (figure 11.13) at low oxygen concentrations. In this case, ATP production varies with environmental conditions. Perhaps because *E. coli* normally grows in habitats such as the intestinal tract that are very rich in nutrients, it does not have to be particularly efficient in ATP synthesis. Presumably the ETC functions when *E. coli* is in an oxic freshwater environment between hosts.

Two other factors affect the yield of ATP from the catabolism of glucose by aerobic respiration, thus making the theoretical maximum a value that is rarely reached. One is that the PMF generated by electron transport is used for functions other than ATP synthesis (e.g., bacterial flagella rotation). The second is related to the amphibolic nature of the pathways used to catabolize glucose. Recall that an important function of these pathways is the generation of precursor metabolites for anabolism. For each molecule of glucose degraded, numerous precursor metabolites are made, and as each is made, a microbe must “decide” if that metabolite is needed for anabolism or if it can continue the catabolic process. If the precursor metabolite is used for biosynthesis, fewer NADH and FADH₂ molecules may be made and fewer ATP molecules generated. Clearly, the flow of the carbons from glucose

must be carefully monitored and regulated such that ATP production is appropriately balanced with biosynthesis. The mechanisms for this regulation are described in chapters 10 and 14.

1. Briefly describe the structure of ETCs and their role in ATP formation. How do mitochondrial chains differ from bacterial and archaeal chains?
2. Describe the current model of oxidative phosphorylation. Briefly describe the structure of ATP synthase and explain how it is thought to function.
3. How do substrate-level phosphorylation and oxidative phosphorylation differ?
4. Calculate the ATP yield when glucose is catabolized completely to six CO₂ by a eukaryotic microbe. How does this value compare to the ATP yield observed for a bacterium? Suppose a bacterium used the Entner-Doudoroff pathway to degrade glucose to pyruvate and then completed the catabolism of glucose via the TCA cycle. How would this affect the total maximum ATP yield? Explain your reasoning.

11.7 Anaerobic Respiration

After reading this section, you should be able to:

- Compare and contrast aerobic respiration and anaerobic respiration using glucose as carbon source
- List examples of terminal electron acceptors used during anaerobic respiration
- Defend this statement: “The use of nitrate (NO_3^-) as a terminal electron acceptor is dissimilatory nitrate reduction.”
- Predict the relative amount of energy released for each of the common terminal electron acceptors used during anaerobic respiration, as compared to energy released during aerobic respiration
- List three examples of the importance of anaerobic respiration

As we have seen, during aerobic respiration, sugars and other organic molecules are oxidized and their electrons transferred to NAD^+ and FAD to generate NADH and FADH_2 , respectively. These carriers then donate the electrons to an ETC that uses O_2 as the terminal electron acceptor. However, it is also possible for other terminal electron acceptors to be used for electron transport. **Anaerobic respiration** is the process whereby an exogenous terminal electron acceptor other than O_2 is used for electron transport. It is carried out by many bacteria and archaea, and some eukaryotic microbes. The most common terminal electron acceptors used during anaerobic respiration are nitrate, sulfate, and CO_2 , but metals and a few organic molecules can also be reduced (**table 11.3**).

The diversity of alternate electron acceptors has important ecological and practical consequences. For instance, numerous soil microbes use nitrate (NO_3^-) as an electron acceptor in anoxic soils. When this occurs in agricultural soils, it depletes the soil nitrogen and decreases the yield from that field. It also forces farmers to use nitrogen-containing fertilizers that can have detrimental consequences such as the contamination of nearby wells, streams, and rivers. The contamination of wells is of particular concern because NO_3^- is toxic to humans and other animals. On the other hand, if NO_3^- is being used as an electron acceptor by bacteria in a sewage treatment plant, NO_3^- levels in the plant effluent are decreased, as is the likelihood that the effluent will cause pollution when it is discharged. Finally, the use of NO_3^- and other electron acceptors by chemoorganotrophs links the carbon cycle to other biogeochemical cycles such as the nitrogen cycle and the sulfur cycle. This is the basis for many of the interactions that occur between microbes in their habitats. ►► *Biogeochemical cycling (section 28.1)*

Many microbes that can carry out anaerobic respiration will perform aerobic respiration instead if oxygen is available. In fact, some bacteria oxidize sugars and other organic molecules to generate NADH and FADH_2 using the exact pathways used for aerobic respiration. Thus, depending on the organism, glycolysis and the TCA cycle function in the same way during both aerobic respiration and anaerobic respiration. Furthermore, most of the ATP

Table 11.3 Some Electron Acceptors Used in Respiration

| | Electron Acceptor | Reduced Products | Examples of Microorganisms |
|------------------|----------------------|---|---|

generated during anaerobic respiration is made by oxidative phosphorylation, as is the case during aerobic respiration.

An example of a bacterium that can carry out both anaerobic respiration and aerobic respiration is *Paracoccus denitrificans*. We have already described the ETC used by this microbe during aerobic respiration (figure 11.12). Under anoxic conditions, *P. denitrificans* uses NO_3^- as its electron acceptor. As shown in **figure 11.18**, the anaerobic ETC is more complex than the aerobic chain. The anaerobic ETC is branched and uses different electron carriers, some of which are located in the periplasmic space. Electrons are passed from coenzyme Q to cytochrome *b* for the reduction of NO_3^- to nitrite (NO_2^-). Electrons then flow through cytochrome *c* for the sequential reduction of nitrite to gaseous dinitrogen (N_2). Not as many protons are pumped across the membrane during anaerobic growth, but nonetheless, a PMF is established.

The anaerobic reduction of NO_3^- makes it unavailable for assimilation into the cell. That is, it can't be used to construct N-containing molecules such as amino acids and nucleotides. Therefore this process is called **dissimilatory nitrate reduction**. When dissimilatory nitrate reduction leads to the production of gaseous compounds such as N_2 that are released into the

Figure 11.18 *Paracoccus denitrificans* Electron Transport Chain Used During Anaerobic Respiration. This branched ETC is made of both membrane and periplasmic proteins. Nitrate is reduced to diatomic nitrogen (N_2) by the collective action of four different reductases that receive electrons from CoQ and cytochrome *c*. Locations of proton movement are shown, but the number of protons involved has not been indicated. Abbreviations used: flavoprotein (FP), nitrate reductase (Nar), nitrite reductase (Nir), nitric oxide reductase (Nor), and nitrous oxide reductase (Nos).

atmosphere, the process is also called **denitrification**. Denitrification carried out by *P. denitrificans* is a multistep process (figure 11.18) with four enzymes participating: nitrate reductase (Nar), nitrite reductase (Nir), nitric oxide reductase (Nor), and nitrous oxide reductase (Nos). The membrane-bound enzyme nitrate reductase catalyzes the reduction of NO_3^- to NO_2^- . Nitrite is reduced to nitric oxide (NO) by the periplasmic enzyme nitrite reductase. Nitric oxide reductase catalyzes the formation of nitrous oxide (N_2O) from NO. It is part of the membrane-bound cytochrome *bc* complex. Finally, the periplasmic enzyme nitrous oxide reductase catalyzes the formation of N_2 from N_2O .

In addition to *P. denitrificans*, some members of the genera *Pseudomonas* and *Bacillus* carry out denitrification. All use denitrification as an alternative to aerobic respiration and are considered facultative anaerobes. Indeed, if O_2 is present, the synthesis of nitrate reductase is repressed and these bacteria use aerobic respiration.

Anaerobic respiration does not produce as much ATP as aerobic respiration. The lower ATP yield is due to the fact that alternate electron acceptors such as NO_3^- have less positive reduction potentials than O_2 . The difference in standard reduction potentials between NADH and NO_3^- is smaller than the difference between NADH and O_2 (figure 11.10). Less energy is available to make ATP in anaerobic respiration because energy yield is directly related to the magnitude of the reduction potential difference. Nevertheless, anaerobic respiration is useful because it allows ATP synthesis by electron transport and oxidative phosphorylation in the absence of O_2 .

2. What is denitrification? Why do farmers dislike this process?
3. *E. coli* can use O_2 , fumarate, or nitrate as a terminal electron acceptor under different conditions. What is the order of energy yield from highest to lowest for these electron acceptors? Explain your answer in thermodynamic terms.

11.8 Fermentation

After reading this section, you should be able to:

- Compare and contrast aerobic respiration, anaerobic respiration, and fermentation of glucose
- List the pathways that may function during fermentation if glucose is the organism's carbon and energy source
- Create a table that lists some of the common fermentation pathways and their products, and gives examples of their importance
- Compare the use of ATP synthase during respiration and fermentation

Despite the tremendous ATP yield obtained by oxidative phosphorylation, some chemoorganotrophic microbes do not respire. These microbes lack ETCs or they repress the synthesis of ETC components under anoxic conditions, making anaerobic respiration impossible. Some facultative anaerobes may find themselves

in an environment that lacks both oxygen and the terminal electron acceptor they use for anaerobic respiration (e.g., nitrate). In each case, NADH produced by the Embden-Meyerhof pathway reactions during glycolysis (figure 11.5) must still be oxidized back to NAD^+ without the help of an ETC. If NAD^+ is not regenerated, the oxidation of glyceraldehyde 3-phosphate will cease and glycolysis will stop. Many microorganisms solve this problem by slowing or stopping pyruvate dehydrogenase activity and using pyruvate or one of its derivatives as an electron acceptor for the reoxidation of NADH in a fermentation process (figure 11.19). There are many kinds of fermentations, and they often are characteristic of particular microbial groups (figure 11.20). A few of the more common fermentations are introduced here.

Four unifying themes should be kept in mind when microbial fermentations are examined: (1) NADH is oxidized to NAD^+ ; (2) O_2 is not needed; (3) the electron acceptor is often either pyruvate or a pyruvate derivative; and (4) an ETC cannot operate, reducing the ATP yield per glucose significantly. Thus in fermentation, the substrate (e.g., glucose) is only partially oxidized and ATP is formed in most organisms exclusively by substrate-level phosphorylation. However, fermenting microbes still need a PMF to do work, in particular to drive transport. To solve the dilemma of how to generate a PMF without an ETC, they use their ATP synthase in the reverse direction. That is, the ATP synthase pumps protons out of the cell, fueling this transport by the energy released when ATP is hydrolyzed to ADP and P_i . Although

fermentation yields considerably less ATP, it is an important component of the metabolic repertoire of many microbes, allowing them to adjust to changes in their habitats.

Fermentation pathways are named after the major acid or alcohol produced. The most common fermentation is lactic acid (lactate) fermentation, the reduction of pyruvate to lactate (figure 11.20, number 1). It occurs in bacteria (lactic acid bacteria, *Bacillus* spp.), protists (*Chlorella* spp. and some water molds), and animal skeletal muscle. Lactic acid fermenters can be separated into two groups. **Homolactic fermenters** use the Embden-Meyerhof pathway and directly reduce almost all their pyruvate to lactate with the enzyme lactate dehydrogenase. **Heterolactic fermenters** form substantial amounts of products other than lactate; many also produce ethanol and CO_2 . Lactic acid bacteria are important to the food industry, where they are used to make a variety of fermented foods (e.g., yogurt). ►► *Microbiology of fermented food (section 41.5)*

Another common fermentation is carried out by many fungi, protists, and some bacteria. These microbes ferment sugars to ethanol and CO_2 in a process called **alcoholic fermentation**. Pyruvate is decarboxylated to acetaldehyde, which is then reduced to ethanol by alcohol dehydrogenase with NADH as the electron donor (figure 11.20, number 2). This fermentation produces the ethanol desired by brewers making beer and ale and by vintners making wine.

Many bacteria, especially members of the family *Enterobacteriaceae*, can metabolize pyruvate to numerous products using several pathways simultaneously. One such complex fermentation is the **mixed acid fermentation**, which results in the excretion of ethanol and a mixture of acids, particularly acetic, lactic, succinic, and formic acids (table 11.4). Members of the genera *Escherichia*, *Salmonella*, and *Proteus* carry out mixed acid fermentation. They use pathways numbered 1, 5, 8, and 9 in figure 11.20 to make all the fermentation products, except succinate. If the enzyme formic

Most of these pathways have been simplified by deletion of one or more steps and intermediates. Pyruvate and major end products are shown in color.

hydrogenlyase is present (figure 11.20, number 6), formate will be degraded to H₂ and CO₂ (see figure 22.30). Another complex fermentation is the **butanediol fermentation**, which is characteristic of members of the genera *Enterobacter*, *Serratia*, *Erwinia*, and some species of *Bacillus*. The predominant pathway used during this fermentation yields butanediol (figure 11.20, number 4). However, large amounts of ethanol also are produced (figure 11.20, number 9), as are smaller amounts of lactic acid (figure 11.20, number 1)

and formic acid (figure 11.20, number 5); in some bacteria, the formic acid is further catabolized to H₂ and CO₂ (figure 11.20, number 6). The use of either mixed acid fermentation or butanediol fermentation is important in differentiating members of the family *Enterobacteriaceae*, many of which are clinically important. ►► **Order Enterobacterales** (section 22.3); **Class Bacilli** (section 23.2); **Identification of microorganisms from specimens** (section 36.3)

Microorganisms carry out a vast array of fermentations using organic substrates other than glucose. Protozoa and fungi ferment a variety of sugars to lactate, ethanol, glycerol, succinate, formate, acetate, butanediol, and additional products. Some members of the genus *Clostridium* ferment mixtures of amino acids. Proteolytic clostridia such as the pathogens *C. sporogenes* and *C. botulinum* carry out the Stickland reaction in which one amino acid is oxidized and a second amino acid acts as the electron acceptor (see figure 23.4). Some ATP is formed by substrate-level phosphorylation, and the fermentation is quite useful for growing in anoxic, protein-rich environments. Other bacteria ferment amino acids by different mechanisms. In addition to sugars and amino acids, organic acids such as acetate, lactate, propionate, and citrate can be fermented. Some of these fermentations are of great practical importance. For example, citrate can be converted to diacetyl and give flavor to fermented milk. ►► *Class Clostridia* (section 23.1); *Microbiology of fermented foods* (section 41.5)

1. What are fermentations and why are they useful to many microorganisms?
2. How do the electron acceptors used in fermentation differ from the terminal electron acceptors used during aerobic respiration and anaerobic respiration?
3. Briefly describe alcoholic, lactic acid, mixed acid, and butanediol fermentations. How do homolactic fermenters and heterolactic fermenters differ? How do mixed acid fermenters and butanediol fermenters differ?
4. What is the net yield of ATP during homolactic, acetate, and butyrate fermentations? How do these yields compare to aerobic respiration in terms of both quantity and mechanism of phosphorylation?
5. When bacteria carry out fermentation, only a few reactions of the TCA cycle operate. What purpose do you think these reactions might serve? Why are some parts of the cycle shut down?

11.9 Catabolism of Organic Molecules Other Than Glucose

After reading this section, you should be able to:

- Discuss the role of ATP and UTP in the catabolism of monosaccharides other than glucose
- Differentiate the catabolism of disaccharides and polysaccharides by hydrolysis from their catabolism by phosphorolysis
- Discuss the fate of the fatty acid and glycerol components of triglycerides when triglycerides are catabolized
- State the name of the enzymes responsible for hydrolyzing proteins into amino acids
- Distinguish deamination from transamination and explain how the two are related
- Draw a simple diagram that illustrates how the pathways used to catabolize reduced organic molecules other than glucose connect to the glycolytic pathways and the TCA cycle

Thus far our main focus has been on the catabolism of glucose. However, microorganisms can catabolize many other organic molecules, including other carbohydrates, lipids, and amino acids. The use of these energy sources is discussed now.

Carbohydrates

The other carbohydrates used by microbes may come either from outside the cell or from internal sources generated during normal metabolism. Often the initial steps in the degradation of external carbohydrate polymers differ from those employed with internal reserves. Figure 11.21 outlines some catabolic pathways for the monosaccharides (single sugars) glucose, fructose, mannose, and galactose. The first three are phosphorylated using ATP and easily enter the Embden-Meyerhof pathway. In contrast, galactose must be converted to uridine diphosphate galactose (UDP-gal, see figure 12.8) after initial phosphorylation, then converted to glucose 6-phosphate in a three-step process.

Figure 11.21 Carbohydrate Catabolism. Examples of enzymes and pathways used in disaccharide and monosaccharide catabolism. UDP is an abbreviation for uridine diphosphate.

MICRO INQUIRY What is the difference between a hydrolase and a phosphorylase?

The common disaccharides are cleaved to monosaccharides by at least two mechanisms (figure 11.21). Maltose, sucrose, and lactose can be directly hydrolyzed to their constituent sugars. Many disaccharides (e.g., maltose, cellobiose, and sucrose) are also split by a phosphate attack on the bond joining the two sugars, a process called phosphorolysis. This yields the two constituent monosaccharides, one of which is phosphorylated.

Polysaccharides, like disaccharides, are cleaved by both hydrolysis and phosphorolysis. Bacteria, archaea, and fungi degrade external polysaccharides by secreting hydrolytic enzymes. These exoenzymes cleave polysaccharides that are too large to cross the plasma membrane into smaller molecules that can then be assimilated. Starch and glycogen are hydrolyzed by amylases to glucose, maltose, and other products. Cellulose is more difficult to digest; many fungi and a few bacteria (some gliding bacteria, clostridia, and actinomycetes) produce extracellular cellulases that hydrolyze cellulose to cellobiose and glucose. Some actinomycetes and members of the bacterial genus *Cytophaga*, isolated from marine habitats, excrete an agarase that degrades agar. Many soil bacteria and bacterial plant pathogens degrade pectin, a polymer of galacturonic acid (a galactose derivative) that is an important constituent of plant cell walls and tissues. Lignin, another important component of plant cell walls, is usually degraded only by certain fungi that release peroxide-generating enzymes (see figure 31.2). ►► *Soils as a microbial habitat (section 31.1)*

Microorganisms often survive for long periods in the absence of exogenous nutrients. Under such circumstances, they catabolize intracellular stores of glycogen, starch, poly- β -hydroxybutyrate, and other carbon and energy reserves. Glycogen and starch are degraded by phosphorylases. Phosphorylases catalyze a phosphorolysis reaction that shortens the polysaccharide chain by one glucose and yields glucose 1-phosphate.

Glucose 1-phosphate can enter glycolytic pathways after conversion to glucose 6-phosphate (figure 11.21).

Poly- β -hydroxybutyrate (PHB) is an important, widespread reserve material. Its catabolism has been studied most thoroughly in the soil bacterium *Azotobacter* sp. This bacterium hydrolyzes PHB to 3-hydroxybutyrate, then oxidizes the hydroxybutyrate to acetoacetate. Acetoacetate is converted to acetyl-CoA, which can be oxidized in the TCA cycle (figure 11.8).

Lipid Catabolism

Chemoorganotrophic microorganisms frequently use lipids as energy sources. Triglycerides (also called triacylglycerols) are composed of a glycerol core to which are attached three fatty acids. They are common energy sources and will serve as our examples (figure 11.22). Triglycerides can be hydrolyzed to glycerol and fatty acids by enzymes called lipases. The glycerol is then phosphorylated and oxidized to dihydroxyacetone phosphate, an intermediate of the Embden-Meyerhof pathway (EMP), which allows for its continued degradation as shown in figure 11.5.

Fatty acids from triacylglycerols and other lipids are often oxidized in the **β -oxidation pathway** after being linked to coenzyme A (figure 11.23). In this pathway, fatty acids are shortened by two carbons with each turn of the cycle. The two carbon units are released as acetyl-CoA, which can be fed into the TCA cycle or used in biosynthesis. One turn of the cycle produces acetyl-CoA, NADH, and FADH₂; NADH and FADH₂ can be oxidized by an ETC to provide more ATP. Fatty acids are a rich source of energy for microbial growth. In a similar fashion, some microorganisms grow well on petroleum hydrocarbons.

Protein and Amino Acid Catabolism

Some bacteria and fungi—particularly pathogenic, food spoilage, and soil microorganisms—use proteins as their source of carbon and energy. They secrete enzymes called **proteases** that hydrolyze proteins to amino acids, which are transported into the cell and catabolized.

The first step in amino acid catabolism is **deamination**, the removal of the amino group from an amino acid. This is often accomplished by **transamination**. The amino group is transferred

Figure 11.22 A Triacylglycerol (Triglyceride). The R groups represent the fatty acid side chains.

Figure 11.23 Fatty Acid β -Oxidation. The portions of the fatty acid being modified are shown in red.

MICRO INQUIRY Why are fatty acids a rich source of energy even though no ATP is generated when they are degraded by the β -oxidation pathway?

Figure 11.24 Transamination. An example of this process. The α -amino group (blue) of alanine is transferred to the acceptor α -ketoglutarate, forming pyruvate and glutamate. The pyruvate can be fermented, catabolized in the tricarboxylic acid cycle, or used in biosynthesis.

from an amino acid to an α -keto acid acceptor (figure 11.24). The organic acid resulting from deamination can be converted to pyruvate, acetyl-CoA, or a TCA cycle intermediate. Depending on the organic acid, it can be fermented or further oxidized in the TCA cycle to release energy. It also can be used as a source of carbon for the synthesis of cell constituents. Excess nitrogen from deamination may be excreted as ammonium ion.

- Briefly discuss the ways in which microorganisms degrade and use common monosaccharides, disaccharides, and polysaccharides from both external and internal sources.
- Can members of the genus *Cytophaga* be cultured on standard solidified media? Why or why not?
- Describe how a microorganism might derive carbon and energy from the lipids and proteins in its diet. What is β -oxidation? Deamination? Transamination?

11.10 Chemolithotrophy

After reading this section, you should be able to:

- Describe in general terms the fueling reactions of chemolithotrophs
- List the molecules commonly used as energy sources and electron donors by chemolithotrophs
- Discuss the use of electron transport chains and oxidative phosphorylation by chemolithotrophs

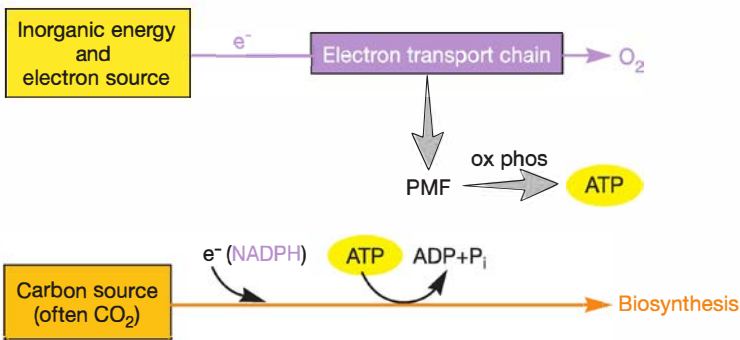

Figure 11.25 Chemolithotrophic Fueling Processes.

Chemolithotrophic bacteria and archaea oxidize inorganic molecules (e.g., H_2S and NH_3), which serve as energy and electron sources. The electrons released pass through an electron transport chain, generating a proton motive force (PMF). ATP is synthesized by oxidative phosphorylation (ox. phos). Most chemolithotrophs use O_2 as the terminal electron acceptor. However, some can use other exogenous molecules as terminal electron acceptors. Note that a molecule other than the energy source provides carbon for biosynthesis. Many chemolithotrophs are autotrophs.

- Predict the relative amount of energy released for each of the commonly used energy sources of chemolithotrophs, as compared to energy released during aerobic and anaerobic respiration of glucose
- Differentiate nitrification from denitrification
- List three examples of important chemolithotrophic processes

So far, we have considered microbes that synthesize ATP with the energy liberated by the oxidation of organic substrates such as carbohydrates, lipids, and proteins. Certain bacteria and archaea are **chemolithotrophs**. These microbes donate electrons to their ETCs by oxidizing inorganic molecules rather than organic nutrients (figure 11.25). Each species is specific in its preferences for electron donors and acceptors (table 11.5). The most common energy sources (electron donors) are hydrogen, reduced nitrogen compounds, reduced sulfur compounds, and ferrous iron (Fe^{2+}). The acceptor is usually O_2 , but sulfate and nitrate may also be used.

Much less energy is available from the oxidation of inorganic molecules than from the complete oxidation of glucose to

Table 11.5 Representative Chemolithotrophs and Their Energy Sources

| Bacteria | Electron Donor | Electron Acceptor | Products |
|--|--|-------------------|---|
| <i>Alcaligenes</i> , <i>Hydrogenophaga</i> , and <i>Pseudomonas</i> spp. | H_2 | O_2 | H_2O |
| <i>Nitrobacter</i> | NO_2^- | O_2 | NO_3^- , H_2O |
| <i>Nitrosomonas</i> | NH_4^+ | O_2 | NO_2^- , H_2O |
| <i>Thiobacillus denitrificans</i> | S^0 , H_2S | NO_3^- | SO_4^{2-} , N_2 |
| <i>Acidithiobacillus ferrooxidans</i> | Fe^{2+} , S^0 , H_2S | O_2 | Fe^{3+} , H_2O , H_2SO_4 |

Table 11.6 Energy Yields from Oxidations Used by Chemolithotrophs

| Reaction | $\Delta G^{\circ'}$ (kcal/mole) ¹ |
|--|---|
| $\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$ | -56.6 |
| $\text{NO}_2^- + \frac{1}{2}\text{O}_2 \rightarrow \text{NO}_3^-$ | -17.4 |
| $\text{NH}_4^+ + 1\frac{1}{2}\text{O}_2 \rightarrow \text{NO}_2^- + \text{H}_2\text{O} + 2\text{H}^+$ | -65.0 |
| $\text{S}^0 + 1\frac{1}{2}\text{O}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{SO}_4$ | -118.5 |
| $\text{S}_2\text{O}_3^{2-} + 2\text{O}_2 + \text{H}_2\text{O} \rightarrow 2\text{SO}_4^{2-} + 2\text{H}^+$ | -223.7 |
| $2\text{Fe}^{2+} + 2\text{H}^+ + \frac{1}{2}\text{O}_2 \rightarrow 2\text{Fe}^{3+} + \text{H}_2\text{O}$ | -11.2 |

¹ The $\Delta G^{\circ'}$ for complete oxidation of glucose to CO_2 is -686 kcal/mole. A kcal is equivalent to 4.184 kJ.

CO_2 (table 11.6). This is because the reduction potentials of most of the inorganic substrates used by chemolithotrophs are much more positive than the reduction potentials of organic molecules such as glucose (figure 11.10). The low yield of ATP means that chemolithotrophs must oxidize a large quantity of inorganic material to grow and reproduce. This is particularly true of chemolithoautotrophs, those chemolithotrophs that fix CO_2 into reduced organic molecules. CO_2 -fixation pathways consume considerable amounts of ATP and reducing power (often NADPH). Because they must consume a large amount of inorganic material, chemolithotrophs have significant ecological impact. They make important contributions to several biogeochemical cycles, including the nitrogen, sulfur, and iron cycles. ►► *CO₂ fixation (section 12.3); Biogeochemical cycling (section 28.1)*

Members of several bacterial and archaeal genera can oxidize hydrogen gas using a hydrogenase enzyme (table 11.5).

The $2\text{H}^+/\text{H}_2$ conjugate redox pair has a very negative standard reduction potential, and its electrons can be donated to either an ETC or NAD^+ , depending on the hydrogenase. If NADH is produced, it can be used in ATP synthesis by electron transport and oxidative phosphorylation, with O_2 , Fe^{3+} , S^0 , and carbon mon-

oxide (CO) as the terminal electron acceptors. Often these hydrogen-oxidizing microorganisms use organic compounds as energy sources when available.

Some bacteria and archaea use the oxidation of nitrogenous compounds as a source of electrons. Among these chemolithotrophs, the **nitrifying bacteria** are best understood. They are soil and aquatic bacteria of considerable ecological significance that carry out **nitrification**—the oxidation of ammonia to nitrate (see figure 22.15). Nitrification is a two-step process that depends on the activity of at least two different bacterial genera, as well as some archaea. In the first step, ammonia is oxidized to nitrite by members of a number of genera, including *Nitrosomonas* as well as some mesophilic archaea. In the second step, the nitrite is oxidized to nitrate by members of genera such as *Nitrobacter*.

Whereas most chemolithotrophs use O_2 as the terminal electron acceptor, some do not. The anammox bacteria (phylum *Planctomycetes*) are an important example. These bacteria carry out **anaerobic ammonia oxidation** (anammox) using a membrane-bound organelle called the anammoxosome. In the anammoxosome, ammonia oxidation is coupled with the reduction of nitrite, generating N_2 and H_2O (see figure 21.15). Thus this is a type of denitrification. Recall that nitrification differs from denitrification in that nitrification involves the oxidation of inorganic nitrogen compounds to yield nitrate. Nitrification is a form of chemolithotrophy in which the nitrogenous compounds donate electrons to an ETC. By contrast, denitrification is the result of anaerobic respiration in which the electron acceptor is an oxidized nitrogenous compound that is reduced to nitrogen gas (p. 248). The anammox reaction is unusual in that it features both the oxidation and reduction of nitrogenous compounds.

Sulfur-oxidizing microbes are the third major group of chemolithotrophs. The metabolism of *Thiobacillus* and *Acidithiobacillus* spp. has been best studied. These bacteria oxidize sulfur (S^0), hydrogen sulfide (H_2S), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), and other reduced sulfur compounds to sulfuric acid; therefore they have a significant ecological impact (**Microbial Diversity & Ecology 11.1**). Interestingly, they generate ATP by both oxidative phosphorylation and substrate-level phosphorylation. Substrate-level phosphorylation involves adenosine 5'-phosphosulfate (APS). This high-energy molecule is formed from sulfite and adenosine monophosphate (figure 11.26).

(a) Direct oxidation of sulfite

(b) Formation of adenosine 5'-phosphosulfate

(c) Adenosine 5'-phosphosulfate

Figure 11.26 Energy Generation by Sulfur Oxidation. (a) Sulfite can be directly oxidized to provide electrons for electron transport and oxidative phosphorylation. (b) Sulfite can also be oxidized and converted to adenosine 5'-phosphosulfate (APS). This route produces electrons for use in electron transport and ATP by substrate-level phosphorylation with APS. (c) The structure of APS.

Microbial Diversity & Ecology

11.1 Acid Mine Drainage

Each year millions of tons of sulfuric acid flow to the Ohio River from the coal mines of the Appalachian Mountains. This sulfuric acid is of microbial origin and leaches enough metals from the mines to make the river reddish and acidic. The primary culprit is *Acidithiobacillus ferrooxidans*, a chemolithotrophic bacterium that derives its energy from oxidizing ferrous ion to ferric ion and sulfide ion to sulfate ion. The combination of these two energy sources is important because of the solubility properties of iron. Ferrous ion is somewhat soluble and can be formed at pH values of 3.0 or less in moderately reducing environments. However, when the pH is greater than 4.0 to 5.0, ferrous ion is spontaneously oxidized to ferric ion by O_2 in the water and precipitates as a hydroxide. If the pH drops below 2.0 to 3.0 because of sulfuric acid production by spontaneous oxidation of sulfur or sulfur oxidation by thiobacilli and other bacteria, the ferrous ion remains reduced, soluble, and available as an energy source. Remarkably, *A. ferrooxidans* grows well at such acidic pHs and actively oxidizes ferrous ion to an insoluble ferric precipitate. The water is rendered toxic for most aquatic life and unfit for human consumption.

The ecological consequences of this metabolic lifestyle arise from the common presence of pyrite (FeS_2) in coal mines. The bacteria oxidize both elemental components of pyrite for their growth and in the process form sulfuric acid, which leaches the remaining minerals.

Autoxidation or bacterial action

A. ferrooxidans

Pyrite oxidation is further accelerated because the ferric ion generated by bacterial activity readily oxidizes more pyrite to sulfuric acid and ferrous ion. In turn, the ferrous ion supports further bacterial growth. It is difficult to prevent *A. ferrooxidans* growth as it requires only pyrite and common inorganic salts. Because *A. ferrooxidans* gets its O_2 and CO_2 from the air, the only feasible method of preventing its damaging growth is to seal the mines to render the habitat anoxic.

Some sulfur-oxidizing microbes are extraordinarily flexible metabolically. For example, *Sulfolobus brierleyi*, an archaeon, and some bacteria can grow aerobically by oxidizing sulfur with oxygen as the electron acceptor (see figure 20.11). However, in the absence of O_2 , they carry out anaerobic respiration and oxidize organic material with sulfur as the electron acceptor. Furthermore, many sulfur-oxidizing chemolithotrophs use CO_2 as their carbon source but will grow heterotrophically if they are supplied with reduced organic carbon sources such as glucose or amino acids.

Energy released by the oxidation of ammonia, nitrite, and sulfur-containing compounds is used to make ATP by oxidative phosphorylation. As we have already noted, the ATP yields for these chemolithotrophs are low. Complicating this already difficult lifestyle is the fact that many of these microbes are also autotrophs, and autotrophs need NAD(P)H (reducing power) as well as ATP to reduce CO_2 and other molecules (figure 11.25). Molecules such as ammonia, nitrite, and H_2S have more positive reduction potentials than the NAD(P) $^+$ /NAD(P)H conjugate redox pair (figure 11.10). Therefore, they cannot directly donate their electrons to NAD(P) $^+$. Recall that electrons spontaneously move only from donors with more negative reduction potentials to acceptors with more positive potentials. Thus these chemolithotrophs face a major dilemma: how to make the NAD(P)H they need. They solve this problem by using a process called **reverse electron flow**. During reverse electron flow, electrons derived from the oxidation of inorganic substrates (reduced

nitrogen or sulfur compounds) are moved up their ETCs to reduce NAD(P) $^+$ to NAD(P)H (figure 11.27). Of course, this is not thermodynamically favorable, so energy in the form of the proton motive force must be diverted from performing other cellular work (e.g., ATP synthesis, transport, motility) to “push” the electrons from molecules of relatively positive reduction potentials to those that are more negative. Chemolithotrophs can afford this inefficiency, as they have no serious competitors for their unique energy sources.

Retrieve, Infer, Apply

1. How do chemolithotrophs obtain their ATP and NAD(P)H? What is their most common source of carbon?
2. Describe energy production by hydrogen-oxidizing bacteria, nitrifying bacteria, and sulfur-oxidizing bacteria.
3. Why can hydrogen-oxidizing bacteria and archaea donate electrons to NAD $^+$, whereas sulfur- and ammonia-oxidizing bacteria and archaea cannot?
4. What is reverse electron flow and why do many chemolithotrophs perform it?
5. Arsenate is a compound that inhibits substrate-level phosphorylation. Compare the effect of this compound on an H_2 -oxidizing chemolithotroph, on a sulfite-oxidizing chemolithotroph, and on a chemoorganotroph carrying out fermentation.

Figure 11.27 Electron Flow in a *Nitrobacter* spp. Electron Transport Chain. *Nitrobacter* spp. oxidize nitrite and carry out normal electron transport to generate proton motive force for ATP synthesis. This is the right-hand branch of the diagram. Some of the proton motive force also is used to force electrons to flow up the reduction potential gradient from nitrite to NAD^+ (left-hand branch). Cytochrome *c* and four complexes are involved: NADH-ubiquinone oxidoreductase (1), ubiquinol-cytochrome *c* oxidoreductase (2), nitrite oxidase (3), and cytochrome *aa*₃ oxidase (4).

11.11 Phototrophy

After reading this section, you should be able to:

- Describe in general terms the fueling reactions of phototrophs
- Differentiate phototrophy from photosynthesis
- Describe the light and dark reactions that occur during photosynthesis
- Summarize the structure and function of the light-absorbing pigments used by oxygenic and anoxygenic phototrophs
- Defend this statement: "Oxidative phosphorylation and photophosphorylation by chlorophyll-based phototrophs differ primarily in the energy source driving the process."
- Distinguish cyclic photophosphorylation from noncyclic photophosphorylation
- Compare and contrast oxygenic photosynthesis, anoxygenic phototrophy, and rhodospin-based phototrophy
- List two examples of the importance of chlorophyll-based phototrophy

Many microbes capture the energy in light and use it to synthesize ATP and reducing power (e.g., NADPH). When the ATP

and reducing power are used to reduce and incorporate CO_2 (CO_2 fixation), the process is called **photosynthesis**. Photosynthesis is one of the most significant metabolic processes on Earth because almost all our energy is ultimately derived from solar energy. Photosynthetic organisms serve as the base of most food webs in the biosphere. One type of photosynthesis is also responsible for replenishing the supply of O_2 in Earth's atmosphere. Although most people associate photosynthesis with plants, over half the photosynthesis on Earth is carried out by microorganisms (**table 11.7**).

Table 11.7 Diversity of Phototrophic Microorganisms

| | |
|-------------------|---|
| Eukaryotes | Multicellular green, brown, and red algae; unicellular protists (e.g., euglenoids, dinoflagellates, diatoms) |
| Bacteria | Cyanobacteria, green sulfur bacteria, green nonsulfur bacteria, purple sulfur bacteria, purple nonsulfur bacteria, heliobacteria, acidobacteria |
| Archaea | Halophiles |

Photosynthesis is divided into two parts. In the **light reactions**, light energy is trapped and converted to chemical energy and reducing power. These are then used to fix CO_2 and synthesize cell constituents in the **dark reactions**. The term **phototrophy** refers to the use of light energy to fuel a variety of cellular activities but not necessarily CO_2 fixation. In this sense, photoheterotrophs, which use light to drive ATP synthesis but not carbon fixation, are considered phototrophs but are not photosynthetic. In this section, three types of phototrophy are discussed: oxygenic photosynthesis, anoxygenic photosynthesis, and rhodopsin-based phototrophy (figure 11.28). The dark reactions of photosynthesis are reviewed in chapter 12. ►► CO_2 fixation (section 12.3)

Chlorophyll-based phototrophy

Rhodopsin-based phototrophy

Figure 11.28 Phototrophic Fueling Reactions. Phototrophs use light to generate a proton motive force (PMF), which is then used to synthesize ATP by a process called photophosphorylation (photo phos). The process requires light-absorbing pigments. When the pigments are chlorophyll or bacteriochlorophyll, the absorption of light triggers electron flow through an electron transport chain, accompanied by the pumping of protons across a membrane. The electron flow can be either cyclic (dashed line) or noncyclic (solid line), depending on the organism and its needs. Rhodopsin-based phototrophy differs in that the PMF is formed directly by the light-absorbing pigment, which is a light-driven proton pump. Many phototrophs are autotrophs and must use much of the ATP and reducing power they make to fix CO_2 .

Light Reactions in Oxygenic Photosynthesis

Photosynthetic eukaryotes and cyanobacteria carry out **oxygenic photosynthesis**, so named because oxygen is generated and released into the environment when light energy is converted to chemical energy. Central to this process, and to all other phototrophic processes, are light-absorbing pigments (table 11.8). In oxygenic phototrophs, the most important pigments are the **chlorophylls**. Chlorophylls are large planar molecules composed of four substituted pyrrole rings with a magnesium atom coordinated to the four central nitrogen atoms (figure 11.29). A long hydrophobic tail attached to the chlorophyll ring aids in its attachment to membranes, the site of the light reactions. Several chlorophylls are found in eukaryotes; the two most important are chlorophyll *a* and chlorophyll *b*. These two molecules differ slightly in their structure and spectral properties. When dissolved in acetone, chlorophyll *a* has a light absorption peak at 665 nm; the corresponding peak for chlorophyll *b* is at 645 nm. In addition to absorbing red light, chlorophylls also absorb blue light strongly (the second absorption peak for chlorophyll *a* is at 430 nm). Because chlorophylls absorb primarily in the red and blue ranges, green light is transmitted, and these organisms appear green.

Other photosynthetic pigments are used to trap light energy. The most widespread of these are the carotenoids, long molecules, usually yellowish in color, that possess an extensive conjugated double bond system (figure 11.30). β -Carotene is present in cyanobacteria belonging to the genus *Prochloron* and most photosynthetic protists; fucoxanthin is found in protists such as diatoms and dinoflagellates. Red algae and cyanobacteria have photosynthetic pigments called **phycobiliproteins**, consisting of a protein with a linear tetrapyrrole attached (figure 11.30). Phycoerythrin is a red pigment with a maximum absorption around 550 nm, and phycocyanin is blue (maximum absorption at 620 to 640 nm).

Carotenoids and phycobiliproteins are often called **accessory pigments** because of their role in photosynthesis. They are important because they absorb light in the range not absorbed by chlorophylls (the blue-green through yellow range; about 470 to 630 nm). This light energy is transferred to chlorophyll. In this way, accessory pigments make photosynthesis possible over a broader range of wavelengths. In addition, this allows organisms to use light not used by other phototrophs in their habitat. Accessory pigments also protect microorganisms from intense sunlight, which could oxidize and damage the photosynthetic apparatus.

Chlorophylls and accessory pigments are assembled in highly organized arrays called **antennas** whose purpose is to create a large surface area to trap as many photons as possible. An antenna has about 300 chlorophyll molecules. Light energy is captured in an antenna and transferred from chlorophyll to chlorophyll until it reaches a **reaction-center chlorophyll pair** that is directly involved in photosynthetic electron transport (see figure 21.9). In oxygenic phototrophs, there are two kinds of antennas associated with two different

Table 11.8 Properties of Chlorophyll-Based Photosynthetic Systems

| Property | Eukaryotes | Cyanobacteria | Green Bacteria, Purple Bacteria, Heliobacteria, and Acidobacteria |
|---------------------------------------|----------------------|-----------------------------------|---|
| Photosynthetic pigment | Chlorophyll <i>a</i> | Chlorophyll <i>a</i> ¹ | Bacteriochlorophyll |
| Number of photosystems | 2 | 2 ² | 1 |
| Photosynthetic electron donors | H ₂ O | H ₂ O | H ₂ , H ₂ S, S, organic matter |
| O ₂ production pattern | Oxygenic | Oxygenic ³ | Anoxygenic |
| Primary products of energy conversion | ATP + NADPH | ATP + NADPH | ATP |
| Carbon source | CO ₂ | CO ₂ | Organic or CO ₂ |

¹ Members of the cyanobacterial genus *Prochlorococcus* have divinyl chlorophyll *a* and *b*.

² A recently discovered cyanobacterium lacks photosystem II.

³ Some cyanobacteria can function anoxygenically under certain conditions. For example, *Oscillatoria* can use H₂S as an electron donor instead of H₂O.

photosystems (figure 11.31). **Photosystem I** absorbs longer wavelength light and funnels the energy to a reaction center chlorophyll *a* pair called P700. The term P700 signifies that this molecule most effectively absorbs light at a wavelength of 700 nm. **Photosystem II** traps light at shorter wavelengths and transfers its energy to the reaction center chlorophyll pair P680.

When the photosystem I antenna transfers light energy to P700, P700 absorbs the energy and is changed into an excited state with a very negative reduction potential. This allows P700 to donate its excited, high-energy electron to a specific acceptor, probably a special chlorophyll *a* molecule or an iron-sulfur protein. The electron is eventually transferred to ferredoxin and then travels in either of two directions. In the cyclic pathway (the dashed lines in figure 11.31), the electron moves in a cyclic route through a series of electron carriers and back to the oxidized P700. The pathway is termed cyclic because the electron from P700 returns to P700 after traveling through the photosynthetic ETC. PMF is formed during cyclic electron transport and used to synthesize ATP. This process is called **cyclic photophosphorylation** because electrons travel in a circle and ATP is formed. Only photosystem I participates.

Electrons also can travel in a noncyclic pathway involving both photosystems. P700 absorbs light and donates electrons to ferredoxin as before. In the noncyclic route, however, reduced ferredoxin reduces NADP⁺ to NADPH (figure 11.31). Because the electrons contributed to NADP⁺ cannot be used to reduce oxidized P700, photosystem II participation is required. It donates electrons to oxidized P700 and generates ATP in the process. The photosystem II antenna absorbs light energy and excites P680, which then reduces pheophytin *a*. Pheophytin *a* is chlorophyll *a* in which two hydrogen atoms have replaced the central magnesium. Electrons subsequently travel down an ETC to reduce P700. Now P680 must also be reduced if it is to accept more light energy. Figure 11.31 indicates that the standard reduction potential of P680 is more positive than that of the $\frac{1}{2}\text{O}_2/\text{H}_2\text{O}$ conjugate redox pair. Thus H₂O can be used to donate electrons to P680, resulting in the release of oxygen. Because electrons flow

from water to NADP⁺ with the aid of energy from two photosystems, ATP is synthesized by **noncyclic photophosphorylation**.

It is worth reemphasizing that although light is the source of energy for chlorophyll-based phototrophy, the process used to make ATP is virtually the same as seen for chemotrophs: oxidation-reduction reactions occurring in ETCs generate a PMF

Figure 11.29 Chlorophyll Structure. The structures of chlorophyll *a*, chlorophyll *b*, and bacteriochlorophyll *a*. The complete structure of chlorophyll *a* is given. Only one group is altered to produce chlorophyll *b*, and two modifications in the ring system are required to change chlorophyll *a* to bacteriochlorophyll *a*. The side chain (R) of bacteriochlorophyll *a* may be either phytyl (a 20-carbon chain also found in chlorophylls *a* and *b*) or geranylgeranyl (a 20-carbon side chain similar to phytyl but with three more double bonds).

Figure 11.30 Representative Accessory Pigments. Beta-carotene is a carotenoid found in photosynthetic protists and plants. Note that it has a long chain of alternating double and single bonds called conjugated double bonds. Fucoxanthin is a carotenoid accessory pigment in several types of algae. Phycocyanobilin is a linear molecule consisting of four pyrrole rings (tetrapyrrole; see figure 11.29); it is attached to a protein to form a phycobiliprotein.

Figure 11.31 Oxygenic Photosynthesis. Cyanobacteria and eukaryotic algae are similar in having two photosystems, although they may differ in some details. The carriers involved in electron transport are ferredoxin (Fd) and other FeS proteins; cytochromes b_6 , b_{559} , and *f*; plastoquinone (PQ); copper-containing plastocyanin (PC); pheophytin *a* (Pheo. *a*); possibly chlorophyll *a* (A); and the unknown quinone Q, which is probably a plastoquinone. Both photosystem I (PS I) and photosystem II (PS II) are involved in noncyclic photophosphorylation; only PS I participates in cyclic photophosphorylation. The oxygen-evolving complex (OEC) that extracts electrons from water contains manganese ions and the substance Z, which transfers electrons to the PS II reaction center.

MICRO INQUIRY When electrons from P700 are used to reduce NADP^+ , what compound supplies electrons for the re-reduction of P700?

that is used by ATP synthase to make ATP. Furthermore, just as is true of mitochondrial electron transport, photosynthetic electron transport takes place within a membrane. Chloroplast granal membranes contain both photosystems and their antennas. **Figure 11.32** shows a thylakoid membrane carrying out non-cyclic photophosphorylation. Protons move to the thylakoid interior during photosynthetic electron transport and return to the stroma when ATP is formed. It is thought that stromal lamellae possess only photosystem I and are involved in cyclic photophosphorylation alone. In cyanobacteria, photosynthetic light reactions are located in thylakoid membranes within the cell.

Photosynthetic Electron Transport and ATP Synthesis

The dark reactions of oxygenic phototrophs use three ATP and two NADPH to reduce one CO_2 to carbohydrate (CH_2O).

Oxygenic phototrophs use noncyclic and cyclic electron flow to supply these needs. The noncyclic system generates one NADPH

and one ATP per pair of electrons; therefore four electrons passing through the system produce two NADPH and two ATP. A total of 8 quanta of light energy (4 quanta for each photosystem) is needed to propel the four electrons from water to NADP^+ . Because the ratio of ATP to NADPH required for CO_2 fixation is 3:2, at least one more ATP must be supplied. Cyclic photophosphorylation probably operates independently to generate the extra ATP. This requires absorption of another 2 to 4 quanta. It follows that around 10 to 12 quanta of light energy are needed to reduce and incorporate one molecule of CO_2 during photosynthesis.

Light Reactions in Anoxygenic Photosynthesis

Certain bacteria carry out a second type of photosynthesis called **anoxygenic photosynthesis**. This phototrophic process derives its name from the fact that molecules other than water are used as an electron source and therefore O_2 is not produced. The process also differs in terms of the photosynthetic pigments used, the participation of just one photosystem, and the mechanisms used

Figure 11.32 The Light Reactions of Photosynthesis. An illustration of the chloroplast thylakoid membrane showing photosynthetic ETC function and noncyclic photophosphorylation. The chain is composed of three complexes: PS I, the cytochrome *bf* complex, and PS II. Two diffusible electron carriers connect the three complexes. Plastoquinone (PQ) connects PS I with the cytochrome *bf* complex, and plastocyanin (PC) connects the cytochrome *bf* complex with PS II. The light-driven electron flow pumps protons across the thylakoid membrane and generates a PMF, which can then be used to make ATP. Water is the source of electrons and the oxygen-evolving complex (OEC) produces oxygen.

to generate reducing power. Members of five bacterial phyla carry out anoxygenic photosynthesis: *Proteobacteria* (purple sulfur and purple nonsulfur bacteria), *Chlorobi* (green sulfur bacteria) *Chloroflexi* (green nonsulfur bacteria), *Firmicutes* (heliobacteria), and *Acidobacteria*. The biology and ecology of these organisms are described in more detail in chapters 21, 22, and 23.

Anoxygenic phototrophs have light-absorbing pigments called **bacteriochlorophylls** (figure 11.29). In some bacteria, these are located in membranous vesicles called chlorosomes. The absorption maxima of bacteriochlorophylls (Bchl) are at longer wavelengths than those of chlorophylls. Bacteriochlorophylls *a* and *b* have maxima in ether at 775 and 790 nm, respectively. In vivo maxima are about 830 to 890 nm (Bchl *a*) and 1,020 to 1,040 nm (Bchl *b*). This shift of absorption maxima into the infrared region better adapts these bacteria to their ecological niches. **▶▶ Photosynthetic bacteria (section 21.4)**

Many differences found in anoxygenic phototrophs are because they have a single photosystem. This means that they are restricted to cyclic photophosphorylation and are unable to produce O_2 from H_2O . Indeed, almost all anoxygenic phototrophs are strict anaerobes. A tentative scheme for the phototrophic ETC of a purple nonsulfur bacterium is given in figures 11.33 and 11.34. When the reaction-center bacteriochlorophyll P870 is excited, it donates an electron to bacteriopheophytin. Electrons then flow to quinones and through an ETC back to P870 while generating sufficient PMF to drive ATP synthesis by ATP synthase. Note that although both green and purple bacteria lack two photosystems, the purple bacteria have a photosynthetic apparatus similar to photosystem II of oxygenic phototrophs, whereas the green sulfur bacteria have a system similar to photosystem I. **▶▶ Purple nonsulfur bacteria (section 22.1); Phylum Chlorobi (section 21.4)**

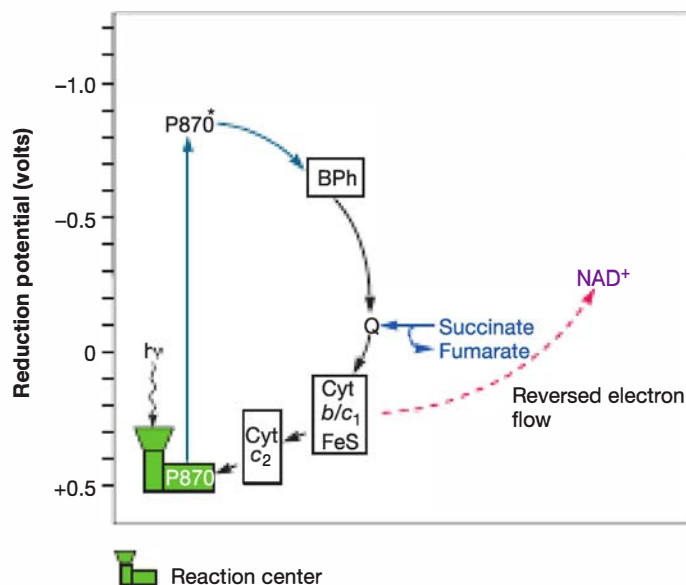

Figure 11.33 Purple Nonsulfur Bacterial Phototrophy. The ETC of the purple nonsulfur bacterium *Rhodobactersphaeroides*. Ubiquinone (Q) is very similar to coenzyme Q. BPh stands for bacteriopheophytin. The electron source succinate is in blue.

Anoxygenic photoautotrophs face a further problem because they also require reducing power (NAD[P]H or reduced ferredoxin) for CO_2 fixation and other biosynthetic processes. They are able to generate reducing power in at least three ways, depending on the bacterium. (1) Some have hydrogenases that are used to produce NAD(P)H directly from the oxidation of hydrogen gas. This is possible because hydrogen gas has a more negative reduction potential than NAD^+ (figure 11.10). (2) Others, such as the photosynthetic purple bacteria, use reverse electron flow to generate NAD(P)H (figure 11.33). In this mechanism, electrons are drawn off the photosynthetic ETC and “pushed” to $NAD(P)^+$ using PMF. This process is similar to that seen for chemolithotrophs having inorganic energy sources with more positive reduction potentials than that of $NAD(P)^+/NAD(P)H$. (3) Phototrophic green bacteria and heliobacteria also draw off electrons from their ETCs. However, because the reduction potential of the carrier where this occurs is more negative than NAD^+ and oxidized ferredoxin, the electrons flow spontaneously to these electron acceptors. Thus these bacteria exhibit a simple form of noncyclic photosynthetic electron flow (figure 11.35). The diversion of electrons from the photosynthetic ETC means that continued generation of PMF will cease unless the electrons are replaced. Electrons from electron donors such as hydrogen sulfide, elemental sulfur, and organic compounds replace the electrons removed from the ETC in this way. **▶ Cyclic and Noncyclic Photophosphorylation**

Rhodopsin-Based Phototrophy

So far, we have discussed chlorophyll-based types of phototrophy; that is, the use of chlorophyll or bacteriochlorophyll to absorb light and initiate the conversion of light energy to chemical

Figure 11.34 Cyclic Electron Flow During Anoxygenic Phototrophy. The photosystem of *Rhodospseudomonas viridis* is illustrated. Bchl, bacteriochlorophyll; Bph, bacteriopheophytin; Q, quinones; and cyt c, cytochrome c.

Figure 11.35 Green Sulfur Bacterial Light Reactions. The photosynthetic ETC in the green sulfur bacterium *Chlorobium limicola*. Light energy is used to make ATP by cyclic photophosphorylation and to move electrons from thiosulfate ($\text{S}_2\text{O}_3^{2-}$) and H_2S (green and blue) to NAD^+ . The ETC has a quinone called menaquinone (MK).

energy. Within the last decade, it has become apparent that many bacteria and archaea are capable of chlorophyll-independent phototrophy. These microbes rely on a form of microbial rhodopsin, a molecule similar to that found in the eyes of many multicellular organisms. The first microbial rhodopsin was discovered several decades ago in certain archaea. In fact, it was first described so long ago that it was called bacteriorhodopsin; we now know that it is more correctly called **archaeorhodopsin**. While a variety of rhodopsins have since been found in members of *Proteobacteria* (and thus called proteorhodopsin), *Flavobacteria*, extremely halophilic bacteria (xanthorhodopsin), and some eukaryotes, the archaeorhodopsin of the halophilic archaeon *Halobacterium salinarum* remains the best studied and is the focus of our discussion here. ►► *Halobacteria* (section 20.3); *Microorganisms in the open ocean* (section 30.2)

H. salinarum normally depends on aerobic respiration for the release of energy from an organic energy source. It cannot grow anaerobically by anaerobic respiration or fermentation. However, under conditions of low oxygen and high light intensity, it synthesizes archaeorhodopsin, a deep-purple pigment. Archaeorhodopsin's chromophore is retinal, a type of carotenoid. The chromophore is covalently attached to the pigment protein, which is embedded in the plasma membrane in such a way that retinal is in the center of the membrane.

Archaeorhodopsin functions as a light-driven proton pump. When retinal absorbs light, a proton is released and the archaeorhodopsin undergoes a sequence of conformation changes that translocate the proton into the periplasmic space (see figure 20.18). The light-driven proton pumping generates a pH gradient that can be used to power the synthesis of ATP by chemiosmosis. This phototrophic capacity is particularly useful to *H. salinarum* because oxygen is not very soluble in concentrated salt solutions and may decrease to an extremely low level in its habitat. When the surroundings become temporarily anoxic, the archaeon uses light energy to synthesize sufficient ATP to survive until oxygen levels rise again. Note that this type of phototrophy does not involve electron transport.

Retrieve, Infer, Apply

1. Define the following terms: light reactions, dark reactions, chlorophyll, carotenoid, phycobiliprotein, antenna, and photosystems I and II.
2. What happens to a reaction center chlorophyll pair, such as P700, when it absorbs light?
3. What is the function of accessory pigments?
4. What is photophosphorylation? What is the difference between cyclic and noncyclic photophosphorylation?
5. Compare and contrast anoxygenic phototrophy and oxygenic photosynthesis. How do these two types of phototrophy differ from rhodopsin-based phototrophy?
6. Suppose you isolated a bacterial strain that carried out oxygenic photosynthesis. What photosystems would it possess, and what group of bacteria would it most likely belong to?

Key Concepts

11.1 Metabolic Diversity and Nutritional Types

- All organisms require a source of carbon, energy, and electrons. Biologists have devised terms to describe how these needs are fulfilled (table 11.1).
- Heterotrophs use reduced organic molecules as their source of carbon. Autotrophs use CO_2 as their primary or sole carbon source.
- Phototrophs use light energy, and chemotrophs obtain energy from the oxidation of chemical compounds.

- Electrons are extracted from reduced inorganic substances by lithotrophs and from reduced organic compounds by organotrophs.
- Most organisms can be placed into one of five nutritional classes: photolithoautotroph, photoorganoheterotroph, chemolithoautotroph, chemolithoheterotroph, and chemoorganoheterotroph (table 11.2).

11.2 Chemoorganotrophic Fueling Processes

- Chemoorganotrophic microorganisms can use three kinds of electron acceptors during energy metabolism (**figure 11.2**). Electrons from the oxidized nutrient can be accepted by an endogenous electron acceptor (fermentation), by oxygen (aerobic respiration), or by another external electron acceptor (anaerobic respiration).
- Chemoorganotrophs can use a variety of molecules as their energy, electron, and carbon source. These molecules are degraded by pathways that funnel into pathways used for glucose catabolism (**figure 11.3**).
- Some of the pathways used by chemoorganotrophs are amphibolic, having both catabolic and anabolic functions (**figure 11.4**).

11.3 Aerobic Respiration

- Aerobic respiration of glucose begins with glycolytic pathways, which catabolize glucose to pyruvate. Pyruvate is fed into the TCA cycle for completion of catabolism.
- The glycolytic pathways and the TCA cycle generate numerous NADH and FADH₂ molecules. These are oxidized by an electron transport chain, using oxygen as the terminal electron acceptor. Electron flow generates a proton motive force (PMF), which is used to synthesize ATP by oxidative phosphorylation.

11.4 From Glucose to Pyruvate

- Glycolysis, used in its broadest sense, refers to all pathways used to break down glucose to pyruvate.
- The Embden-Meyerhof pathway has a net production of two NADH and two ATP, the latter being produced by substrate-level phosphorylation. It also produces several precursor metabolites (**figure 11.5**).
- In the Entner-Doudoroff pathway, glucose is catabolized to pyruvate and glyceraldehyde 3-phosphate (**figure 11.6**). The latter product can be oxidized by enzymes of the Embden-Meyerhof pathway to provide ATP, NADH, and another molecule of pyruvate.
- In the pentose phosphate pathway, glucose 6-phosphate is oxidized twice and converted to pentoses and other sugars. It is a source of NADPH, ATP, and several precursor metabolites (**figure 11.7**).

11.5 Tricarboxylic Acid Cycle

- Pyruvate from the glycolytic pathways is fed into the tricarboxylic acid cycle by a reaction that converts pyruvate to acetyl-CoA. In the process, one of pyruvate's carbons is released in the form of carbon dioxide.
- The tricarboxylic acid cycle oxidizes acetyl-CoA to CO₂ and forms one GTP or ATP, three NADH, and one FADH₂ per acetyl-CoA (**figure 11.8**). It also generates several precursor metabolites.

11.6 Electron Transport and Oxidative Phosphorylation

- The NADH and FADH₂ produced from the oxidation of reduced organic molecules can be oxidized in an electron transport chain (ETC). Electrons flow from carriers with more negative reduction potentials to those with more positive potentials (**figures 11.9–11.11**). As electrons flow through an ETC, protons are transported across the membrane, generating proton motive force (PMF). PMF is used for ATP synthesis by oxidative phosphorylation.
- Bacterial and archaeal ETCs are often different from eukaryotic chains with respect to such aspects as carriers and branching (**figures 11.12 and 11.13**).
- ATP synthase catalyzes the synthesis of ATP (**figure 11.16**). In eukaryotes, it is located on the inner surface of the inner mitochondrial membrane. Bacterial and archaeal ATP synthases are on the inner surface of the plasma membrane. ATP synthase uses the PMF for ATP synthesis (**figure 11.11**).
- In eukaryotes, the P/O ratio for NADH is about 2.5 and that for FADH₂ is around 1.5; P/O ratios are usually much lower in bacterial and archaeal chains. Aerobic respiration in eukaryotes can theoretically yield a maximum of 32 ATP (**figure 11.17**).

11.7 Anaerobic Respiration

- Anaerobic respiration uses an exogenous molecule other than O₂ as the terminal electron acceptor for electron transport. The most common acceptors are nitrate, sulfate, and CO₂ (**figure 11.18 and table 11.3**).
- For some microorganisms, the same pathways used to aerobically respire an organic energy source are also used for anaerobic respiration. However, less energy is provided by anaerobic respiration than aerobic respiration because the alternate electron acceptors have reduction potentials that are less positive than the reduction potential of oxygen.

11.8 Fermentation

- During fermentation, an endogenous electron acceptor is used to reoxidize any NADH generated by the catabolism of glucose to pyruvate (**figure 11.19**). Flow of electrons from the electron donor to the electron acceptor does not involve an ETC, and in most organisms, ATP is synthesized only by substrate-level phosphorylation.
- There are many different fermentation pathways. These are of practical importance in clinical and industrial settings (**figure 11.20**).

11.9 Catabolism of Organic Molecules Other Than Glucose

- Microorganisms catabolize many extracellular carbohydrates. Monosaccharides are taken in and

phosphorylated; disaccharides may be cleaved to monosaccharides by either hydrolysis or phosphorolysis. External polysaccharides are degraded by hydrolysis and the products are absorbed. Intracellular glycogen and starch are converted to glucose 1-phosphate by phosphorolysis (**figure 11.21**).

- Triglycerides are hydrolyzed to glycerol and fatty acids by enzymes called lipases. Fatty acids are usually oxidized to acetyl-CoA in the β -oxidation pathway (**figure 11.23**).
- Proteins are hydrolyzed to amino acids that are then deaminated (**figure 11.24**). The carbon skeletons produced by deamination can be fermented or fed into the TCA cycle (**figure 11.3**).

11.10 Chemolithotrophy

- Chemolithotrophs synthesize ATP by oxidizing inorganic compounds—usually hydrogen, reduced nitrogen and sulfur compounds, or ferrous iron—with an ETC. O_2 is the usual electron acceptor (**figure 11.25** and **table 11.5**). The PMF produced is used by ATP synthase to make ATP.
- Many of the energy sources used by chemolithotrophs have a more positive standard reduction potential than the $NAD^+/NADH$ conjugate redox pair. These chemolithotrophs must expend energy (PMF) to drive reverse electron flow and produce the NADH they need for CO_2 fixation and other processes (**figure 11.27**).

11.11 Phototrophy

- In oxygenic photosynthesis, eukaryotes and cyanobacteria trap light energy with chlorophyll and accessory pigments, and move electrons through photosystems I and II to make ATP and NADPH (the light reactions). The ATP and NADPH are used in the dark reactions to fix CO_2 .
- Cyclic photophosphorylation involves the activity of photosystem I alone and generates ATP only. In noncyclic photophosphorylation, photosystems I and II operate together to move electrons from water to $NADP^+$, producing ATP, NADPH, and O_2 (**figure 11.31**). In both cases, electron flow generates PMF, which is used by ATP synthase to make ATP.
- Anoxygenic phototrophs differ from oxygenic phototrophs in possessing bacteriochlorophyll and having only one photosystem (**figures 11.33–11.35**). Cyclic electron flow generates a PMF, which is used by ATP synthase to make ATP (i.e., cyclic photophosphorylation). They are anoxygenic because they use molecules other than water as an electron donor for electron flow and the production of reducing power.
- Some bacteria and archaea use a type of phototrophy that involves a rhodopsin, a proton-pumping pigment. This type of phototrophy generates PMF but does not involve an ETC.

Compare, Hypothesize, Invent

1. Without looking in chapters 21 and 22, predict some characteristics that would describe niches occupied by green and purple photosynthetic bacteria.
2. From an evolutionary perspective, discuss why most microorganisms use aerobic respiration to generate ATP.
3. How would you isolate a thermophilic chemolithotroph that uses sulfur compounds as a source of energy and electrons? What changes in the incubation system would be needed to isolate bacteria using sulfur compounds in anaerobic respiration? How would you tell which process is taking place through an analysis of the sulfur molecules present in the spent medium?
4. Certain chemicals block ATP synthesis by allowing protons and other ions to “leak across membranes,” disrupting the charge and proton gradients established by electron flow through an ETC. Does this observation support the chemiosmosis hypothesis? Explain your reasoning.
5. Two flasks of *E. coli* are grown in batch culture in the same medium (2% glucose and amino acids; no nitrate) and at the same temperature (37°C). Culture #1 is well

aerated. Culture #2 is anoxic. After 16 hours the following observations are made:

- Culture #1 has a high cell density; the cells appear to be in stationary phase, and the glucose level in the medium is reduced to 1.2%.
- Culture #2 has a low cell density; the cells appear to be in logarithmic phase, although their doubling time is prolonged (over 1 hour). The glucose level is reduced to 0.2%.

Why does culture #2 have so little glucose remaining relative to culture #1, even though culture #2 displayed slower growth and has less biomass?

6. A cyanobacterium having photosystem I but not photosystem II has been discovered. It is unable to fix CO_2 . How do you think this microbe makes ATP? Reducing power? Why is it to this microbe's advantage to be a heterotroph?
7. Review the description of the Berkeley Pit Lake in this chapter's opening case study. In addition to heavy metals, the water has a high concentration of sulfate. Predict the nutritional types that might be isolated from

the lake. What might they use as energy and electron sources? What might any chemotrophs in the lake use as terminal electron acceptors for their ETCs?

8. The archaeon *Metallosphaera sedula* is of great interest to microbiologists in the field of biomining because it might be used to recover base and precious metals. This aerobic thermoacidophile can use organic carbon, ferrous iron (Fe^{2+}), and reduced inorganic sulfur compounds including elemental sulfur (S^0) and tetrathionate ($\text{S}_4\text{O}_6^{2-}$) as a source of electrons. Thus *M. sedula* can grow chemoorganotrophically and chemolithotrophically. Genome sequencing reveals that *M. sedula* has five major terminal oxidase complexes.

Refer to table 10.2 and figure 11.10 to propose the flow of electrons through the electron transport chain when using each of these compounds as the electron source. Which will conserve the most energy and which the least? Why do you think this microbe requires five different terminal oxidases if it always uses O_2 as the terminal electron acceptor?

Anabolism: The Use of Energy in Biosynthesis

An Author's Life Saved

When one of the authors of this text (LS) was an infant, she developed pneumonia. If she had been born a few years earlier, this story would not be told, and a different author would be writing this textbook. What saved her life was the availability of antibiotics.

The story of Alexander Fleming's discovery of penicillin in 1929 is well known. However, Fleming had little to do with developing penicillin as a treatment for infectious disease. After some initial experiments, he abandoned the study of its activity. Fortunately, Ernst Chain developed an interest in the chemical and eventually purified it. In 1940, as many nations battled each other in World War II, Howard Florey and his assistants began clinical trials with penicillin. By that time, Selman Waksman had discovered several other antibacterial agents and had coined the term antibiotic. The penicillin trials were successful, and the need for antibiotics during World War II to treat wound infections was the impetus for finding and developing more antibiotics for clinical use. Thus an author's life was saved.

Antibiotics are interesting molecules for several reasons. One is that they are made at all. Why would a microbe expend materials and energy to make an antibiotic? What selective advantage do they provide? How do they contribute to the ecology of the microbe? Do they serve a purpose other than killing other microbes (see *chapter 24 opening story*)? These questions are still not fully answered. Another reason these molecules are interesting is that they are structurally complex. Despite this, they are built using the same precursor metabolites and many of the same biochemical processes used in the anabolic pathways that sustain life.

During anabolism, an organism begins with simple inorganic molecules and a carbon source, and constructs ever more complex molecules until new organelles and cells arise (**figure 12.1**). Thus anabolism is the creation of order. Because a cell is highly ordered and

Thanks to PENICILLIN
...He Will Come Home!

This World War II poster dramatically illustrates the importance of penicillin to the war effort.

immensely complex, much energy is required for biosynthesis. This is readily apparent from estimates of the biosynthetic capacity of rapidly growing *Escherichia coli* (**table 12.1**). Furthermore, even nongrowing cells need energy for the biosynthetic processes they carry out. This is because nongrowing cells continuously degrade and resynthesize cellular molecules during a process known as turnover. Thus cells are never the same from one instant to the next. Although there is considerably less diversity in anabolic processes as compared to catabolic processes, anabolism is amazing in its own right. Using just 12 precursor metabolites, the cell is able to manufacture the myriad of molecules from which it is constructed. In this chapter, we discuss the synthesis of some of the most important types of cell constituents.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Distinguish metabolism, catabolism, and anabolism
- ✓ List the products of the fueling reactions (section 11.1)
- ✓ Describe how carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur are used by cells
- ✓ Differentiate between heterotrophy and autotrophy (section 11.1)
- ✓ Describe the components of a biochemical pathway and how they are organized (section 10.5)
- ✓ Discuss the function of ATP and how that function is related to its phosphate transfer potential (section 10.2)
- ✓ State the function of enzymes and ribozymes (section 10.6)

12.1 Principles Governing Biosynthesis

After reading this section, you should be able to:

- Describe in general terms the steps organisms use to convert a carbon source and inorganic molecules to cells
- Discuss the principles that govern biosynthesis

The problem faced by all cells is how to make the many molecules they need as efficiently as possible. They have solved this problem by carrying out biosynthesis using a few basic principles. Six are now briefly discussed.

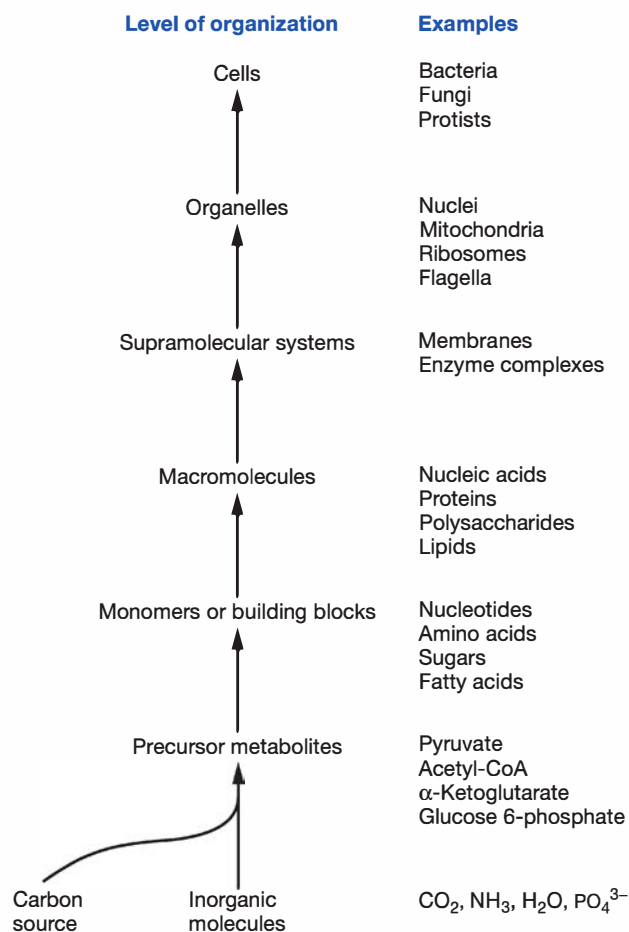

Figure 12.1 The Construction of Cells. The biosynthesis of cells and their constituents is organized in levels of ever greater complexity.

1. **Large molecules are made from small molecules.** The construction of large **macromolecules** (complex molecules) from a few simple structural units (monomers) saves much genetic storage capacity, biosynthetic raw material, and energy. A consideration of protein synthesis clarifies this. Proteins—whatever size, shape, or function—are made of only 20 common amino acids joined by peptide bonds. Different proteins simply have different amino acid sequences rather than new and dissimilar amino acids. Suppose that proteins were composed of 40 different amino acids instead of 20. The cell would then need the enzymes to manufacture twice as many amino acids (or would have to obtain the extra amino acids in its diet). Genes would be required for the extra enzymes, and the cell would have to invest raw materials and energy in the synthesis of these additional genes, enzymes, and amino acids. Clearly, the use of a few monomers linked together by a single type of covalent bond makes the synthesis of macromolecules highly efficient. ▶▶ *Proteins (appendix I); Protein structure (section 13.2)*
2. **Many enzymes do double duty.** As discussed in chapter 11, many enzymes are used for both catabolic and anabolic processes in pathways that are said to be amphibolic (*see figure 11.4*), saving additional materials and energy.
3. **Some enzymes in amphibolic pathways function in one direction only.** Although many steps of amphibolic pathways are catalyzed by enzymes that act reversibly, some are not. These steps require the use of separate enzymes: one to catalyze the catabolic reaction, the other to catalyze the anabolic reaction. The use of two enzymes allows independent regulation of catabolism and anabolism. Thus catabolic and anabolic pathways are never identical, even though they share many enzymes. Although both types of pathways can be regulated by their end products as well as by the concentrations of ATP, ADP, AMP, and NAD⁺/NADH, end-product regulation generally assumes more importance in anabolic pathways.

Table 12.1 Biosynthesis in *Escherichia coli*

| Cell Constituent | Number of Molecules per Cell ¹ | Molecules Synthesized per Second | Molecules of ATP Required per Second for Synthesis |
|------------------|---|----------------------------------|--|
| DNA | 1 ² | 0.00083 | 60,000 |
| RNA | 15,000 | 12.5 | 75,000 |
| Polysaccharides | 39,000 | 32.5 | 65,000 |
| Lipids | 15,000,000 | 12,500.0 | 87,000 |
| Proteins | 1,700,000 | 1,400.0 | 2,120,000 |

¹ Estimates for a cell with a volume of $2.25 \mu\text{m}^3$, a total weight of 1×10^{-12} g, a dry weight of 2.5×10^{-13} g, and a 20-minute cell division cycle.

² It should be noted that bacteria can contain multiple copies of their genomic DNA.

4. **Anabolism consumes energy.** Many reactions in anabolic pathways are endergonic and will not proceed in the direction of biosynthesis. Cells solve this problem by connecting endergonic biosynthetic reactions to the breakdown of ATP and other nucleoside triphosphates. When these two processes are coupled, the free energy made available during nucleoside triphosphate breakdown drives the biosynthetic reaction to completion. ◀◀ ATP (section 10.2)
5. **Catabolism and anabolism can be physically separated.** Catabolic and anabolic pathways can be localized into distinct cellular compartments—a process called compartmentation. In eukaryotes, this is easily done because eukaryotic cells have numerous membrane-bound organelles that carry out specific functions. Compartmentation also occurs in bacterial and archaeal cells. For instance, carboxysomes separate CO₂ fixation from other processes in bacteria. Compartmentation makes it easier for catabolic and anabolic pathways to operate simultaneously yet independently.
6. **Catabolism and anabolism often use different cofactors.** Usually catabolic oxidations produce NADH, a substrate for electron transport. In contrast, when an electron donor is needed during biosynthesis, NADPH often serves as the donor.

After macromolecules have been constructed from simpler precursors, they are assembled into larger, more complex structures such as supramolecular systems and organelles by a process called **self-assembly** (figure 12.1). This is possible because macromolecules normally contain the necessary information to self-assemble. For example, ribosomes are large assemblages of many proteins and ribonucleic acid molecules, yet they arise by the self-assembly of their components without the involvement of other molecules.

Retrieve, Infer, Apply

1. Summarize the six principles by which biosynthetic pathways are organized.
2. What is self-assembly? What biological entity also exhibits self-assembly?

12.2 Precursor Metabolites

After reading this section, you should be able to:

- List the central metabolic pathways, noting which precursor metabolites are generated by each pathway
- Draw a simple diagram that lists all the precursor metabolites and illustrates how they are used in biosynthesis

Generation of the **precursor metabolites** is critical to anabolism because they give rise to all other molecules made by the cell. Precursor metabolites are carbon skeletons (i.e., carbon chains) used as the starting substrates for the synthesis of monomers and other building blocks needed to make macromolecules (see figure 11.1). Precursor metabolites are referred to as carbon skeletons because they lack functional moieties such as amino and sulfhydryl groups; these are added during the biosynthetic process. The precursor metabolites and how they are used in biosynthesis are shown in **figures 12.2 and 12.3**. Several things should be noted in figure 12.2. First, all the precursor metabolites are intermediates of the glycolytic pathways (Embden-Meyerhof, Entner-Doudoroff, and the pentose phosphate pathways) and the tricarboxylic acid (TCA) cycle. Therefore these pathways play a central role in metabolism and are often referred to as the **central metabolic pathways**. Note, too, that most of the precursor metabolites are used for synthesis of amino acids and nucleotides. ◀◀ *From glucose to pyruvate* (section 11.4); *Tricarboxylic acid cycle* (section 11.5) ▶▶ *Common metabolic pathways* (appendix II)

If an organism is a chemoorganotroph using glucose as its energy, electron, and carbon source (either aerobically or anaerobically), it generates the precursor metabolites as it generates ATP and reducing power. But what if the chemoorganotroph is using an amino acid as its sole source of carbon, electrons, and energy? And what about autotrophs? How do they generate precursor metabolites from CO₂, their carbon source? Heterotrophs growing on something other than glucose convert that carbon source into one or more intermediates of the central metabolic pathways. From there, they can generate the remaining precursor metabolites. Autotrophs must first convert CO₂ into organic carbon from which they can generate the precursor metabolites. Many of the reactions that autotrophs use to synthesize the precursor metabolites are reactions of the central metabolic pathways, operating in either the catabolic direction or the anabolic direction. Thus the central metabolic pathways are important to the anabolism of both heterotrophs and autotrophs.

We begin our discussion of anabolism by first considering CO₂ fixation by autotrophs. Once CO₂ is converted to organic carbon, the synthesis of other precursor metabolites, amino acids, nucleotides, and additional building blocks is very similar in both autotrophs and heterotrophs. Recall that the precursor metabolites provide the carbon skeletons for the synthesis of other important organic molecules. In the process of transforming a precursor metabolite into an amino acid or a nucleotide, the carbon skeleton is modified in a number of ways, including the addition of nitrogen, phosphorus, and sulfur. Thus as we discuss the synthesis of monomers from precursor metabolites, we also address the assimilation of nitrogen, sulfur, and phosphorus.

🌀 *A Biochemical Pathway*

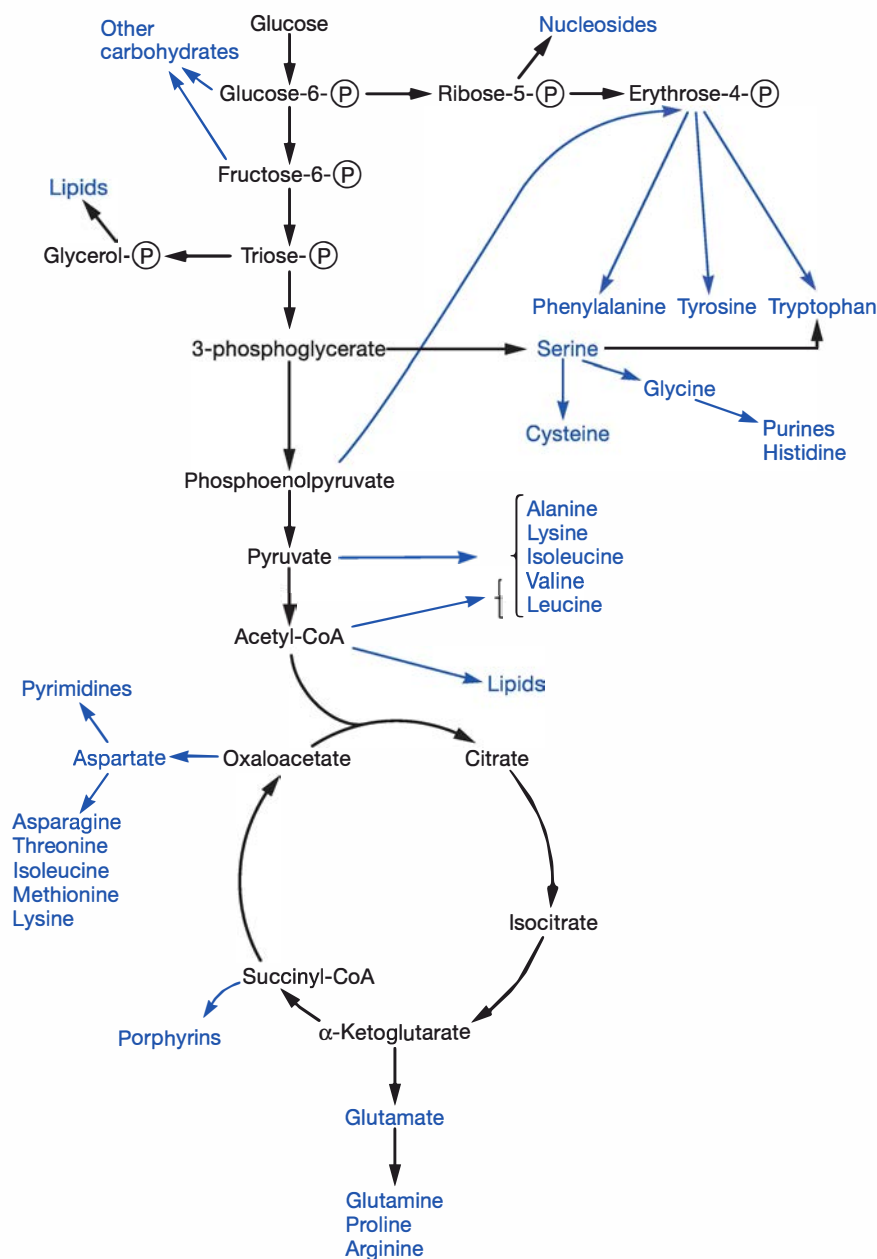

Figure 12.3 The 12 Precursor Metabolites. In chemoorganoheterotrophs, these are produced by the central metabolic pathways. Autotrophs use CO₂-fixation pathways and other pathways (e.g., gluconeogenesis) to make precursor metabolites.

Figure 12.2 The Organization of Anabolism. Biosynthetic products (in blue) are derived from precursor metabolites.

12.3 CO₂ Fixation

After reading this section, you should be able to:

- List the six pathways used by microbes to fix CO₂, noting the types of organisms that use each pathway
- Describe in general terms the three phases of the Calvin cycle
- Identify the steps in the Calvin cycle that consume ATP and NADPH

Autotrophs use CO₂ as their sole or principal carbon source, and the reduction and incorporation of CO₂ requires much energy. Photoautotrophs obtain energy by trapping light during the light reactions of photosynthesis, and chemolithoautotrophs derive energy from the oxidation of inorganic electron donors. Autotrophic CO₂ fixation is crucial to life on Earth because it provides the organic matter on which heterotrophs depend.

◀◀ *Chemolithotrophy* (section 11.10); *Phototrophy* (section 11.11);

▶▶ *Carbon cycle* (section 28.1)

Six different CO₂-fixation pathways have been identified in microorganisms. Most autotrophs use the **Calvin cycle**, which is also called the Calvin-Benson cycle or the reductive pentose

phosphate cycle. The Calvin cycle is found in photosynthetic eukaryotes and most photosynthetic bacteria. Other pathways are used by some obligatory anaerobic and microaerophilic bacteria and archaea. We consider the Calvin cycle first and then briefly introduce the other CO₂-fixation pathways.

Calvin Cycle

The Calvin cycle is also called the reductive pentose phosphate cycle because it is essentially the reverse of the pentose phosphate pathway. Thus many of the reactions are similar, in particular the sugar transformations. The reactions of the Calvin cycle occur in the chloroplast stroma of eukaryotic autotrophs. In cyanobacteria, some nitrifying bacteria, and thiobacilli (sulfur-oxidizing chemolithotrophs), the Calvin cycle is associated with inclusions called **carboxysomes**. These polyhedral structures contain the enzyme critical to the Calvin cycle and are the site of CO₂ fixation. ◀◀ *Pentose phosphate pathway (section 11.4); Inclusions (section 3.6)*

The Calvin cycle is divided into three phases: carboxylation phase, reduction phase, and regeneration phase (figure 12.4 and appendix II). During the carboxylation phase, the enzyme **ribulose 1,5-bisphosphate carboxylase/oxygenase** (RubisCO) catalyzes the addition of CO₂ to the 5-carbon molecule ribulose 1,5-bisphosphate (RuBP), forming a 6-carbon intermediate that rapidly and spontaneously splits into two molecules of 3-phosphoglycerate (PGA). Note that PGA is an intermediate of the Embden-Meyerhof pathway (EMP), and in the reduction phase of the Calvin cycle, PGA is reduced to glyceraldehyde 3-phosphate by two reactions that reverse two EMP reactions. The difference is that the Calvin cycle enzyme glyceraldehyde 3-phosphate dehydrogenase uses NADPH (compare figures 12.4 and 11.5). Finally, in the regeneration phase, RuBP is reformed, so that the cycle can repeat. In addition, this phase produces carbohydrates such as glyceraldehyde 3-phosphate, fructose 6-phosphate, and glucose 6-phosphate, all of which are precursor metabolites (figures 12.2 and 12.3). This portion of the cycle is similar to the pentose phosphate pathway and involves transketolase and transaldolase reactions. 🌀 *The Calvin Cycle*

To synthesize fructose 6-phosphate or glucose 6-phosphate from CO₂, the cycle must operate six times to yield the desired hexose and reform the six RuBP molecules.

The incorporation of one CO₂ into organic material requires three ATP and two NADPH. The formation of glucose from CO₂ may be summarized by the following equation:

Other CO₂-Fixation Pathways

The reactions of the Calvin cycle were determined in the 1940s and 1950s. At the time, it was thought that this pathway was used by all autotrophic organisms. This was shown not to be the case in the mid-1960s, when a second CO₂-fixation pathway was discovered. Over the years, and at an increasingly rapid rate, four more

pathways were discovered. Many microbiologists think that there are still others. Why so many pathways have evolved is still an unanswered question. However, evidence suggests that certain pathways correlate with certain lifestyles. In other words, the ecological niche occupied by a microbe has shaped the evolution of its CO₂-fixation pathway.

Figure 12.4 The Calvin Cycle. This overview of the cycle shows only the carboxylation and reduction phases in detail. Three ribulose 1,5-bisphosphates are carboxylated (the incorporated carbon atom is shaded in pink) to give six 3-phosphoglycerates in the carboxylation phase. These are converted to six glyceraldehyde 3-phosphates, which can be converted to dihydroxyacetone phosphate (DHAP). Five of the six trioses (glyceraldehyde phosphate and dihydroxyacetone phosphate) are used to reform three ribulose 1,5-bisphosphates in the regeneration phase. The remaining triose is used in biosynthesis. The numbers in parentheses at the lower right indicate this carbon flow.

Figure 12.5 The Reductive TCA Cycle. This cycle is used by green sulfur bacteria and some chemolithotrophic bacteria to fix CO₂. The cycle runs in the opposite direction as the TCA cycle. ATP and reducing power (NADH, NADPH, and [H]) drive the reversal. The product of the pathway is acetyl-CoA, which can be used to synthesize other organic molecules and precursor metabolites.

The first alternative CO₂-fixation pathway discovered was the **reductive TCA cycle** (figure 12.5), which is used by some autotrophs in the bacterial phyla *Aquificae*, *Proteobacteria*, *Nitrospirae*, and *Chlorobi*. The reductive TCA cycle is so named because it runs in the reverse direction of the normal, oxidative TCA cycle (compare figures 12.5 and 11.8). ►► *Aquificae* and *Thermotogae* (section 21.1); *Phylum Chlorobi* (section 21.4); *Class Epsilonproteobacteria* (section 22.5)

A third pathway is used by green nonsulfur bacteria (a group of anoxygenic phototrophs). **Figure 12.6** shows the **3-hydroxypropionate bi-cycle** as it functions in *Chloroflexus aurantiacus*. An interesting aspect of the pathway is that the left half produces glyoxylate, which is then used in the right half to make pyruvate. ►► *Phylum Chloroflexi* (section 21.4)

The remaining CO₂-fixation pathways are used by several archaeal taxa: the reductive acetyl-CoA pathway (see figure 20.3) is used by some methanogens; the 3-hydroxypropionate/4-hydroxybutyrate pathway (see figure 20.4) is used by members of the order *Sulfolobales*; and the dicarboxylate/4-hydroxybutyrate cycle (see figure 20.4) was discovered in members of orders *Thermoproteales* and *Desulfurococcales*. These pathways are discussed in chapter 20.

Figure 12.6 The 3-Hydroxypropionate Bi-Cycle. This pathway functions in green nonsulfur bacteria, a group of anoxygenic phototrophs. CO₂ exists as HCO₃⁻ when it is added to intermediates of the pathway.

12.4 Synthesis of Carbohydrates

After reading this section, you should be able to:

- Compare and contrast gluconeogenesis and the Embden-Meyerhof pathway
- Describe the role of ATP and UTP in the synthesis of monosaccharides (other than glucose) and polysaccharides
- Outline the major steps in peptidoglycan synthesis
- Evaluate the effectiveness of targeting antibiotics to peptidoglycan synthesis

Many microbes need to synthesize glucose for anabolic purposes. The synthesis of glucose from noncarbohydrate precursors is called **gluconeogenesis**. The gluconeogenic pathway shares six enzymes with the Embden-Meyerhof pathway. However, the two pathways are not identical (**figure 12.7**). Four reactions are catalyzed by enzymes that are specific for gluconeogenesis. Two of these enzymes are involved in the conversion of pyruvate to phosphoenolpyruvate. Fructose biphosphatase catalyzes the formation of fructose 6-phosphate from fructose 1,6-bisphosphate. Finally, glucose 6-phosphatase removes the phosphate from glucose 6-phosphate to generate glucose.

Synthesis of Monosaccharides and Polysaccharides

As can be seen in **figure 12.7**, gluconeogenesis synthesizes fructose 6-phosphate and glucose 6-phosphate. Once these two precursor metabolites have been formed, other common sugars can be manufactured. For example, mannose comes directly from fructose 6-phosphate by a simple rearrangement of a hydroxyl group (*see figure A1.9*). Several sugars are synthesized while attached to a nucleoside diphosphate. The most important nucleoside diphosphate sugar is **uridine diphosphate glucose (UDPG)**, which is formed when glucose reacts with uridine triphosphate (**figure 12.8**). Uridine diphosphate (UDP) carries glucose around the cell for participation in enzyme reactions much like ADP bears phosphate in the form of ATP. Other important uridine diphosphate sugars are UDP-galactose and UDP-glucuronic acid.

Nucleoside diphosphate sugars also play a central role in the synthesis of polysaccharides such as starch and glycogen, both of which are long chains of glucose. Again, biosynthesis is not simply a direct reversal of catabolism. For instance, during the synthesis of glycogen and starch in bacteria and protists, adenosine diphosphate glucose (ADP-glucose) is formed from glucose 1-phosphate and ATP. It then donates glucose to the end of growing glycogen and starch chains.

Synthesis of Peptidoglycan

Nucleoside diphosphate sugars also participate in the synthesis of peptidoglycan. Recall that peptidoglycan is a large, complex

Figure 12.7 Gluconeogenesis Pathway Used by Many

Microorganisms. The names of the four enzymes catalyzing irreversible reactions that are different from those found in the Embden-Meyerhof pathway (EMP) are in shaded boxes. EMP steps are shown in blue for comparison.

MICRO INQUIRY Why is it important that the enzymes dedicated to gluconeogenesis (rather than those used in both catabolic and anabolic reactions) are found in both the 3-carbon and 6-carbon stages?

Figure 12.8 Uridine Diphosphate Glucose.

molecule consisting of long polysaccharide chains made of alternating *N*-acetylmuramic acid (NAM) and *N*-acetylglucosamine (NAG) residues. The NAM groups bear peptides consisting of five amino acids. During peptidoglycan synthesis, adjacent polysaccharide chains are cross-linked by bonds formed between the pentapeptides. In Gram-negative bacteria and many Gram-positives, the pentapeptide chains are directly linked. In some Gram-positive bacteria, the pentapeptides are connected by an interbridge consisting of one or more amino acids (see figures 3.19 and 3.22). ◀◀ *Bacterial cell walls* (section 3.4)

Not surprisingly, such an intricate structure requires an equally intricate biosynthetic process, especially because some reactions occur in the cytoplasm, others in the plasma membrane, and others in the periplasmic space. Peptidoglycan synthesis involves two carriers. The first, uridine diphosphate, functions in the cytoplasmic reactions. The second carrier, bactoprenol phosphate, is needed for reactions that occur in the plasma membrane.

In the first step of peptidoglycan synthesis, UDP derivatives of NAM and NAG are formed (figure 12.9). Amino acids are then added sequentially to UDP-NAM to form the pentapeptide. NAM-pentapeptide is then transferred to bactoprenol phosphate (also called undecaprenyl phosphate), which is located at the cytoplasmic side of the plasma membrane (figure 12.10). The resulting intermediate is often called Lipid I. Bactoprenol is a 55-carbon, isoprene-derived alcohol that is linked to NAM by two phosphates (pyrophosphate; figure 12.11). Next UDP transfers NAG to the bactoprenol-NAM-pentapeptide complex (Lipid I) to generate Lipid II. This creates the peptidoglycan repeat unit. The repeat unit is transferred across the membrane by bactopre-

nol. If the peptidoglycan unit requires an interbridge, it is added while the repeat unit is within the membrane. Bactoprenol pyrophosphate stays within the membrane and does not enter the periplasmic space. After releasing the peptidoglycan repeat unit into the periplasmic space, bactoprenol pyrophosphate is dephosphorylated to bactoprenol phosphate and returns to the cytoplasmic side of the plasma membrane, where it can function in the next round of synthesis. Meanwhile, the peptidoglycan repeat unit is added to a peptidoglycan chain. The final step in peptidoglycan synthesis is **transpeptidation** (figure 12.12), which creates the peptide cross-links between the peptidoglycan chains. The enzyme that catalyzes the reaction removes the terminal D-alanine as the cross-link is formed. 🌀 *Peptidoglycan Biosynthesis*

To grow and divide efficiently, a bacterial cell must add new peptidoglycan to its cell wall in a precise and well-regulated way while maintaining wall shape and integrity in the presence of high osmotic pressure (see figure 7.7). Because peptidoglycan is a continuous, enormous network, the growing bacterium must be able to degrade it just enough to provide acceptor ends for the incorporation of new peptidoglycan units. This limited peptidoglycan digestion is accomplished by enzymes known as **autolysins**, some of which attack the polysaccharide chains, while others hydrolyze the peptide cross-links. Unregulated autolysin activity would be very dangerous, as it would lead to weakening of the peptidoglycan sacculus. Therefore autolysin activity is tightly controlled. ◀◀ *Cellular growth and determination of cell shape* (section 7.2)

Peptidoglycan is a particularly effective target for antimicrobial agents because of its importance to bacterial cell wall structure and function and because it is absent in animal cells. Inhibition of any stage of synthesis weakens the cell wall and can lead to lysis. Many commonly used antibiotics interfere with peptidoglycan synthesis. For example, penicillin inhibits the transpeptidation reaction (figure 12.12), and bacitracin blocks the dephosphorylation of bactoprenol pyrophosphate (figure 12.10). ◀◀ *Inhibitors of cell wall synthesis* (section 9.4)

12.5 Synthesis of Amino Acids

After reading this section, you should be able to:

- Discuss the three mechanisms microorganisms use to assimilate nitrogen and the role of transaminases in them
- Describe the two methods microbes use to assimilate sulfur
- Differentiate assimilatory nitrate reduction from dissimilatory nitrate reduction and assimilatory sulfate reduction from dissimilatory sulfate reduction

- Evaluate the efficiency of using branched pathways for synthesizing amino acids
- List the major types of anaplerotic reactions or pathways and explain their importance

Many of the precursor metabolites serve as starting substrates for the synthesis of amino acids (figure 12.2). In the amino acid biosynthetic pathways, the carbon skeleton is remodeled and an amino group, and sometimes sulfur, is added. In this section, we first examine the mechanisms by which nitrogen and sulfur are assimilated

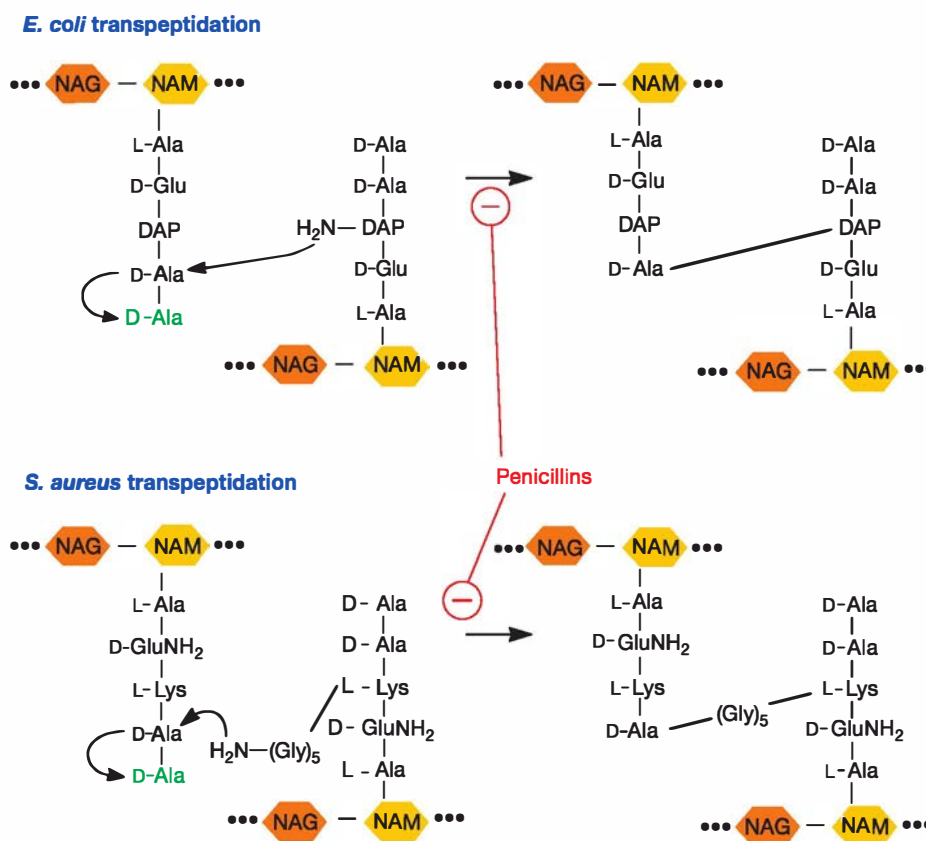

Figure 12.12 Transpeptidation. The transpeptidation reactions in the formation of the peptidoglycans of *E. coli* and *Staphylococcus aureus*.

and incorporated into amino acids. This is followed by a brief consideration of the organization of amino acid biosynthetic pathways.

Nitrogen Assimilation

Nitrogen is a major component not only of proteins but also of nucleic acids, coenzymes, and many other cell constituents. Thus the cell's ability to assimilate inorganic nitrogen is exceptionally important. Although nitrogen gas is abundant in the atmosphere, only a few bacteria and archaea can reduce the gas and use it as a nitrogen source. Most incorporate either ammonia or nitrate. We examine ammonia and nitrate assimilation first and then discuss nitrogen assimilation in microbes that fix N_2 .

Ammonia Incorporation

Ammonia can be incorporated into organic material relatively easily and directly because it is more reduced than other forms of inorganic nitrogen. Ammonia is initially incorporated into carbon skeletons by one of two mechanisms: reductive amination or the glutamine synthetase–glutamate synthase system. Once incorporated, the nitrogen can be transferred to other carbon skeletons by enzymes called transaminases.

The major **reductive amination pathway** involves the formation of glutamate from α -ketoglutarate, catalyzed in many bacteria and fungi by glutamate dehydrogenase when the ammonia concentration is high (figure 12.13).

Figure 12.13 Ammonia Assimilation by Reductive Amination and Transaminases. Either NADPH- or NADH-dependent glutamate dehydrogenases may be involved. This route is most active at high ammonia concentrations. GDH is glutamate dehydrogenase.

Once glutamate has been synthesized, the newly formed α -amino group can be transferred by enzymes called **transaminases** to other carbon skeletons. Microorganisms have a number of transaminases, each of which catalyzes the formation of several amino acids.

Many bacteria use the **glutamine synthetase–glutamate synthase (GS-GOGAT) system** to assimilate ammonia when its levels are low (**figure 12.14**). Incorporation of ammonia begins

when it is used to synthesize glutamine from glutamate in a reaction catalyzed by glutamine synthetase ([figure 12.15](#)). In this reaction, the carboxyl group found in the side chain of glutamate reacts with ammonia, and the incorporated nitrogen exists as an amide in glutamine. The amide nitrogen is transferred to α -ketoglutarate to generate a new glutamate molecule. This reaction is catalyzed by glutamate synthase ([figure 12.15](#)). Because glutamate acts as an amino donor in transaminase reactions, ammonia may be used to synthesize all common amino acids when suitable transaminases are present.

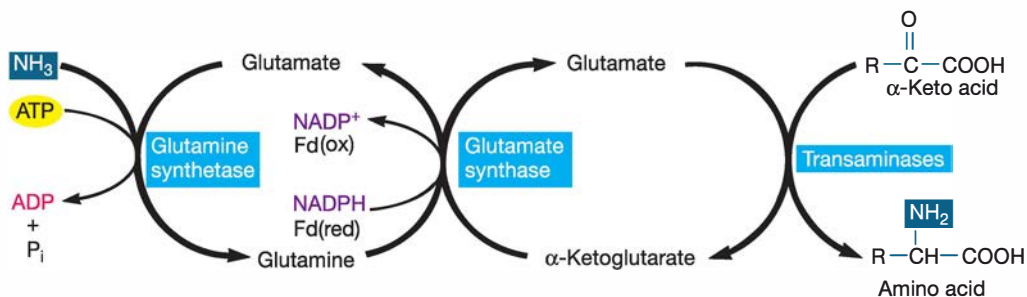

Figure 12.14 Ammonia Incorporation Using Glutamine Synthetase, Glutamate Synthase, and Transaminases. This route is effective at low ammonia concentrations. Fd is ferredoxin in either its reduced (Fd_{red}) state or oxidized (Fd_{ox}) form.

Glutamine synthetase reaction

Glutamate synthase reaction

Figure 12.15 Glutamine Synthetase and Glutamate Synthase Reactions Involved in Ammonia Assimilation. Some glutamate synthases use NADPH as an electron source; others use reduced ferredoxin (Fd).

MICRO INQUIRY What purpose is served for the cell when these reactions are used to produce two glutamate rather than a single glutamine?

Assimilatory Nitrate Reduction

The nitrogen in nitrate (NO_3^-) is much more oxidized than that in ammonia. Therefore nitrate must first be reduced to ammonia before the nitrogen can be converted to an organic form. This reduction of nitrate is called **assimilatory nitrate reduction**. It is important to clearly distinguish assimilatory nitrate reduction from the type of nitrate reduction discussed in chapter 11—dissimilatory nitrate reduction. In dissimilatory nitrate reduction, nitrate serves as the terminal electron acceptor for anaerobic respiration. The reduced forms of nitrogen produced (e.g., N_2 , N_2O) are released into the environment and therefore are not incorporated into cell components. In assimilatory nitrate reduction, nitrate is incorporated into cell material (biomass) and does not participate in energy conservation. The process is widespread among bacteria, fungi, and photosynthetic protists, and it is an important step in the nitrogen cycle. ◀◀ *Anaerobic respiration (section 11.7); ▶▶ Nitrogen cycle (section 28.1)*

Assimilatory nitrate reduction takes place in the cytoplasm in bacteria. The first step in nitrate assimilation is its reduction to nitrite by **nitrate reductase**, an enzyme that contains both FAD and molybdenum (**figure 12.16**). NADPH is the electron donor.

Figure 12.16 Assimilatory Nitrate Reduction. This sequence is thought to operate in bacteria that can reduce and assimilate nitrate nitrogen.

Nitrite is next reduced to ammonia through a series of two electron additions catalyzed by nitrite reductase and possibly other enzymes. The ammonia is then incorporated into amino acids by the routes already described.

Nitrogen Fixation

The reduction of atmospheric gaseous nitrogen to ammonia is called **nitrogen fixation**. Only a few bacteria and archaea carry out nitrogen fixation (eukaryotic cells completely lack this ability). Nitrogen fixation occurs in (1) free-living chemotrophic bacteria and archaea (e.g., *Azotobacter*, *Klebsiella*, *Clostridium*, and *Methanococcus* species), (2) bacteria living in symbiotic associations with plants such as legumes (e.g., *Rhizobium* spp., see figure 31.9), and (3) cyanobacteria (e.g., *Nostoc*, *Anabaena*, and *Trichodesmium* species). These microbes play a critical role in the nitrogen cycle. They complete the cycle from NO_3^- (the most oxidized form of nitrogen) to ammonia (the most reduced form of nitrogen) via N_2 , which has an intermediate oxidation state. The biological aspects of nitrogen fixation are discussed in chapters 28 and 31. The biochemistry of nitrogen fixation is the focus of this section.

The reduction of nitrogen to ammonia is catalyzed by the enzyme **nitrogenase**. It is thought that nitrogen is reduced by two-electron additions in a way similar to that illustrated in figure 12.17. The reduction of molecular nitrogen to ammonia is quite exergonic, but the reaction has a high activation energy because molecular nitrogen is an unreactive gas with a triple bond connecting the two nitrogen atoms. Therefore nitrogen reduction is expensive, requiring a large ATP expenditure—at least 8 electrons and 16 ATP molecules (4 ATP per pair of electrons). Ferredoxin is used as the electron donor.

Nitrogenase is a complex enzyme consisting of two major protein components, a MoFe protein (MW 220,000) joined with one or two Fe proteins (MW 64,000). The MoFe protein has an organic

Figure 12.17 Nitrogen Reduction. The proposed sequence of nitrogen reduction by nitrogenase.

Figure 12.18 Mechanism of Nitrogenase Action. The flow of two electrons from ferredoxin to nitrogen is outlined. This process is repeated three times in order to reduce N_2 to two molecules of ammonia. The stoichiometry at the bottom includes proton reduction to H_2 .

cofactor that contains molybdenum, iron, and sulfur atoms, whereas the Fe protein associates with iron atoms. Fe protein is first reduced by ferredoxin and then binds ATP (figure 12.18). ATP binding changes the conformation of the Fe protein and lowers its reduction potential (-0.29 to -0.40 V), enabling it to reduce the MoFe protein. ATP is hydrolyzed when this electron transfer occurs. Finally, reduced MoFe protein donates electrons

to atomic nitrogen. Nitrogenase is quite sensitive to O_2 and must be protected from O_2 inactivation within the cell. Microbes use a variety of strategies to protect nitrogenase, as we discuss more fully in chapters 22 and 31.

The reduction of N_2 to NH_3 occurs in three steps, each of which requires an electron pair (figures 12.17 and 12.18). Six electron transfers take place, and this uses a total of 12 ATP per N_2 reduced. The overall process actually requires at least 8 electrons and 16 ATP because nitrogenase also catalyzes an additional reaction that “short-circuits” the nitrogen-fixation process. The additional reaction is the reduction of protons to H_2 . The H_2 then reacts with diimine ($HN=NH$) to regenerate N_2 (and also form H_2). Thus nitrogen fixation becomes even more expensive. Symbiotic nitrogen-fixing bacteria can consume almost 20% of the ATP produced by the host plant. Once molecular nitrogen has been reduced to ammonia, the ammonia can be incorporated into organic compounds.

Sulfur Assimilation

Sulfur is needed for the synthesis of the amino acids cysteine and methionine. It is also needed for the synthesis of several coenzymes (e.g., coenzyme A and biotin). Sulfur is obtained from two sources: (1) the amino acids cysteine and methionine, and (2) sulfate. Many microorganisms use cysteine and methionine obtained from either external sources or intracellular amino acid reserves. Because the sulfur is already in a reduced organic form, it is readily incorporated into other organic molecules. The sulfur atom in sulfate is more oxidized than it is in cysteine and methionine; thus sulfate must be reduced before it can be assimilated. This process is known as **assimilatory sulfate reduction** to distinguish it from the dissimilatory sulfate reduction that takes place when sulfate acts as an electron acceptor during anaerobic respiration. ◀◀ *Anaerobic respiration* (section 11.7); ▶▶ *Sulfur cycle* (section 28.1)

Assimilatory sulfate reduction involves sulfate activation through the formation of phosphoadenosine 5'-phosphosulfate (figure 12.19). Sulfate activation prepares the sulfate for reduction, which follows. As shown in figure 12.20, sulfate is first reduced to sulfite (SO_3^{2-}), then to hydrogen sulfide. Cysteine can be synthesized from hydrogen sulfide in two ways (figure 12.21). Fungi appear to combine hydrogen sulfide with serine to form cysteine (figure 12.21a), whereas many bacteria join hydrogen

Figure 12.19 Phosphoadenosine 5'-phosphosulfate (PAPS). The sulfate group is in color.

Figure 12.20 The Sulfate Reduction Pathway.

Figure 12.21 Incorporation of Sulfur from H_2S . H_2S is the product of sulfate reduction, as shown in figure 12.20.

sulfide with O-acetylserine instead (figure 12.21b). Once formed, cysteine can be used in the synthesis of other sulfur-containing organic compounds, including the amino acid methionine.

Amino Acid Biosynthetic Pathways

Some amino acids are made directly by transamination of a precursor metabolite. For example, alanine and aspartate are made directly from pyruvate and oxaloacetate, respectively, using glutamate as the amino group donor. However, most precursor

metabolites must be altered by more than just the addition of an amino group. In many cases, the carbon skeleton must be reconfigured, and for cysteine and methionine, the carbon skeleton must be amended by the addition of sulfur. These biosynthetic pathways are more complex, and they often involve many steps and are branched. By using branched pathways, a single precursor metabolite can be used for the synthesis of a family of related amino acids. For example, the amino acids lysine, threonine, isoleucine, and methionine are synthesized from oxaloacetate by a branching route (**figure 12.22**). Because of the need to conserve nitrogen, carbon, and energy, amino acid synthetic pathways are usually tightly regulated by feedback mechanisms. **◀◀ Post-translational regulation of enzyme activity (section 10.7)**

Anaplerotic Reactions and Amino Acid Biosynthesis

When an organism is actively synthesizing amino acids, a heavy demand for precursor metabolites is placed on the central metabolic pathways, especially the TCA cycle. Therefore it is critical that TCA cycle intermediates be readily available. This is especially true for organisms carrying out fermentation, where the TCA cycle does not function in the catabolism of glucose. To ensure an adequate supply of TCA cycle-generated precursor metabolites, microorganisms use **anaplerotic reactions** (Greek *anaplerotic*, filling up) to replenish TCA cycle intermediates.

Most microorganisms replace TCA cycle intermediates using two reactions that generate oxaloacetate from either phosphoenolpyruvate or pyruvate, both of which are intermediates of the Embden-Meyerhof pathway (**figure 12.23**). These 3-carbon molecules are converted to oxaloacetate by the addition of CO_2 to the molecule, forming a carboxyl group (a carboxylation reaction).

The conversion of pyruvate to oxaloacetate is catalyzed by the enzyme pyruvate carboxylase, which requires the cofactor biotin (**figure 12.23**). Biotin is often the cofactor for enzymes catalyzing carboxylation reactions. Because of its importance, biotin is a required growth factor for many species. The pyruvate carboxylase reaction is observed in yeasts and some bacteria. Other microorganisms, such as *E. coli* and *Salmonella* spp., have the enzyme phosphoenolpyruvate carboxylase, which catalyzes the carboxylation of phosphoenolpyruvate (**figure 12.23**).

Other anaplerotic reactions are part of the **glyoxylate cycle**, which functions in some bacteria, fungi, and protists (**figure 12.24**). This cycle is made possible by two unique enzymes, isocitrate lyase and malate synthase. The glyoxylate cycle is actually a modified TCA cycle. The two decarboxylations of the TCA cycle are bypassed, making possible the conversion of acetyl-CoA to oxaloacetate without the loss of the acetyl-CoA carbons as CO_2 . In this fashion, acetate and any molecules that give rise to it can contribute carbon to the cycle and support microbial growth. **◀◀ Tricarboxylic acid cycle (section 11.5)**

Figure 12.22 The Branching Synthetic Pathway to Methionine, Threonine, Isoleucine, and Lysine. Notice that most arrows represent numerous enzyme-catalyzed reactions. Not shown is the consumption of reducing power and ATP. For instance, the synthesis of isoleucine consumes two ATP and three NADPH.

MICRO INQUIRY Suppose a mutant microbial strain were unable to produce homoserine. What amino acids would it have to obtain from its diet?

12.6 Synthesis of Purines, Pyrimidines, and Nucleotides

After reading this section, you should be able to:

- Distinguish a purine from a pyrimidine, and identify which nitrogenous bases are purines and which are pyrimidines
- Draw a simple diagram that illustrates the chemical moieties found in nucleosides and nucleotides
- Discuss in general terms how phosphorus is assimilated
- Compare and contrast purine and pyrimidine biosynthesis
- Discuss the methods used to convert ribonucleotides to deoxyribonucleotides

Purine and pyrimidine biosynthesis is critical for all cells because these molecules are used to synthesize ATP, several cofactors, ribonucleic acid (RNA), deoxyribonucleic acid (DNA), and other important cell components. Nearly all microorganisms can synthesize their own purines and pyrimidines as these are crucial to cell function. ►► *DNA replication in bacteria* (section 13.3); *Transcription in bacteria* (section 13.5)

Purines and pyrimidines are cyclic nitrogenous bases with several double bonds. **Adenine** and **guanine** are purines, consisting of two joined rings, whereas pyrimidines (**uracil**, **cytosine**, and **thymine**) have only one ring. A purine or pyrimidine base joined with a pentose sugar, either ribose or deoxyribose, is a **nucleoside**. A **nucleotide** is a nucleoside with one or more phosphate groups attached to the sugar.

Amino acids participate in the synthesis of nitrogenous bases and nucleotides in a number of ways, including providing the nitrogen that is part of all purines and pyrimidines. The phosphorus present in nucleotides is provided by other mechanisms. We begin this section by examining phosphorus assimilation. We then examine the pathways for synthesis of nitrogenous bases and nucleotides.

Phosphorus Assimilation

In addition to nucleic acids, phosphorus is found in proteins (i.e., phosphorylated proteins), phospholipids, and coenzymes such as NADP^+ . The most common phosphorus sources are inorganic phosphate and organic molecules containing a phosphoryl group. Inorganic phosphate is incorporated through the formation of ATP in one of three ways: (1) photophosphorylation, (2) oxidative phosphorylation, and (3) substrate-level phosphorylation. ◀◀ *From glucose to pyruvate* (section 11.4); *Electron transport and oxidative phosphorylation* (section 11.6); *Phototrophy* (section 11.11)

Microorganisms may obtain organic phosphates from their surroundings in dissolved or particulate form. **Phosphatases** very often hydrolyze organic phosphate-containing molecules to release inorganic phosphate. Gram-negative bacteria have phosphatases in the periplasmic space, which allows phosphate to be taken up immediately after release. On the other hand, protists can directly use organic phosphates after ingestion or hydrolyze them in lysosomes and then incorporate the phosphate.

Purine Biosynthesis

The biosynthetic pathway for purines is a complex, 11-step sequence (see appendix II) in which seven different molecules contribute parts to the final purine skeleton (figure 12.25). The pathway begins with ribose 5-phosphate, and the purine skeleton is constructed on this sugar. Therefore the first purine product of the pathway is the nucleotide inosinic acid, not a free purine base. The cofactor folic acid is very important in purine biosynthesis because folic acid derivatives contribute two carbons to the purine skeleton.

Once inosinic acid has been formed, relatively short pathways synthesize adenosine monophosphate and guanosine monophosphate (figure 12.26), and produce nucleoside

Figure 12.25 Sources of the Nitrogen and Carbon in Purines.

The nitrogen numbered 9 is linked to the sugar ribose 5-phosphate, and the base is built while attached to the sugar.

Figure 12.26 Synthesis of Adenosine Monophosphate and Guanosine Monophosphate. The highlighted groups differ from those in inosinic acid.

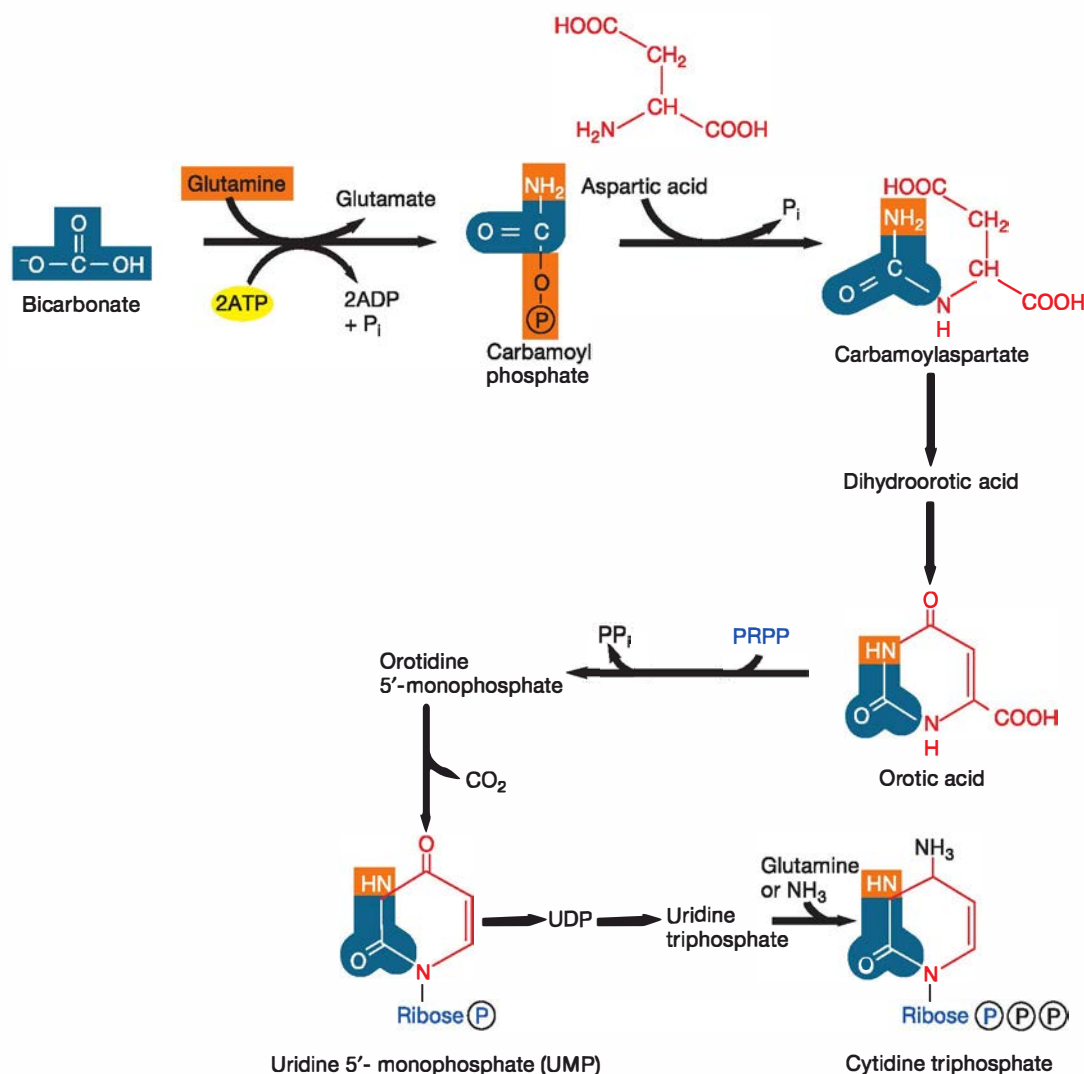

Figure 12.27 Pyrimidine Synthesis. PRPP stands for 5-phosphoribosyl 1-pyrophosphate, which provides the ribose 5-phosphate. The parts derived from bicarbonate and glutamine are shaded.

diphosphates and triphosphates by phosphate transfers from ATP. At this point, the cell has synthesized ribonucleotides. However, it needs deoxynucleotides for DNA synthesis. In deoxyribonucleotides there is an H atom rather than a hydroxyl group on carbon two of the sugar. Thus, to convert a ribonucleotide into a deoxyribonucleotide, that carbon must be reduced. Deoxyribonucleotides arise from the reduction of nucleoside diphosphates or nucleoside triphosphates by two different routes. Some microorganisms reduce the triphosphates with a system requiring vitamin B₁₂ as a cofactor. Others, such as *E. coli*, reduce the ribose in nucleoside diphosphates. Both systems employ a small, sulfur-containing protein called thioredoxin as their reducing agent.

Pyrimidine Biosynthesis

Pyrimidine biosynthesis is equally as complex as purine synthesis. However, the two processes differ in an important way: purines are synthesized by adding chemical moieties to ribose

5-phosphate and never exist as free bases; construction of pyrimidine rings is completed before ribose is attached.

Pyrimidine biosynthesis begins with aspartic acid and carbamoyl phosphate, a high-energy molecule synthesized from bicarbonate and ammonia provided by the amino acid glutamine (figure 12.27). Aspartate carbamoyltransferase catalyzes the joining (condensation) of these two substrates to form carbamoylaspartate, which is then converted to the initial pyrimidine product, orotic acid. The high-energy molecule 5-phosphoribosyl 1-pyrophosphate (PRPP) provides the ribose 5-phosphate that is attached to orotic acid to form a nucleotide.

Orotidine monophosphate is sequentially converted to uridine monophosphate, uridine triphosphate, and cytidine triphosphate. These ribonucleotides are reduced to deoxy-forms in the same way that purine ribonucleotides are. That leaves the cell with only one deoxynucleotide yet to be made: deoxythymidine monophosphate. It is made when deoxyuridine monophosphate is methylated with a folic acid derivative (figure 12.28).

Figure 12.28 Deoxythymidine Monophosphate Synthesis.

Deoxythymidine differs from deoxyuridine in having the shaded methyl group.

Retrieve, Infer, Apply

1. How is phosphorus assimilated? What roles do phosphatases play in phosphorus assimilation? Why can phosphate be directly incorporated into cell constituents, whereas nitrate, nitrogen gas, and sulfate cannot?
2. Explain the difference between a purine and a pyrimidine, and between a nucleoside and a nucleotide.
3. Outline the way in which purines and pyrimidines are synthesized. How is the deoxyribose component of deoxyribonucleotides made?

12.7 Lipid Synthesis

After reading this section, you should be able to:

- Describe the role of acetyl-CoA, acyl carrier protein (ACP), and fatty acid synthase in fatty acid synthesis
- Distinguish saturated fatty acids from unsaturated fatty acids
- Describe the roles of dihydroxyacetone phosphate and fatty acids in the synthesis of triacylglycerol
- Describe the roles of diacylglycerol and CTP in the synthesis of phospholipids

Lipids are absolutely required by cells, as they are the major components of cell membranes. Most bacterial and eukaryal lipids contain fatty acids or their derivatives. Fatty acids consist of a carboxyl group (i.e., they are monocarboxylic acids) attached to a long chain of carbons (alkyl chains); the chains usually have an even number of carbons (the average length is 18 carbons). Some fatty acids have alkyl chains that are unsaturated; that is, they have one or more double bonds. Most microbial fatty acids are straight chained, but some are branched and some have one or more cyclopropane rings. The synthesis of lipids is complex and is the target of some antimicrobial agents used to treat infectious disease caused by eukaryotic pathogens. ►► *Lipids (appendix I);* ►► *Antifungal drugs (section 9.5)*

Fatty acid synthesis is catalyzed by the **fatty acid synthase** complex with acetyl-CoA and malonyl-CoA as the substrates and NADPH as the electron donor. Malonyl-CoA arises from the ATP-driven carboxylation of acetyl-CoA (figure 12.29). Synthesis takes place after acetate (a 2-carbon molecule) and malonate (a 3-carbon molecule)

have been transferred from coenzyme A (CoA) to acyl carrier protein (ACP), a small protein that carries the growing fatty acid chain during synthesis. Fatty acid synthase adds two carbons at a time to the carboxyl end of the growing fatty acid chain in a two-stage process (figure 12.29). First, malonyl-ACP reacts with the fatty acyl-ACP to form a fatty acyl-ACP two carbons longer. Malonate's third carbon is released as CO₂, and this loss drives the reaction to completion. Notice that ATP is used to add CO₂ to acetyl-CoA, forming malonyl-CoA. The same CO₂ is lost when malonyl-ACP donates carbons to the chain. Thus carbon dioxide is essential to fatty acid synthesis but is not permanently incorporated. Indeed, some microorganisms require CO₂ for optimum growth, but they can do without it in the presence of a fatty acid such as oleic acid (an 18-carbon unsaturated fatty acid). In the second stage of synthesis, the β-keto group arising from the initial condensation reaction is removed in a three-step process involving two reductions and a dehydration. The fatty acid is then ready for the addition of two more carbon atoms.

Unsaturated fatty acids are synthesized in two ways. Eukaryotes and aerobic bacteria such as *Bacillus megaterium* employ an aerobic pathway using both NADPH and O₂.

Figure 12.29 Fatty Acid Synthesis. The cycle is repeated until the proper chain length has been reached. Carbon dioxide carbon and the remainder of malonyl-CoA are shown in red. ACP stands for acyl carrier protein.

A double bond is formed between carbons nine and ten, and O_2 is reduced to water with electrons supplied by both the fatty acid and NADPH. Anaerobic bacteria and some aerobes create double bonds during fatty acid synthesis by dehydrating hydroxy fatty acids. Oxygen is not required for double-bond synthesis by this pathway. The anaerobic pathway is present in a number of Gram-negative bacteria (e.g., *E. coli*, *Salmonella* spp., and cyanobacteria), and Gram-positive bacteria (e.g., *Lactobacillus plantarum* and *Clostridium pasteurianum*).

Eukaryotic microorganisms and a few Gram-positive bacteria can store carbon and energy as **triacylglycerol**, glycerol linked to three fatty acids by ester bonds (see figure A1.7). Glycerol arises from the reduction of the precursor metabolite dihydroxyacetone phosphate to glycerol 3-phosphate, which is then esterified with two fatty acids to give phosphatidic acid (figure 12.30). Phosphate is hydrolyzed from phosphatidic acid, giving a diacylglycerol, and the third fatty acid is attached to yield a triacylglycerol.

Phospholipids are major components of eukaryotic and bacterial cell membranes. Their synthesis usually proceeds by way of phosphatidic acid and a cytidine diphosphate (CDP) carrier that plays a role similar to that of uridine and adenosine diphosphate carriers in carbohydrate biosynthesis. For example, bacteria synthesize phosphatidylethanolamine, a major cell membrane

component, through the initial formation of CDP-diacylglycerol (figure 12.30). This CDP derivative then reacts with serine to form the phospholipid phosphatidylserine, and decarboxylation yields phosphatidylethanolamine. In this way, a complex membrane lipid is constructed from the products of glycolysis, fatty acid biosynthesis, and amino acid biosynthesis.

Retrieve, Infer, Apply

1. What is a fatty acid? Describe in general terms how fatty acid synthase manufactures a fatty acid.
2. How are unsaturated fatty acids made?
3. Briefly describe the pathways for triacylglycerol and phospholipid synthesis. Of what importance are phosphatidic acid and CDP-diacylglycerol?
4. Activated carriers participate in carbohydrate, peptidoglycan, and lipid synthesis. Briefly describe these carriers and their roles. Are there any features common to all the carriers? Explain your answer.

Figure 12.30 Triacylglycerol and Phospholipid Synthesis.

Key Concepts

12.1 Principles Governing Biosynthesis

- Many important cell constituents are macromolecules, large polymers constructed of simple monomers.
- Although many catabolic and anabolic pathways share enzymes, making metabolism more efficient, some of their enzymes are separate and independently regulated.
- Macromolecular components often undergo self-assembly to form the final molecule or complex.

12.2 Precursor Metabolites

- Precursor metabolites are carbon skeletons used as the starting substrates for biosynthetic pathways. They are intermediates of glycolytic pathways and the TCA cycle (i.e., the central metabolic pathways) (figures 12.2 and 12.3).
- Most precursor metabolites are used for amino acid biosynthesis; others are used for synthesis of purines, pyrimidines, and lipids.

12.3 CO₂ Fixation

- Six different CO₂-fixation pathways have been identified in autotrophic microorganisms: the Calvin cycle, the reductive TCA cycle, the acetyl-CoA pathway, the 3-hydroxypropionate bi-cycle, the 3-hydroxypropionate/4-hydroxybutyrate pathway, and the dicarboxylate/4-hydroxybutyrate cycle.
- The Calvin cycle is used by most autotrophs to fix CO₂. It can be divided into three phases: the carboxylation phase, the reduction phase, and the regeneration phase (figure 12.4). Three ATP and two NADPH are used during the incorporation of one CO₂.
- The reductive TCA cycle is used by a number of autotrophs belonging to the bacterial phyla *Aquificae*, *Chlorobi*, *Proteobacteria*, and *Nitrospirae*. The 3-hydroxypropionate bi-cycle is used by autotrophs belonging to the bacterial phylum *Chloroflexi*. The remaining CO₂-fixation pathways function in various archaeal taxa (figures 12.5 and 12.6).

12.4 Synthesis of Carbohydrates

- Gluconeogenesis is the synthesis of glucose and related sugars from nonglucose precursors.
- Glucose, fructose, and mannose are gluconeogenic intermediates or are made directly from them (figure 12.7); galactose is synthesized with nucleoside diphosphate derivatives (figure 12.8). Bacteria and protists synthesize glycogen and starch from adenosine diphosphate glucose.
- Peptidoglycan synthesis is a complex process involving both UDP derivatives and the lipid carrier bactoprenol, which transports NAG-NAM-pentapeptide units across

the plasma membrane. Cross-links are formed by transpeptidation (figures 12.9–12.12).

12.5 Synthesis of Amino Acids

- The addition of nitrogen to the carbon chain provided by a precursor metabolite is an important step in amino acid biosynthesis. Ammonia, nitrate, or N₂ can serve as the source of nitrogen.
- Ammonia can be directly assimilated by the activity of transaminases and either glutamate dehydrogenase or the glutamine synthetase–glutamate synthase system (figures 12.13–12.15).
- Nitrate is incorporated through assimilatory nitrate reduction catalyzed by the enzymes nitrate reductase and nitrite reductase (figure 12.16).
- Nitrogen fixation is catalyzed by nitrogenase. Atmospheric molecular nitrogen is reduced to ammonia, which is then incorporated into amino acids (figures 12.17 and 12.18).
- Microorganisms can use cysteine, methionine, and inorganic sulfate as sulfur sources. Sulfate must be reduced to sulfide before it is assimilated. This occurs during assimilatory sulfate reduction (figures 12.20 and 12.21).
- Some amino acids are made directly by the addition of an amino group to a precursor metabolite, but most amino acids are made by pathways that are more complex. Many amino acid biosynthetic pathways are branched. Thus a single precursor metabolite can give rise to several amino acids (figure 12.22).
- Anaplerotic reactions replace TCA cycle intermediates to keep the cycle in balance while it supplies precursor metabolites. The anaplerotic reactions include the glyoxylate cycle (figures 12.23 and 12.24).

12.6 Synthesis of Purines, Pyrimidines, and Nucleotides

- Purines and pyrimidines are nitrogenous bases found in DNA, RNA, and other molecules. The nitrogen is supplied by certain amino acids. Phosphorus is provided by either inorganic phosphate or organic phosphate.
- Phosphorus can be assimilated directly by phosphorylation reactions that form ATP from ADP and P_i. Organic phosphorus sources are the substrates of phosphatases that release phosphate from the organic molecule.
- The purine skeleton is synthesized beginning with ribose 5-phosphate and initially produces inosinic acid (figures 12.25 and 12.26). Pyrimidine biosynthesis starts with carbamoyl phosphate and aspartate, and ribose is added after the skeleton has been constructed (figures 12.27 and 12.28).

12.7 Lipid Synthesis

- Fatty acids are synthesized from acetyl-CoA, malonyl-CoA, and NADPH by fatty acid synthase. During synthesis, the intermediates are attached to the acyl carrier protein (**figure 12.29**). Double bonds can be added in two different ways.
- Triacylglycerols are made from fatty acids and glycerol phosphate. Phosphatidic acid is an important intermediate in this pathway (**figure 12.30**).
- Phospholipids can be synthesized from phosphatidic acid by forming CDP-diacylglycerol, then adding an amino acid.

Compare, Hypothesize, Invent

1. What would happen if a microorganism that depended on the glyoxylate cycle no longer produced the enzyme isocitrate lyase? Could this defect be corrected by nutrients in the media? If so, which nutrients?
2. Intermediary carriers are in a limited supply: When they cannot be recycled because of a metabolic block, serious consequences ensue. Think of some examples of these consequences.
3. Magnetotactic bacteria are morphologically and metabolically complex microbes that produce intracellular, membrane-bound magnetic crystals (*see figure 3.39*). The magnetotactic bacterial isolates called MV-1 and MC-1

both grow chemolithoautotrophically. However, MV-1 uses the Calvin-Benson cycle to fix carbon, whereas MC-1 uses the reductive TCA cycle.

Refer to figures 12.4 and 12.5 to identify key enzymatic steps in each pathway. How do you think the microbiologists studying these fascinating microbes were able to conclude that these two bacterial isolates use two different pathways for carbon fixation?

Bacterial Genome Replication and Expression

Making Code

Since ancient times, humans have sent important messages in code. Julius Caesar sent coded messages to his generals. Mary Queen of Scots used code to detail her plans to overthrow Queen Elizabeth the First. George Washington regularly communicated to his troops in code, as have commanders in all wars. Today work continues to create codes that are harder to break and more content rich.

Code writing is related to another field: storage of information, which often involves converting the information using a code—a process termed encryption. The history of information storage parallels the history of communicating secrets in code. Initially coded messages were spoken; likewise, information was stored in song and dance. Later, coded messages were hand-written on paper; manuscripts and books stored valuable data. As codes became more sophisticated and their content larger, the physical form of coded messages evolved to include radio communications, tape recordings, and binary digits in computers. Similar methods were developed to store data sets.

In the early years of this century, scientists began exploring a new method of encrypting and storing valuable data. This new method is called biostorage or bioencryption, and it stores coded data in pieces of DNA inserted into the chromosome of a bacterium. Scientists turned to DNA because they estimated that the information in about 1,000 books having 500 pages of small print is the equivalent of the information stored in one strand of human DNA. They chose bacteria because even though their DNA molecules are smaller, bacteria are easier to manipulate.

In 2007 a group of Japanese scientists used a soil bacterium to store Einstein's famous equation $E=MC^2$. The methods used to insert the equation into the bacterium's genome are similar to techniques routinely used to cut and paste DNA molecules together (see chapter 17). However, this single equation is much smaller than the large amounts of data scientists hope to biostore. So it was obvious to them that methods for increasing storage capacity must be developed.

A potential breakthrough came in 2011, and it was accomplished by a group of students attending Hong Kong's Chinese University. The students developed a method of encrypting data that compressed it, thereby making it take up less space in the bacterial genome. They also divided the data into smaller sets that could be inserted into different cells. Thus a collection of unique bacterial strains contained the entire data set, much like different volumes of an encyclopedia together encompass all the information stored in the encyclopedia. The students also created a "map" that allowed them to find the particular bacterial strain that contained a certain piece of information. This is similar to the alphabetical organization of entries in an encyclopedia.

For millennia cellular organisms have used DNA to store genetic information, and they have devised methods for replicating, recoding, and decoding genetic information—processes called DNA replication, transcription, and translation, respectively. All three construct polymers (DNA, RNA, protein) from monomers and are required for survival. In this chapter, we explore the metabolic reactions called polymerization reactions that generate these polymers (see figure 11.1).

Polymerization reactions are central to the inheritance of characteristic traits of organisms. This understanding resulted from the work of many scientists. In the mid-1800s Gregor Mendel established how various traits in pea plants were inherited. At that time, chemists had not yet discovered DNA. Unfortunately, Mendel's work went largely unnoticed. However, in the early twentieth century, Mendel's work was rediscovered and furthered by scientists working with fruit flies and plants such as corn. The use of microorganisms as models for genetic studies soon followed. Microorganisms, especially bacteria, have significant advantages as model organisms, in part because of their unique characteristics. One important feature of bacteria is the nature of their genomes, which are haploid (1N). In addition, they often carry plasmids, which are useful to cells because they allow genetic information to move from one cell to another. Plasmids are also useful to scientists for genetic analyses and recombinant DNA technologies. Using bacteria (and often their viruses) as model systems was important in the elucidation of the nature of genetic information,

gene structure, the genetic code, and mutation. Thus we begin by considering bacterial genetics in this chapter and the next. Because of the distinctive characteristics of eukaryotes and archaea, the replication and expression of their genomes are discussed in chapter 15.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Define the terms genome, chromosome, plasmid, haploid, diploid, genotype, and phenotype
- ✓ Outline the flow of genetic information, identifying the processes used
- ✓ Draw a simple diagram that illustrates the chemical moieties found in nucleotides (section 12.6)
- ✓ State the base-pairing rules
- ✓ Describe the structure of bacterial genomes (section 3.6)

13.1 DNA as Genetic Material

After reading this section, you should be able to:

- Summarize Griffith's experiments on transformation
- Relate how the contributions of Avery, MacLeod, McCarty, Hershey, and Chase confirmed that DNA stores genetic material

Although it is now hard to imagine, it was once thought that DNA was too simple a molecule to store genetic information. It is composed of only four different nucleotides, and it seemed that a molecule of much greater complexity must house the genetic information of a cell. It was argued that proteins, being composed of 20 different amino acids, were the better candidate for this important cellular function.

The early work of Fred Griffith in 1928 on the transfer of virulence in the pathogen *Streptococcus pneumoniae*, commonly called pneumococcus, set the stage for research showing that DNA was indeed the genetic material. Griffith found that if he boiled virulent bacteria and injected them into mice, the mice were not affected and no pneumococci could be recovered from the animals (**figure 13.1**). When he injected a combination of killed virulent bacteria and a living nonvirulent strain, the mice died; moreover, he could recover living virulent bacteria from the dead mice. Griffith called this change of nonvirulent bacteria into virulent pathogens transformation.

Oswald Avery and his colleagues then set out to discover which constituent in the heat-killed virulent pneumococci was responsible for transformation. These investigators used enzymes to selectively destroy DNA, RNA, or protein in purified extracts of virulent pneumococci (S cells). They then exposed nonvirulent

pneumococcal strains (R strains) to the treated extracts. Transformation of the nonvirulent bacteria was blocked only if the DNA was destroyed, suggesting that DNA was carrying the information required for transformation (**figure 13.2**).

The publication of these studies by Avery, C. M. MacLeod, and M. J. McCarty in 1944 provided the first evidence that DNA carried genetic information.

Eight years later, Alfred Hershey and Martha Chase wanted to know if protein or DNA carried the genetic information of a bacterial virus called T2 bacteriophage. They performed experiments in which they made the virus's DNA radioactive with ^{32}P , or they labeled its protein coat with ^{35}S . They mixed radioactive virions with *Escherichia coli* and incubated the mixture for a few minutes. This allowed the virions to attach to *E. coli* and begin multiplying. The suspension was then agitated violently in a blender to shear off any adsorbed bacteriophage particles (**figure 13.3**). After centrifugation, radioactivity in the supernatant (where the phage particles remained) versus the bacterial cells in the pellet was determined. They found that most radioactive protein was released into the supernatant, whereas ^{32}P DNA remained within the bacteria. Since DNA entered the cells and T2 progeny were produced, the phage DNA must have been carrying the genetic information. Some luck was involved in their discovery, for the genetic material of many viruses is RNA and the researchers happened to select a DNA virus for their studies. Imagine the confusion if T2 had been an RNA virus! The controversy surrounding the nature of genetic information might have lasted considerably longer than it did.

Subsequent studies on the genetics of viruses and bacteria were largely responsible for the rapid development of molecular genetics. Furthermore, much of the recombinant DNA technology described in chapter 17 has arisen from studies of bacterial and viral genetics. Research in microbial genetics has had a profound impact on biology as a science and on technology that affects everyday life.

Retrieve, Infer, Apply

1. Briefly summarize the experiments of Griffith; Avery, MacLeod, and McCarty; and Hershey and Chase.
2. Explain how protein was ruled out as the molecule of genetic information storage in each of the experiments performed by these important microbiologists.

13.2 Nucleic Acid and Protein Structure

After reading this section, you should be able to:

- Draw schematic representations of DNA, RNA, and amino acids that show their major features
- Compare and contrast the structure of DNA and RNA
- Identify the covalent bonds that are used to link nucleotides together to form a nucleic acid and amino acids together to form a polypeptide

DNA, RNA, and proteins are often called informational molecules. The information exists as the sequence of monomers from which they are built. Here we describe the monomers and how they are linked together to form these important macromolecules.

Figure 13.1 Griffith's Transformation Experiments. (a) Mice died of pneumonia when injected with pathogenic strains of pneumococci, which have a capsule and form smooth-looking colonies (S strains). (b) Mice survived when injected with nonpathogenic strains of pneumococci, which lack a capsule and form rough colonies (R strains). (c) Injection with heat-killed S strains had no effect. (d) Injection with a live R strain and a heat-killed S strain gave the mice pneumonia, and live S strain pneumococci could be isolated from the dead mice.

MICRO INQUIRY Based on what we now know about proteins, why can we conclude from this experiment that genetic information was unlikely to be carried by proteins?

DNA Structure

Deoxyribonucleic acid (DNA) is a polymer of deoxyribonucleotides (figure 13.4) linked together by phosphodiester bonds (figure 13.5a). It contains the bases adenine, guanine, cytosine, and thymine. DNA molecules are very large and are usually composed of two polynucleotide chains coiled together to form a double helix 2.0 nm in diameter (figure 13.5). The monomers of DNA are called deoxyribonucleotides because the sugar found in them is deoxyribose (figure 13.4b). The bond that links the monomers together to form the polymer is

called a phosphodiester bond because it consists of a phosphate that forms a bridge between the 3'-hydroxyl of one sugar and the 5'-hydroxyl of an adjacent sugar. Purine and pyrimidine bases are attached to the 1'-carbon of the deoxyribose sugars, and the bases extend toward the middle of the cylinder formed by the two chains. (The numbers designating the carbons in the sugars are given a prime to distinguish them from the numbers designating the carbons and nitrogens in the nitrogenous bases.) The bases from each strand interact with those of the other strand, forming base pairs. The base pairs are

The experiments:

- 1 Mix R cells and DNA extract from S cells (treated or untreated).
- 2 Allow DNA to be taken up by R cells.
- 3 Add antibodies that cause untransformed R cells to aggregate.
- 4 Gently centrifuge to remove aggregated R cells, leaving only S cells.
- 5 Plate sample of mixture and incubate.

Figure 13.2 Some Experiments on the Transforming Principle. Earlier experiments done by Avery, MacLeod, and McCarty had shown that only DNA extracts from S cells caused transformation of R cells to S cells. To demonstrate that contaminating molecules in the DNA extract were not responsible for transformation, the DNA extract from S cells was treated with RNase, DNase, or protease, and then mixed with R cells. Only treatment of the DNA extract from S cells with DNase destroyed the ability of the extract to transform the R cells.

Figure 13.3 The Hershey-Chase Experiment.

(a) When *E. coli* was infected with a T2 phage containing ^{35}S protein, most of the radioactivity remained outside the host cell. (b) When a T2 phage containing ^{32}P DNA was mixed with the host bacterium, the radioactive DNA was injected into the cell and phages were produced. Thus DNA was carrying the virus's genetic information.

Figure 13.4 The Composition of Nucleic Acids. (a) A diagram showing the relationships of various nucleic acid components. Combination of a purine or pyrimidine base with ribose or deoxyribose gives a nucleoside (a ribonucleoside or deoxyribonucleoside). A nucleotide contains a nucleoside and one or more phosphates. Nucleic acids result when nucleotides are connected together in polynucleotide chains. (b) Examples of nucleosides—adenosine and 2'-deoxyadenosine—and the nucleotide 2'-deoxyadenosine monophosphate. The carbons of nucleoside and nucleotide sugars are indicated by numbers with primes to distinguish them from the carbons in the bases.

MICRO INQUIRY To which carbon of ribose (deoxyribose) is each of the following bonded: adenine and the hydroxyls of adenosine and deoxyadenosine?

stacked on top of each other in the center, one base pair every 0.34 nm. The purine adenine (A) of one strand is always paired with the pyrimidine thymine (T) of the opposite strand by two hydrogen bonds. The purine guanine (G) pairs with cytosine (C) by three hydrogen bonds. This AT and GC base pairing means that the two strands in a DNA double helix are **complementary**. In other words, the bases in one strand match up with those of the other according to specific base-pairing rules. Because the sequences of bases in these strands encode genetic information, considerable effort has been devoted to determining the base sequences of DNA and RNA from many organisms, including hundreds of microbes. ► *Microbial genomics (chapter 18)*

The two polynucleotide strands of DNA fit together much like the pieces in a jigsaw puzzle. Inspection of figure 13.5b,c shows that the two strands are not positioned directly opposite one another. Therefore when the strands twist about one another, a wide major groove and narrower minor groove are formed by the backbone. There are 10.5 base pairs per turn of the helix, and each turn of the helix has a vertical length of 3.4 Å. The helix is right-handed; that is, the chains turn counterclockwise as they approach a viewer looking down the longitudinal axis. The two backbones are antiparallel, which means they run in opposite directions with respect to the orientation of their sugars. One end of each strand has an exposed 5'-hydroxyl group, often with phosphates attached, whereas the other end has a free 3'-hydroxyl group (figure 13.5a). In a given direction, one strand is oriented 5' to 3' and the other, 3' to 5' (figure 13.5b).

The structure of DNA just described is that of the B form, the most common form in cells. Two other forms of DNA have been identified. The A form primarily differs from the B form in that it has 11 base pairs per helical turn, rather than 10.5, and a vertical length of 2.6 Å, rather than 3.4. Thus it is wider than the B form. The Z form is dramatically different, having a left-handed

helical structure, rather than right-handed as seen in the B and A forms. The Z form has 12 base pairs per helical turn and a vertical rise of 3.7 Å. Thus it is more slender than the B form. At this time, it is unclear whether the A form is found in cells. However, evidence exists that small portions of chromosomes can be in the Z form. The role, if any, for these stretches of Z DNA is unknown. ❁ *DNA Structure*

There is another property of DNA that needs to be addressed: supercoiling. DNA is helical; that is, it is a coil. Whenever the rotation of a coil is restrained in some way, it causes the coil to coil on itself. The coiling of a coil is supercoiling. Recall that most bacterial chromosomes are closed, circular double-stranded DNA molecules. In this state, the two strands are unable to rotate freely relative to each other, and the molecule is said to be strained. The strain is relieved by supercoiling. There are two types of supercoiling: positive and negative. For DNA, these are defined by the change in number of base pairs per turn in the double helix. As just discussed, the B form of DNA has 10.5 base pairs per turn of the helix. Supercoiling that decreases the number of base pairs per turn is said to be negative supercoiling. Likewise, supercoiling that increases the number of base pairs per turn is called positive supercoiling. Bacterial chromosomes are generally negatively supercoiled.

What is the importance of supercoiling? Supercoiling helps compact DNA so that it fits into the cell. Importantly for this chapter, supercoiling also “loosens” up the DNA, making it easier to separate the two strands from each other. Separation of the two strands is an important early step in both DNA replication and transcription, as we discuss in sections 13.3 and 13.5, respectively. Furthermore, positive supercoiling is often introduced into DNA during DNA replication. This can interfere with DNA replication and must be removed, as we discuss in section 13.3.

RNA Structure

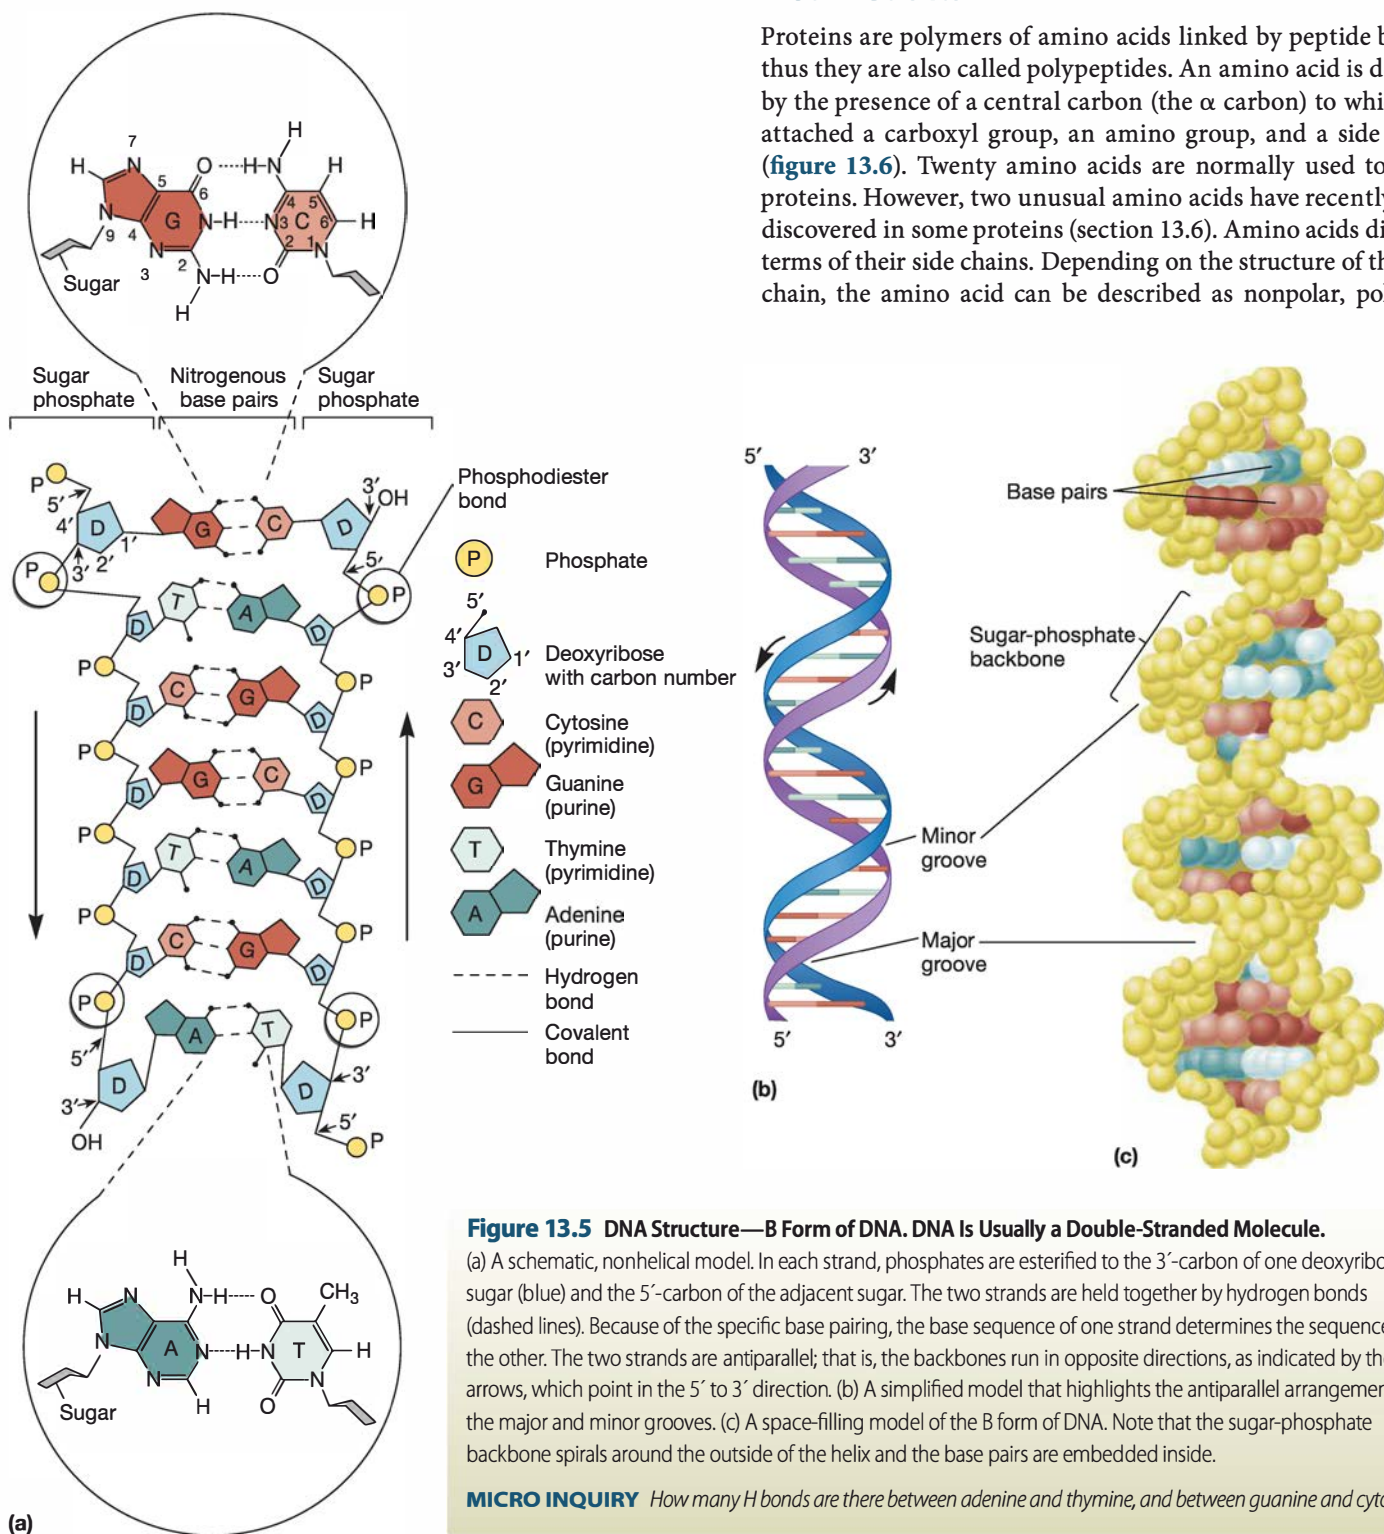

Ribonucleic acid (RNA) is a polymer of ribonucleotides (figure 13.4) that contains the sugar ribose and the bases adenine, guanine, cytosine, and uracil (instead of thymine). The nucleotides are joined by a phosphodiester bond, just as they are in DNA. Most RNA molecules are single stranded. How-

ever, an RNA strand can coil back on itself to form secondary structures such as hairpins with complementary base pairing and helical organization (p. 304). The formation of double-stranded regions in RNA is often critical to its function.

▶▶ *Regulation of transcription elongation (section 14.3)*

Protein Structure

Proteins are polymers of amino acids linked by peptide bonds; thus they are also called polypeptides. An amino acid is defined by the presence of a central carbon (the α carbon) to which are attached a carboxyl group, an amino group, and a side chain (figure 13.6). Twenty amino acids are normally used to form proteins. However, two unusual amino acids have recently been discovered in some proteins (section 13.6). Amino acids differ in terms of their side chains. Depending on the structure of the side chain, the amino acid can be described as nonpolar, polar, or

Figure 13.6 The General Structure of an Amino Acid. All amino acids have a central carbon (the α carbon) to which are attached a carboxyl group (COOH), an amino group (NH_2), and a side chain (R). Amino acids differ in terms of their side chains, which may be nonpolar, polar, negatively charged (acid), or positively charged (basic).

charged. The peptide bonds linking the amino acids together are formed by a reaction between the carboxyl group of one amino acid and the amino group of the next amino acid in the protein (figure 13.7). A polypeptide has polarity just as DNA and RNA do. At one end of the chain is an amino group, and at the other end is a carboxyl group. Thus a polypeptide has an amino or N terminus and a carboxyl or C terminus.

Proteins do not typically exist as extended chains of amino acids. Rather, they fold back on themselves to form three-dimensional structures, often more or less spherical in shape. The final shape is determined to a large extent by the sequence of amino acids in the polypeptide. This sequence is called the primary structure. Secondary and tertiary structures result from the folding of the chain. Finally, two or more polypeptide strands can interact to form the final, functional protein. This level of structure is called quaternary structure. These higher levels of structure are stabilized by intra- (and inter-) chain bonds. Protein structure is described in more detail in Appendix I.

Retrieve, Infer, Apply

1. What are nucleic acids? How do DNA and RNA differ in structure?
2. What does it mean to say that the two strands of the DNA double helix are complementary and antiparallel? Examine figure 13.5b and explain the differences between the minor and major grooves.
3. Amino acids are described as nonpolar, polar, and charged, depending on the molecular makeup of their side chains. Which type of amino acid might be found in the transmembrane portion of a polypeptide located in a cell's plasma membrane? Explain your answer.

13.3 DNA Replication in Bacteria

After reading this section, you should be able to:

- Describe a bacterial replicon
- Summarize the events that occur during the three phases of DNA replication
- Create a table or concept map that illustrates the function of the major proteins found in a bacterial replisome
- List the enzymatic and structural elements needed by DNA polymerases for DNA synthesis
- Outline the major events that occur at the replication fork

Figure 13.7 Peptide Bonds Link Amino Acids Together in Peptide Chains. A tetrapeptide chain is shown. One of the peptide bonds linking the four amino acids together is highlighted in blue. At one end of the peptide is an amino group (amino or N terminal); at the other end is a carboxyl group (carboxyl or C terminal).

MICRO INQUIRY Identify the two other peptide bonds of the tetrapeptide chain.

Figure 13.8 Semiconservative DNA Replication. The replication fork of DNA showing the synthesis of two progeny strands. Newly synthesized strands are purple. Each copy contains one new and one old strand.

DNA replication is an extraordinarily important and complex process upon which all life depends. During DNA replication, the two strands of the double helix are separated; each then serves as a template for the synthesis of a complementary strand according to the base-pairing rules. Each of the two progeny DNA molecules consists of one new strand and one old strand, and DNA replication is said to be semiconservative (figure 13.8). DNA

replication is also extremely accurate; *E. coli* makes errors with a frequency of only 10^{-9} or 10^{-10} per base pair replicated (or about one in a million [10^{-6}] per gene per generation). Despite its complexity and accuracy, replication is very rapid. In bacteria, replication rates approach 750 to 1,000 base pairs per second. Most of our discussion in this section is based on studies of chromosomal DNA replication in *E. coli*.

Bacterial DNA Replication Initiates from a Single Origin of Replication

The replication of chromosomal DNA begins at a single point, the **origin of replication**. Synthesis of DNA occurs at the **replication fork**, the place at which the DNA helix is unwound and individual strands are replicated. Two replication forks move outward from the origin until they have copied the whole **replicon**—the portion of the genome that contains an origin that is

replicated as a unit. When the replication forks move around the circular chromosomes observed in most bacteria, a structure shaped like the Greek letter theta (θ) is formed (**figure 13.9**). Because the bacterial chromosome is a single replicon, the forks meet on the other side and two separate chromosomes are released. Less is known about the replication of linear bacterial chromosomes. One well-studied organism with linear chromosomes belongs to the spirochete genus *Borrelia*. The replication of its chromosomes is considered on p. 300.  **DNA Replication Fork; Bidirectional DNA Replication**

Replication Machinery

DNA replication is essential to organisms, and a great deal of effort has been devoted to understanding its mechanism. The replication of *E. coli* DNA requires at least 30 proteins. As we describe in chapter 15, many of the archaeal and eukaryotic

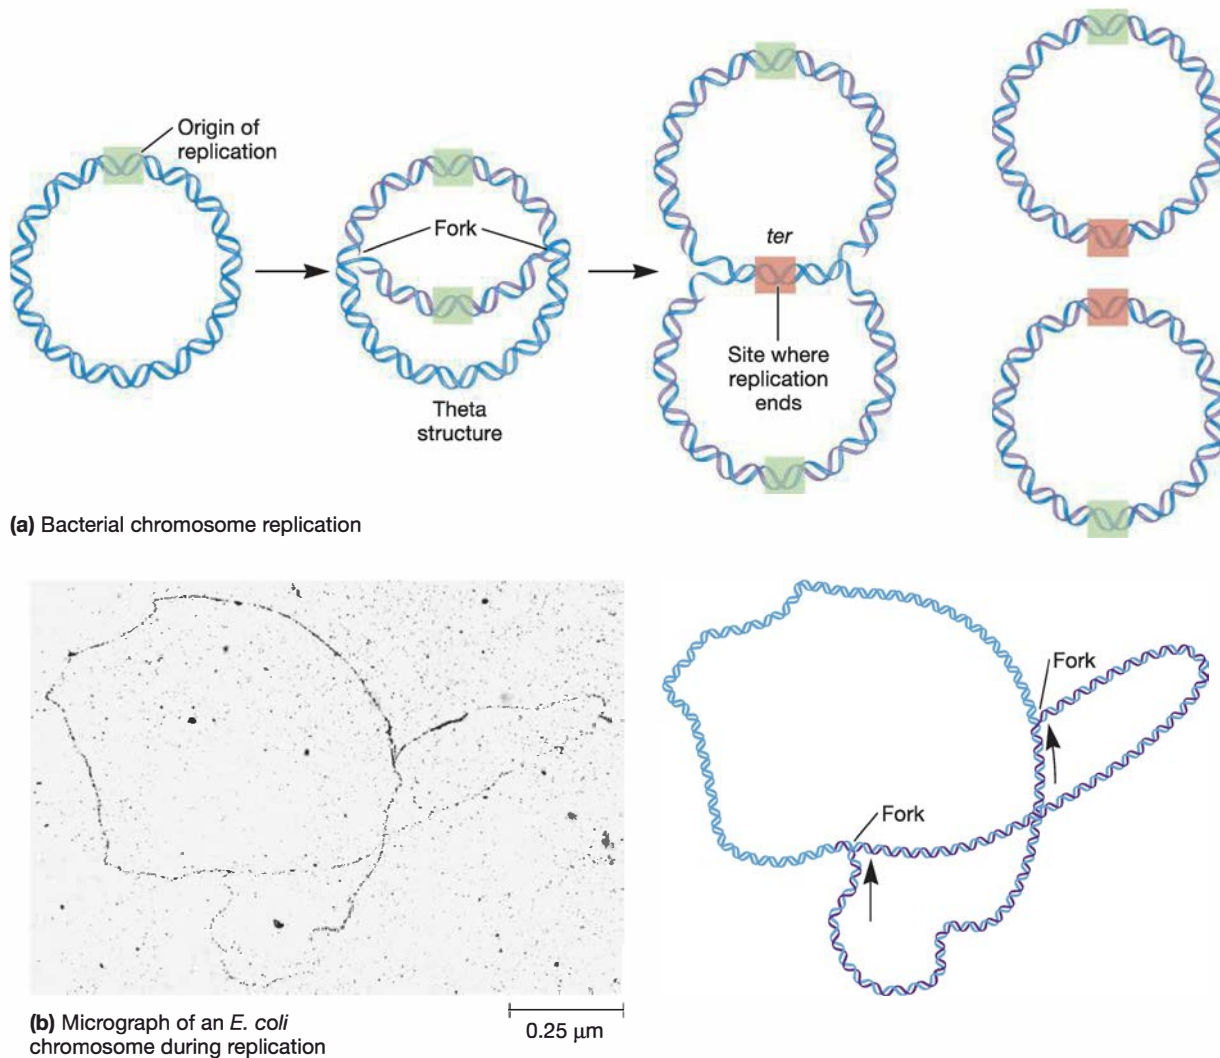

Figure 13.9 Bidirectional Replication of the *E. coli* Chromosome. (a) Replication begins at one site on the chromosome, called the origin of replication. Two replication forks proceed in opposite directions from the origin until they meet at a site called the replication termination site (*ter*). A theta structure is a commonly observed intermediate of the process. (b) An autoradiograph of a replicating *E. coli* chromosome; about one-third of the chromosome has been replicated. To the right is a schematic representation of the chromosome. Parental DNA is blue; new DNA strands are purple; arrow represents direction of fork movement.

replication enzymes and proteins differ from those used by bacterial cells. In general, the archaeal replication machinery is more similar to the eukaryotic machinery than it is to the bacterial system. Despite these differences, the overall process of DNA replication is similar in all organisms.

Enzymes called **DNA polymerases** catalyze DNA synthesis. All known DNA polymerases catalyze the synthesis of DNA in the 5' to 3' direction, and the nucleotide to be added is a deoxynucleoside triphosphate (dNTP). Deoxynucleotides are linked by phosphodiester bonds formed by a reaction between the hydroxyl group at the 3' end of the growing DNA strand and the phosphate closest to the 5' carbon (the α -phosphate) of the incoming deoxynucleotide (**figure 13.10**). The energy needed to form the phosphodiester bond is provided by release of the terminal two phosphates as pyrophosphate (PP_i) from the nucleotide that is added. The PP_i is subsequently hydrolyzed to two separate phosphates (P_i). Thus the deoxynucleoside triphosphates dATP, dTTP,

dCTP, and dGTP serve as DNA polymerase substrates while deoxynucleoside monophosphates (dNMPs: dAMP, dTMP, dCMP, dGMP) are incorporated into the growing chain. **How Nucleotides Are Added in DNA Replication**

For DNA polymerase to catalyze the synthesis of DNA, it needs three things. The first is a template, which is read in the 3' to 5' direction and is used to direct the synthesis of a complementary DNA strand. The second is a primer (e.g., an RNA strand or a DNA strand) to provide a free 3'-hydroxyl group to which nucleotides can be added (**figure 13.10**). The third is a set of dNTPs. *E. coli* has five different DNA polymerases (DNA polymerase I-V). DNA polymerase III plays the major role in replication, although it is assisted by DNA polymerase I.

DNA polymerase III holoenzyme is a multifunctional enzyme composed of 10 different proteins. Most evidence suggests that within the complex are found two core enzymes (**figure 13.11**), although some evidence for three core polymerases exists. Each core enzyme binds one strand of DNA and is responsible for catalyzing DNA synthesis and proof-reading the product to ensure fidelity of replication. Associated with each core enzyme is a subunit called the β clamp. The β clamp tethers a core enzyme to the DNA. At the center of the holoenzyme, and represented by an octopus-like structure in **figure 13.11**, is a complex of proteins called the clamp loader, which is responsible for loading the β clamp onto DNA. A dimer of another protein (tau) holds the holoenzyme together. Because there are two core enzymes, both strands of DNA are bound by a single DNA polymerase III holoenzyme.

DNA polymerase III holoenzyme is only one component of a huge complex of proteins called the **replisome** (**table 13.1**).

DNA polymerase reaction

The mechanism of chain growth

Figure 13.10 The DNA Polymerase Reaction. The hydroxyl of the 3' terminal deoxyribose makes a nucleophilic attack on the α -phosphate of the nucleotide substrate (in this example, adenosine attacks cytidine triphosphate).

MICRO INQUIRY What provides the energy to fuel this reaction?

Figure 13.11 DNA Polymerase III Holoenzyme. The holoenzyme consists of two core enzymes (each composed of three different proteins; α , ϵ , θ , not shown) and several other proteins. Each core enzyme is associated with a β clamp, which tethers a DNA template to the core enzyme. The two tau (τ) proteins connect the two core enzymes to a large complex called the clamp loader, so named because it loads β clamps onto DNA.

Table 13.1 Components of the *E. coli* Replication Machinery

| Protein | Function |
|-------------------------------|---|
| DnaA | Initiation of replication; binds origin of replication (<i>oriC</i>) |
| DnaB | Helicase (5'→3'); breaks hydrogen bonds holding two strands of double helix together; promotes DNA primase activity; involved in primosome assembly |
| DNA gyrase | Relieves supercoiling of DNA produced as DNA strands are separated by helicases; separates daughter molecules in final stages of replication |
| SSB proteins | Bind single-stranded DNA after strands are separated by helicases |
| DnaC | Helicase loader; helps direct DnaB protein (helicase) to DNA template |
| DNA primase | Synthesis of RNA primer; component of primosome |
| DNA polymerase III holoenzyme | Complex of about 20 polypeptides; catalyzes most of the DNA synthesis that occurs during DNA replication; has 3'→5' exonuclease (proofreading) activity |
| DNA polymerase I | Removes RNA primers; fills gaps in DNA formed by removal of RNA primer |
| Ribonuclease H | Removes RNA primers |
| DNA ligase | Seals nicked DNA, joining DNA fragments together |
| Tus | Termination of replication |
| Topoisomerase IV | Separation of chromosomes upon completion of DNA replication |

Other proteins found in the replisome include helicases, single-stranded DNA binding proteins, and topoisomerases (figure 13.12). **Helicases** are responsible for separating (unwinding) the DNA strands just ahead of the replication fork, using energy from ATP hydrolysis. **Single-stranded DNA binding proteins (SSBs)** keep the strands apart once they have been separated, and **topoisomerases** relieve the tension generated by the rapid unwinding of the double helix (the replication fork may rotate as rapidly as 75 to 100 revolutions per second). This is important because rapid unwinding can lead to the formation of positive supercoils in the helix ahead of the replication fork, and these can impede replication if not removed. Topoisomerases change the structure of DNA by transiently breaking one or two strands without altering the nucleotide sequence of the DNA (e.g., a topoisomerase might tie or untie a knot in a DNA strand). **DNA gyrase** is an important topoisomerase in *E. coli*. It is not only important during DNA replication but also for introducing negative supercoiling in the bacterial chromosome that helps compact it.  **Nucleoid** (section 3.6)

Once the template is prepared, the primer needed by DNA polymerase III can be synthesized. An enzyme called **primase** synthesizes a short RNA strand, usually around 10 nucleotides long and complementary to the DNA; this serves as the primer (figure 13.12). RNA is used as the primer because unlike DNA polymerase, RNA polymerases (such as primase) can initiate RNA

synthesis without an existing 3'-OH. It appears that primase requires the assistance of several other proteins, and the complex of primase and its accessory proteins is called the **primosome** (table 13.1). The primosome is another important component of the replisome.

As noted, DNA polymerase enzymes synthesize DNA in the 5' to 3' direction. Therefore only one of the strands, called the **leading strand**, can be synthesized continuously at its 3' end as the DNA unwinds (figure 13.12). The other strand, called the **lagging strand**, cannot be extended in the same direction as the movement of the replication fork because there is no free 3'-OH to which a nucleotide can be added. As a result, the lagging strand is synthesized discontinuously in the 5' to 3' direction (i.e., in the direction opposite of the movement of the replication fork) and produces a series of fragments called **Okazaki fragments**, after their discoverer, Reiji Okazaki. Discontinuous synthesis occurs as primase makes many RNA primers along the template strand. DNA polymerase III then extends these primers with DNA, and eventually the Okazaki fragments are joined to form a complete strand. Thus while the leading strand requires only one RNA primer to initiate synthesis, the lagging strand has many RNA primers that must eventually be removed. Okazaki fragments are about 1,000 to 2,000 nucleotides long in bacteria and approximately 100 nucleotides long in eukaryotic cells.  **DNA Replication; Structural Basis of DNA Replication**

Figure 13.12 Other Replisome Proteins. A single replication fork showing the activity of replisome proteins other than DNA polymerase III holoenzyme (not shown) is illustrated. DnaB helicase is responsible for separating the two strands of parental DNA. The strands are kept apart by single-stranded DNA binding proteins (SSB), which allows for synthesis of an RNA primer by DNA primase. DNA gyrase eases the strain introduced into the DNA double helix by helicase activity. Both leading strand and lagging strand synthesis are illustrated. The lagging strand is synthesized in short fragments called Okazaki fragments. A new RNA primer is required for the synthesis of each Okazaki fragment.

MICRO INQUIRY What is the difference between helicase and gyrase? Which is a topoisomerase?

Events at the Replication Fork

The details of DNA replication are outlined in [figure 13.13](#). We present replication as a series of discrete steps, but in the cell these events occur quickly and simultaneously on both the leading and lagging strands. In *E. coli*, DNA replication is initiated at specific nucleotides called the *oriC* locus (for *origin* of chromosomal replication). This site is AT rich. Recall that adenines pair with thymines using only two hydrogen bonds, so AT-rich segments of DNA become single stranded more readily than do GC-rich regions. This is important for initiation of replication.

1. The bacterial initiator protein DnaA is responsible for triggering DNA replication. DnaA proteins bind regions in *oriC* throughout the cell cycle, but to initiate replication, DnaA proteins must bind a few particular *oriC* sequences. The presence of DnaA at these sites recruits a helicase (usually DnaB helicase) to the origin.
2. The helicase unwinds the helix with the aid of topoisomerases such as DNA gyrase ([figure 13.13](#), step 1). The single strands are kept separate by SSBs.
3. Primase synthesizes RNA primers as needed ([figure 13.13](#), step 1). A single DNA polymerase III holoenzyme catalyzes both leading strand and lagging strand synthesis from the RNA primers. Lagging strand synthesis is particularly amazing because of the “gymnastic” feats performed by the holoenzyme. It must discard old β clamps ([figure 13.13](#), step 3), load new β clamps ([figure 13.13](#), step 2), and tether the template to the core enzyme with each new round of Okazaki fragment synthesis. All of this occurs as DNA polymerase III is synthesizing DNA.
4. After most of the lagging strand has been synthesized by the formation of Okazaki fragments, DNA polymerase I removes the RNA primers. DNA polymerase I does this because, unlike other DNA polymerases, it has the ability to snip off nucleotides one at a time starting at the 5' end while moving toward the 3' end of the RNA primer. This ability is referred to as 5' to 3' exonuclease activity. DNA polymerase I begins its exonuclease activity at the free 5' end of each RNA primer. With the removal of each ribonucleotide, the adjacent 3'-OH from the deoxynucleotide is used by DNA polymerase I to fill the gap between Okazaki fragments ([figure 13.14](#)).
5. Finally, the Okazaki fragments are joined by the enzyme **DNA ligase**, which forms a phosphodiester bond between the 3'-OH of the growing strand and the 5'-phosphate of an Okazaki fragment ([figure 13.15](#)).

Amazingly, DNA polymerase III, like all DNA polymerases (except DNA polymerases called reverse transcriptases), has an additional function that is critically important: **proofreading**. Proofreading is the removal of a mismatched base immediately after it has been added; its removal must occur before the next base is incorporated. One of the protein subunits of the DNA polymerase III core enzyme (the ϵ subunit) has 3' to 5' exonuclease activity. This activity enables the polymerase core enzyme to check each newly incorporated base to see that it forms stable hydrogen bonds. In this way, mismatched bases can be detected. If the wrong base has been mistakenly added, the exonuclease activity is used to remove it ([figure 13.16](#)). A mismatched base can be removed only as long as it is still at the 3' end of the growing strand. Once removed, holoenzyme backs up and adds the proper nucleotide in its place. DNA proofreading is not 100% efficient, and as discussed in chapter 16, the mismatch repair system is the cell's second line of defense against the potential harm caused by the incorporation of the incorrect nucleotide. 🌀 *Proofreading Function of DNA Polymerase*

Figure 13.13 Events at the Replication Fork. DNA polymerase III holoenzyme and other components of the replisome are responsible for the synthesis of both leading and lagging strands. The arrows show the movement of each DNA core polymerase. After completion of each new Okazaki fragment, the old β clamp is discarded and a new one loaded onto the template DNA (steps 2 and 3). This is achieved by the activity of the clamp loader (figure 13.11). Okazaki fragments are eventually joined together after removal of the RNA primer and synthesis of DNA to fill the gap, both catalyzed by DNA polymerase I (figure 13.14); DNA ligase then seals the nick and joins the two fragments (figure 13.15).

Figure 13.14 Completion of Lagging Strand Synthesis. NMPs, nucleoside monophosphates; dNTPs, deoxynucleoside triphosphates; NAD⁺, nicotinamide adenine dinucleotide; NMN, nicotinamide mononucleotide.

As we have seen, DNA polymerase III is a remarkable multiprotein complex, with several enzymatic activities. In *E. coli*, the polymerase component is encoded by the *dnaE* gene. *Bacillus subtilis*, a Gram-positive bacterium that is another important experimental model, has a second polymerase gene called *dnaE_{BS}*. Its protein product appears to be responsible for synthesizing the lagging strand. Thus while the overall mechanism by which DNA is replicated is highly conserved, there can be variations in replisome components.

Termination of Replication

In *E. coli*, DNA replication stops when the replisome reaches a termination site (*ter*) on the DNA. A protein called Tus binds to the *ter* sites and halts progression of the forks. In many other bacteria, replication stops spontaneously when the forks meet. Regardless of how fork movement is stopped, there are two problems that often must be solved by the replisome. One is the formation of interlocked chromosomes called **catenanes** (figure 13.17a). The other is a dimerized chromosome—two chromosomes joined together to form a single chromosome twice as long (figure 13.17b). Catenanes are produced when topoisomerases break and rejoin DNA strands to ease supercoiling ahead of the replication fork. The two daughter DNA molecules are separated by the action of other topoisomerases that break both strands of one molecule, pass the other DNA molecule

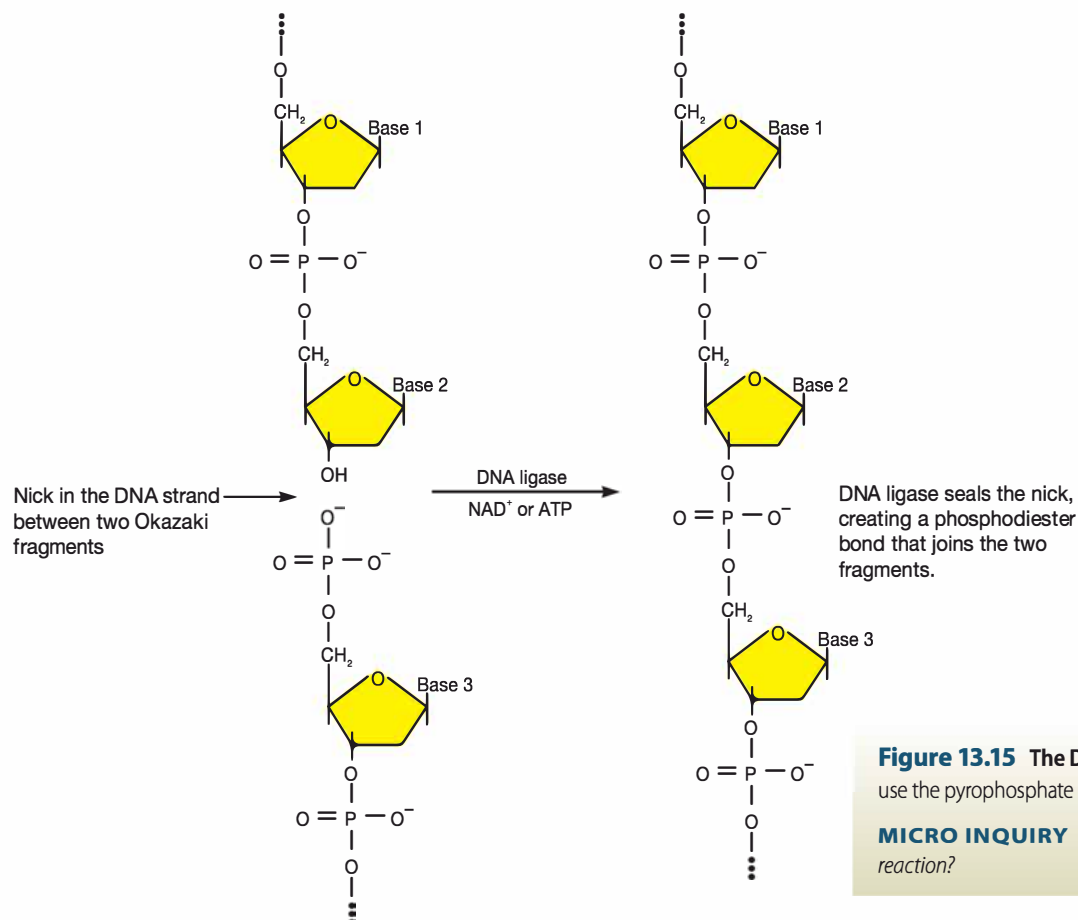

Figure 13.15 The DNA Ligase Reaction. Bacterial ligases use the pyrophosphate bond of NAD⁺ or ATP as an energy source.

MICRO INQUIRY Why can't DNA polymerase I perform this reaction?

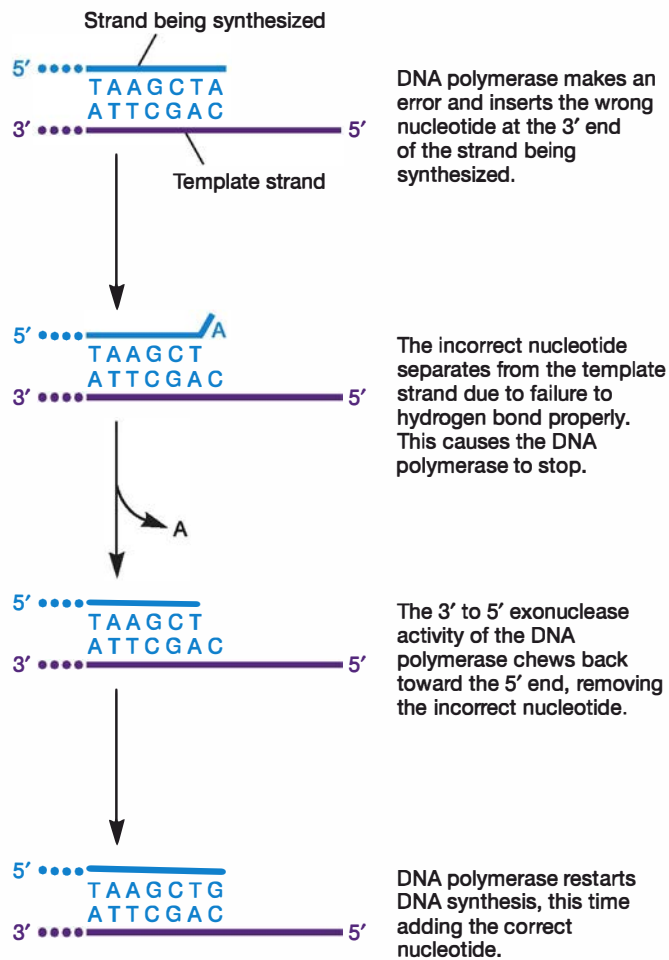

Figure 13.16 The Proofreading (Editing) Function of DNA Polymerase.

through the break, and then rejoin the strands (figure 13.17a). Dimerized chromosomes result from DNA recombination that sometimes occurs between two daughter molecules during DNA replication. Recombinase enzymes (e.g., XerCD in *E. coli*) catalyze an intramolecular cross-over that separates the two chromosomes (figure 13.17b).

Replication of Linear Chromosomes

All eukaryotic chromosomes and some bacterial chromosomes are linear. In both cases, this poses a problem during replication because all DNA polymerases synthesize DNA in the 5' to 3' direction from a primer that provides a free 3'-OH. When the RNA primer for the Okazaki fragment at the 5' end of the daughter strand is removed, the daughter molecule is shorter than the parent molecule. Over numerous rounds of DNA replication and cell division, this leads to a progressively shortened chromosome. Ultimately the chromosome loses critical genetic information, which is lethal to the cell. This problem is called the “end replication problem,” and a cell must solve it if it is to survive. Eukaryotic cells have solved the end replication problem with an

Figure 13.17 Resolving Catenated and Dimerized Chromosomes.

(a) Catenated chromosomes arise from the activity of topoisomerases during chromosome replication. Accordingly, they are resolved by topoisomerases. (b) Dimerized chromosomes arise from recombination events that can occur during chromosome replication between the daughter chromosomes. They are resolved by recombinase enzymes such as XerCD of *E. coli*. These enzymes catalyze a cross-over that separates the two chromosomes.

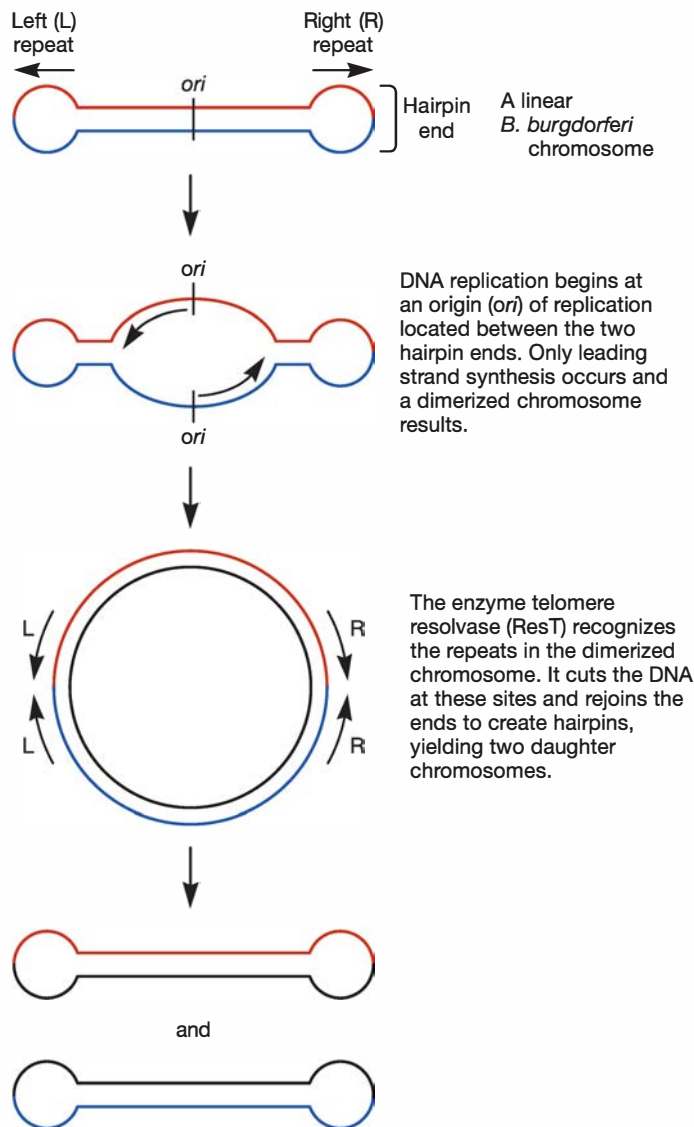

Figure 13.18 Replication of a *Borrelia burgdorferi* Linear Chromosome.

enzyme called telomerase, as we describe in chapter 15. Bacteria have taken a different approach. ►► *Telomeres and telomerases* (section 15.2).

Of those bacteria having linear chromosomes, the best understood mechanism for solving the end replication problem is that used by *Borrelia burgdorferi*. The approach *B. burgdorferi* cells use is to disguise the ends so well that they aren't really ends. How are the ends disguised? Consider a typical linear, double-stranded DNA molecule. At each terminus of the double helix is a strand having a 3'-OH and the complementary strand having a 5'-phosphate. Now examine **figure 13.18**, which shows that *B. burgdorferi* chromosomes do not have these free ends. Rather, a phosphodiester bond links the two complementary strands together. This is made possible by inverted repeats at each terminus and the formation of a hairpin. The origin of replication is located between the hairpins. Interestingly, only leading strand

synthesis occurs at each replication fork. When replication is complete, a circular molecule has been formed that is twice the length of the parent chromosome. Thus it is a dimerized chromosome. An enzyme called telomere resolvase (ResT) cuts the two chromosomes apart as it forms hairpin ends for each daughter molecule.

Retrieve, Infer, Apply

1. How many replicons do typical bacterial cells have (i.e., those having a single chromosome)? How many replication forks are used to replicate a circular chromosome? Is a primosome part of the replisome, or is the replisome part of the primosome? What is the function of each?
2. Describe the nature and functions of the following replication components and intermediates: DNA polymerases I and III, topoisomerase, DNA gyrase, helicase, single-stranded DNA binding proteins, Okazaki fragment, DNA ligase, leading strand, lagging strand, and primase.
3. Outline the steps involved in DNA synthesis at the replication fork. How do DNA polymerases correct their mistakes?
4. What is the end replication problem? How does *B. burgdorferi* solve it?

13.4 Bacterial Gene Structure

After reading this section, you should be able to:

- Draw a typical bacterial protein-coding gene, and label the important portions of the gene and the conventions for numbering base pairs in the gene
- Draw typical tRNA- and rRNA-coding genes

DNA replication allows genetic information to be passed from one generation to the next. But how is the information used? To answer that question, we must first look at how genetic information is organized. The basic unit of genetic information is the gene. Genes have been regarded in several ways. At first, it was thought that a gene contained information for the synthesis of one enzyme—the one gene—one enzyme hypothesis. This was modified to the one gene—one polypeptide hypothesis because of the existence of enzymes and other proteins composed of two or more different polypeptide chains (subunits) coded for by separate genes. A segment of DNA that encodes a single polypeptide is sometimes termed a cistron. However, not all genes encode proteins; some code instead for ribosomal RNA (rRNA) and transfer RNA (tRNA), both of which function in protein synthesis (**figure 13.19**). In addition, it is now known that some eukaryotic genes encode more than one protein. Thus a **gene** might be defined as a polynucleotide sequence that codes for one or more functional products (i.e., a polypeptide, tRNA, or rRNA). In this section, we consider the structure of each of these three types of genes.

*The sizes of RNA are enlarged to show details.

Figure 13.19 Transcription Yields Three Major Types of RNA Molecules.

Messenger RNA (mRNA) molecules arise from transcription of protein-coding genes. They are translated into protein with the aid of the other two major types of RNA: transfer RNA (tRNA) molecules carry amino acids to the ribosome during translation; ribosomal RNA (rRNA) molecules have several functions, including catalyzing peptide bond formation.

Protein-Coding Genes

Most of the genes found in bacterial genomes encode proteins. However, DNA does not serve directly as the template for protein synthesis. Rather, the genetic information in the gene is transcribed to give rise to a messenger RNA (mRNA), which is translated (section 13.7) into a protein (figure 13.19). For this to occur, protein-coding genes must contain signals that indicate where transcription should start and stop, and signals in the resulting mRNA that indicate where translation should start and stop. As we describe in more detail in section 13.5, during transcription only one strand of a gene directs mRNA synthesis. This strand is called the **template strand**, and the complementary DNA strand

is known as the **coding strand** because it is the same nucleotide sequence as the mRNA, except in DNA bases (figure 13.20). Messenger RNA is synthesized from the 5' to the 3' end in a manner similar to DNA synthesis. Therefore the polarity of the DNA template strand is 3' to 5'. In other words, the beginning of the gene is at the 3' end of the template strand.

An important site called the **promoter** is located at the start of the gene. The promoter is the binding site for RNA polymerase, the enzyme that synthesizes RNA. The promoter is neither transcribed nor translated; it functions strictly to orient RNA polymerase so it is a specific distance from the first DNA nucleotide that will serve as a template for RNA synthesis. The promoter thus specifies which strand is to be transcribed and where transcription should begin. As we discuss in chapter 14, the sequences near the promoter often are very important in regulating when and at what rate a gene is transcribed. ►► *Regulation of transcription initiation (section 14.2)*

The transcription start site (labeled +1 in figure 13.20) represents the first nucleotide in the mRNA synthesized from the gene. However, the initially transcribed portion of the gene does not necessarily code for amino acids. Instead, it is a **leader** that is transcribed into mRNA but is not translated into amino acids. In bacteria, the leader includes a region called the **Shine-Dalgarno sequence**, which is important in the initiation of translation. The leader sometimes is also involved in regulation of transcription and translation. ►► *Regulation of transcription elongation (section 14.3); Regulation of translation (section 14.4)*

Immediately next to (and downstream of) the leader is the most important part of the gene, the **coding region** (figure 13.20). The coding region typically begins with the template DNA sequence 3'-TAC-5'. This is transcribed into the start codon, 5'-AUG-3', which codes for the first amino acid of the polypeptide encoded by the gene. The remainder of the coding region is transcribed into a sequence of codons that specifies the sequence of amino acids for the rest of the protein. The coding region ends with a sequence that, when transcribed, is a stop codon. It signals the end of the protein and stops the ribosome during translation. The stop codon is immediately followed by the **trailer**, which is transcribed but not translated. The trailer contains sequences that prepare the RNA polymerase for release from the template strand. Indeed, just beyond the trailer (and sometimes slightly overlapping it) is the **terminator**. The terminator is a sequence that signals the RNA polymerase to stop transcription.

In bacteria, the coding region is usually continuous, unlike the coding regions of eukaryotic genes, which are often interrupted by noncoding sequences called **introns**. Those rare bacterial genes that do contain introns are transcribed into an intron-containing mRNA. The introns are eventually removed but by a mechanism different than that used to remove introns from eukaryotic mRNAs.

tRNA and rRNA Genes

Actively growing cells need a ready supply of tRNA and rRNA molecules so that protein synthesis can occur. To ensure this, bacterial cells often have more than one gene for each of these

Figure 13.20 A Bacterial Structural Gene and Its mRNA Product. (a) The organization of a typical structural gene in a bacterial cell. Some genes lack leaders or trailers or both. Transcription begins at the +1 position in DNA and proceeds to the right, as shown. The numbering of nucleotides to the left of this spot is in a negative direction, while the numbering to the right is in a positive direction. For example, the nucleotide that is immediately to the left of the +1 nucleotide is numbered -1, and the nucleotide to the right of the +1 nucleotide is numbered +2. There is no zero nucleotide in this numbering system. In many bacterial promoters, sequence elements at the -35 and -10 regions play a key role in promoting transcription. During transcription, the template is read in the 3' to 5' direction. (b) Messenger RNA product of the gene shown in part a. The first nucleotide incorporated into mRNA is usually GMP or AMP. Translation of the mRNA begins with the AUG start codon. Regulatory sites are not shown but are usually upstream of or overlap with the promoter.

MICRO INQUIRY Why is the nontemplate strand called the “coding strand”?

molecules. Furthermore, it is important that the number of each tRNA or rRNA relative to other tRNAs or rRNAs be controlled. This is accomplished in part by having several tRNA or rRNA genes transcribed together, under the control of a single promoter.

In bacteria, genes for tRNA consist of a promoter, tRNA coding region, leader, and trailer. When more than one tRNA is transcribed from the promoter, the coding regions are separated by short spacer sequences (figure 13.21a). Whether the gene encodes a single tRNA or multiple tRNAs, the initial transcript must be processed to remove the noncoding sequences (i.e., leader, trailer, and spacers, if present). This is called posttranscriptional modification, and it is accomplished by ribonucleases—enzymes (and in some cases ribozymes) that cut RNA. In addition, many bacterial (and archaeal) tRNA genes contain introns that must be removed during tRNA maturation.

◀◀ **Ribozymes** (section 10.6)

Bacterial cells usually contain more than one rRNA gene. Each gene has a promoter, trailer, and terminator, and encodes all three types of rRNA (figure 13.21b). Thus, as seen for tRNA genes,

the transcript from an rRNA gene is a single, large precursor molecule that is cut up by ribonucleases to yield the final rRNA products. Interestingly, in many bacteria, the trailer regions and the spacers often contain tRNA genes. Thus the precursor rRNA encodes for both tRNA and rRNA.

Retrieve, Infer, Apply

1. The coding region of a gene is said to be “downstream” from the leader. Conversely, the leader is said to be “upstream” of the coding region. For each of the following portions of a gene, indicate whether it is downstream or upstream of the coding region: promoter, +1 nucleotide, trailer, terminator. Which portions of a gene are transcribed but not translated?
2. Which strand of a gene has sequences that correspond to the start (i.e., ATG rather than AUG) and stop codons in the mRNA product of the gene?
3. Briefly discuss the general organization of tRNA and rRNA genes. How does their expression differ from that of protein-coding genes with respect to posttranscriptional modification of the gene product?

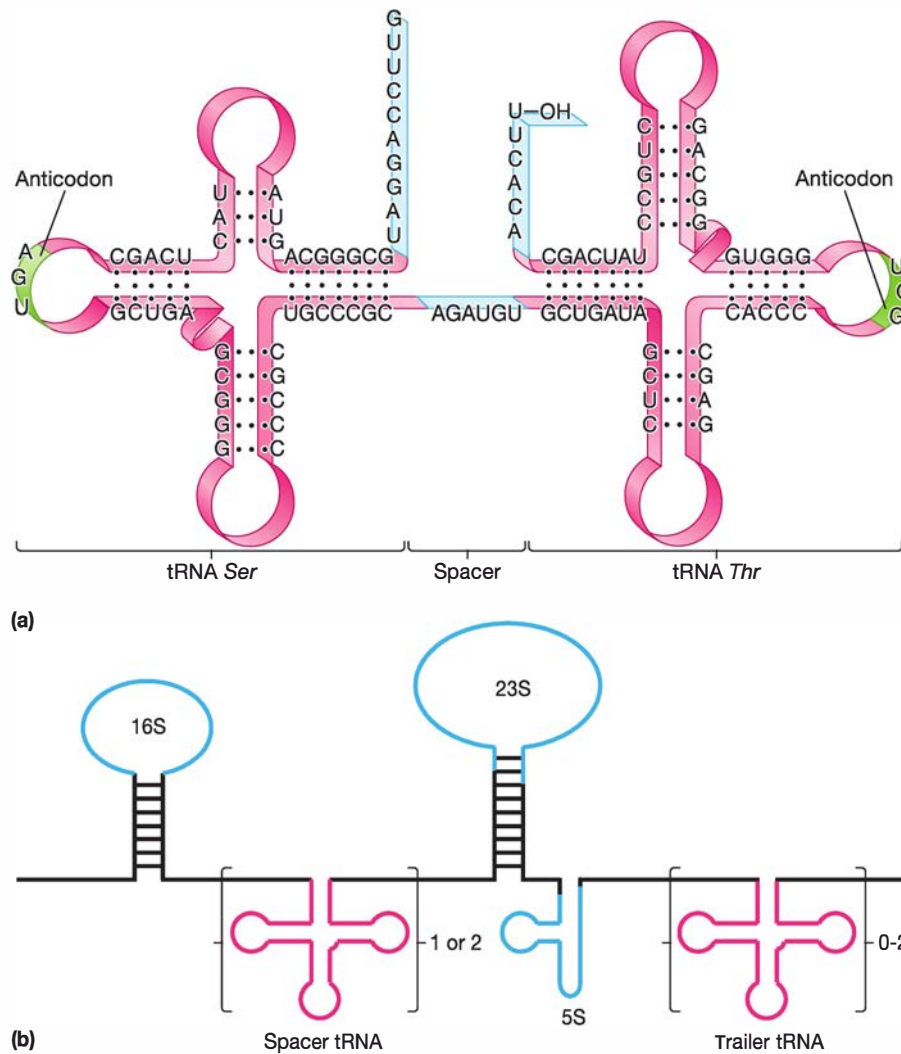

Figure 13.21 tRNA and rRNA Genes. (a) A tRNA precursor from *E. coli* that contains two tRNA molecules. The spacer and extra nucleotides at both ends are removed during processing. (b) The *E. coli* rRNA gene codes for a large transcription product that is cleaved into three rRNAs and one to three tRNAs. The 16S, 23S, and 5S rRNA segments are represented by blue lines, and tRNA sequences are placed in brackets. The seven copies of this gene vary in the number and kind of tRNA sequences.

13.5 Transcription in Bacteria

After reading this section, you should be able to:

- Illustrate the organization of bacterial genes in a typical operon
- Describe the structure of a typical bacterial RNA polymerase holoenzyme
- Outline the events that occur during the three phases of transcription
- Discuss the role of bacterial promoters and sigma factors in transcription initiation
- Distinguish factor-independent termination of transcription from rho-dependent termination of transcription

Synthesis of RNA under the direction of DNA is called transcription, and the RNA product has a sequence complementary to the DNA template directing its synthesis. Although adenine directs the incorporation of thymine during DNA replication, it usually codes for uracil during RNA synthesis. Transcription generates three major kinds of RNA. **Transfer RNA (tRNA)** carries amino acids during protein synthesis, and **ribosomal RNA (rRNA)** molecules are components of ribosomes. **Messenger RNA (mRNA)** bears the message for protein synthesis. Bacterial genes encoding proteins involved in a related process (e.g., encoding enzymes for synthesis of an amino acid) are often located close to each other and are transcribed from a single promoter. Such a transcriptional unit is termed an **operon**. Transcription of an operon yields an mRNA consisting of a

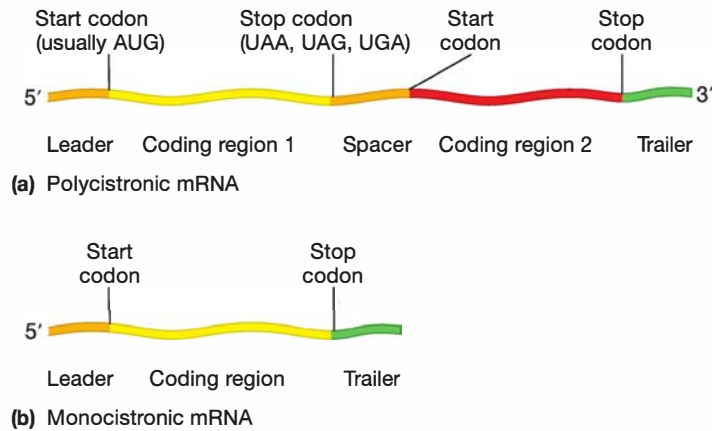

Figure 13.22 Polycistronic and Monocistronic mRNAs. Polycistronic mRNAs are commonly observed in bacteria and archaea. Eukaryotic genes usually give rise to monocistronic mRNAs.

leader followed by one coding region, which is separated by a space from the second coding region, and so on, with the final sequence of nucleotides being the trailer. Such mRNAs are said to be **polycistronic mRNAs** (figure 13.22a). Each coding region in the polycistronic mRNA is defined by a start and stop codon. Thus each coding region is translated separately to give rise to a single polypeptide. Many archaeal mRNAs are also polycistronic. However, polycistronic mRNAs are rare in eukaryotes. Instead, their mRNAs are usually **monocistronic mRNAs** (figure 13.22b), containing information of a single gene. ►► *Transcription* (section 15.3)

Bacterial RNA Polymerases

RNA is synthesized by enzymes called **RNA polymerases**. In bacteria, a single RNA polymerase transcribes all genes. Most bacterial RNA polymerases contain five types of polypeptide chains: α , β , β' , ω , and σ (figure 13.23). The **RNA polymerase core enzyme** is composed of five polypeptides (two α subunits, β , β' , and ω) and catalyzes RNA synthesis. Interestingly, the subunits that form the core enzyme are conserved in archaeal and eukaryal RNA polymerases. However, their RNA polymerases consist of additional proteins and are larger and more complex than the bacterial enzyme (see table 15.3). The **sigma factor** (σ) has no catalytic activity but helps the core enzyme recognize the promoter. When sigma is bound to the core enzyme, the six-subunit complex is termed **RNA polymerase holoenzyme**. Only holoenzyme can begin transcription, but the core enzyme completes RNA synthesis once it has been initiated.

Stages of Transcription

Transcription involves three separate processes: initiation, elongation, and termination, which together are often referred to as the transcription cycle (figure 13.24). Sigma factor is critical to

Figure 13.23 RNA Polymerase Structure. The holoenzyme-DNA complex of the bacterium *Thermus aquaticus*. Protein surfaces that contact the DNA are in green and are located on the σ factor. The -10 and -35 elements in the promoter are in yellow. The internal active site is covered by the β subunit in this view.

the initiation process. It positions the RNA polymerase core enzyme at the promoter. Many bacterial promoters have two characteristic features: a sequence of six bases (often TTGACA) about 35 base pairs before (upstream) the transcription starting point and a TATAAT sequence called the **Pribnow box**, usually about 10 base pairs upstream of the transcriptional start site (figure 13.25; also figure 13.20). These regions are called the -35 and -10 sites, respectively, because these are their distances in nucleotides upstream of the first nucleotide to be transcribed (i.e., the $+1$ site). Sigma factor recognizes the -10 and -35 sequences, and directs the RNA polymerase core enzyme to them. 🌀 *Stages of Transcription*

At this point in our discussion, it is worth noting that bacterial cells produce more than one type of sigma factor. Each sigma factor preferentially directs the RNA polymerase to a distinct set of promoters. For instance, in *E. coli*, most genes have promoters recognized by a sigma factor called σ^{70} . This sigma factor recognizes promoters having the -10 and -35 sequences shown in figure 13.25 and table 13.2. These sequences are the **consensus sequences** for σ^{70} -recognized promoters. Promoters recognized by other sigma factors have different consensus sequences. The use of different sigma factors to initiate transcription is a common bacterial regulatory mechanism, as we describe in chapter 14. Our focus here is on transcription of genes recognized by σ^{70} .

Figure 13.24 The Bacterial Transcription Cycle.

Figure 13.25 A σ^{70} Promoter. Many bacterial promoters are recognized by the sigma factor σ^{70} . Its promoters have a characteristic set of nucleotides centered at about -10 and -35 . Shown are the consensus sequences for these two important promoter sites. Bacterial cells produce additional sigma factors that recognize different promoter sequences (table 13.2).

MICRO INQUIRY Are the -35 and -10 regions considered “upstream” or “downstream” of the $+1$ nucleotide?

Once bound to the promoter, RNA polymerase unwinds the DNA (**figure 13.26**). The -10 site is rich in adenines and thymines, making it easier to break the hydrogen bonds that keep the DNA double stranded; when the DNA is unwound at this region, it is called an open complex. A region of unwound DNA equivalent to about 16 to 20 base pairs becomes the “transcription bubble,” which moves with the RNA polymerase as it synthesizes mRNA from the template DNA strand during elongation (**figure 13.27**). Within the transcription bubble, a temporary RNA:DNA hybrid is formed. As RNA polymerase holoenzyme progresses along the DNA template, the sigma factor dissociates from the other subunits and can help another RNA polymerase core enzyme initiate transcription (**figure 13.24**).

The reaction catalyzed by RNA polymerase is quite similar to that catalyzed by DNA polymerase (**figure 13.10**). ATP, GTP, CTP, and UTP are used to produce RNA complementary to the DNA template, and pyrophosphate is produced as ribonucleoside monophosphates are incorporated into the growing RNA chain. Pyrophosphate is hydrolyzed to fuel the process. RNA synthesis also proceeds in a $5'$ to $3'$ direction with new nucleotides being added to the $3'$ end of the growing chain, making the RNA

Table 13.2 *E. coli* Sigma Factors and the Sequences They Recognize

| Sigma Factor | Consensus Promoter Sequences ¹ | | Genes Transcribed from Promoter |

2 N indicates any nucleotide.

Figure 13.26 Initiation of Transcription in Bacteria. The sigma factor of the RNA polymerase holoenzyme is responsible for positioning the core enzyme properly at the promoter. Sigma factor recognizes two regions in the promoter, one centered at -35 and the other centered at -10. Once positioned properly, the DNA at the -10 region unwinds to form an open complex. The sigma factor dissociates from the core enzyme after transcription is initiated.

complementary and antiparallel to the template DNA. As elongation of the mRNA continues, single-stranded mRNA is released, and the two strands of DNA behind the transcription bubble resume their double helical structure. As shown in figure 13.24, RNA polymerase is a remarkable enzyme capable of several activities, including unwinding the DNA, moving along the template, and synthesizing RNA.

Key points:

- RNA polymerase slides along the DNA, creating an open complex as it moves.
- The template strand is used to make a complementary copy of RNA as an RNA-DNA hybrid.
- The RNA is synthesized in a 5' to 3' direction using ribonucleoside triphosphates as precursors. Pyrophosphate is released (not shown).
- The complementarity rule is the same as the AT/GC rule except that U is substituted for T in the RNA.

Figure 13.27 The "Transcription Bubble."

Figure 13.28 Factor-Independent Termination of Transcription.

This type of terminator contains an inverted repeat and an A-rich sequence downstream from the repeat. A protein called NusA stimulates termination.

Termination of transcription occurs when the core RNA polymerase dissociates from the template DNA. This is brought about by the terminator. There are two kinds of terminators. The first type causes factor-independent termination (**figure 13.28**). This terminator consists of an inverted repeat followed by an A-rich nucleotide sequence. RNA polymerase transcribes the inverted repeat, but it pauses within the A-rich region. This allows the inverted repeat to fold back on itself, forming a hairpin-shaped stem-loop structure. The A-U base pairs holding the DNA and RNA together in the transcription bubble are too weak to hold the RNA:DNA duplex together and RNA polymerase falls off.

The second kind of terminator is termed factor-dependent terminator because it requires the aid of a protein. The best-studied termination factor is rho factor (ρ). Rho factor can be involved in transcription termination of all types of genes, but its action is best studied for protein-coding genes. Current models propose that rho binds to mRNA at a site called *rut* for rho-utilization site. For rho to bind, *rut* must be free of ribosomes, as shown in **figure 13.29**. Rho uses energy supplied by ATP hydrolysis to move along the mRNA, as it tries to catch up with RNA polymerase. However, rho's rate of movement is slower than that of RNA polymerase. Thus rho can only catch up with RNA polymerase if the polymerase pauses at a rho-dependent pause site. If this occurs, rho catches up with RNA polymerase and causes RNA polymerase to dissociate from DNA. How rho does this is not completely clear. However, it is known that rho factor has hybrid RNA:DNA helicase activity. This activity may cause unwinding of the mRNA-DNA complex. *mRNA Synthesis*

Figure 13.29 Rho-Factor (ρ)-Dependent Termination of Transcription. The *rut* site stands for rho utilization site.

13.6 The Genetic Code

After reading this section, you should be able to:

- Explain the importance of the reading frame of a protein-coding gene
- Describe the universal genetic code
- List deviations from the universal genetic code that have been identified in some microorganisms
- Explain how the wobble hypothesis enables organisms to encode fewer tRNA molecules

The final step in the expression of protein-coding genes is translation. Protein synthesis is called translation because it is a decoding process. The information encoded in the language of nucleic acids must be rewritten in the language of proteins. During translation, the sequence of nucleotides is “read” in discrete sets of three nucleotides, each set being a **codon**. Each codon codes for a single amino acid. The sequence of codons is “read” in only one way—the **reading frame** (figure 13.30)—to give rise to the amino acid sequence of a polypeptide. Deciphering the genetic code was one of the great achievements of the twentieth century. Here we examine the nature of the genetic code. Translation is considered in section 13.7.

The genetic code, presented in RNA form, is summarized in **table 13.3**. Close inspection of the code reveals several features that are related not only to the way cells use DNA to store information but also to why it is valuable for storing data, as described in the chapter opening story. One feature is that the code words (codons) are three letters (bases) long; thus one small “word” conveys a significant amount of information. Each codon is recognized by an anticodon present on a tRNA molecule. Another

feature is that the code has “punctuation.” One codon, AUG, is almost always the first codon in the protein-coding portion of mRNA molecules. It is called the **start codon** because it serves as the start site for translation by coding for the initiator tRNA. Three other codons (UGA, UAG, and UAA) are involved in termination of translation and are called **stop** or **nonsense codons**. These codons do not encode an amino acid and therefore do not have a tRNA bearing their anticodon. Thus only 61 of the 64 codons in the code, the **sense codons**, direct amino acid incorporation into protein. Finally, the genetic code exhibits **code degeneracy**; that is, there are up to six different codons for a given amino acid.

Despite the existence of 61 sense codons, there are fewer than 61 different tRNAs. It follows that not all codons have a corresponding tRNA. Cells can successfully translate mRNA using fewer tRNAs because loose pairing between the 5′ base in the anticodon and the 3′ base of the codon is tolerated. Thus as long as the first and second bases in the codon correctly base pair with an anticodon, the tRNA bearing the correct amino acid will bind to the mRNA during translation. This is evident on inspection of the code. Note that the codons for a particular amino acid most often differ at the third position (table 13.3). This somewhat loose base pairing is known as **wobble**, and it relieves cells of the need to synthesize so many tRNAs (figure 13.31). Wobble also decreases the effects of some mutations. ►► *Mutations* (section 16.1)

The description of the genetic code just provided is of the universal genetic code. However, there are exceptions to the code (table 13.4). The first exceptions discovered were stop codons that encoded one of the 20 amino acids. For instance, some protists have a single stop codon (UGA); the other two stop codons are recognized by tRNAs bearing glutamine (Gln). More dramatic deviations from the code have also been

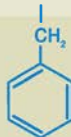

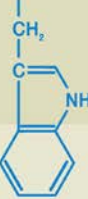

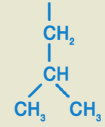

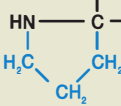

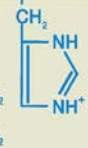

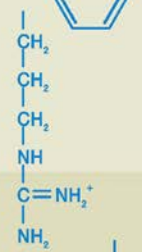

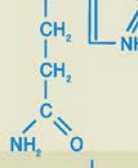

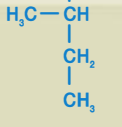

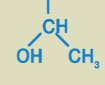

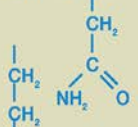

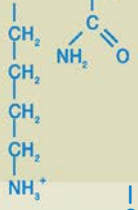

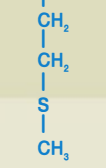

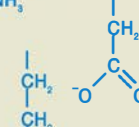

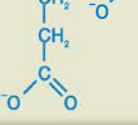

Figure 13.30 Reading Frame. During transcription, an mRNA complementary to the template strand of DNA is synthesized. The nucleotides in the mRNA are organized into groups of three, each group being a codon. The first codon translated into protein is the start codon. It establishes the reading frame and therefore the sequence of amino acids in the polypeptide chain that is made from the mRNA.

First Position (5' End)¹

Third Position (3' End)

1 The code is presented in RNA form. Codons run in the 5' to 3' direction. The 3- and 1-letter abbreviations for the amino acids designated by the codon are provided, as is the structure of the R chain of that amino acid.

2 Proline is an imino acid, rather than an amino acid.

discovered. Proteins from members of all three domains of life have been discovered to contain the amino acid selenocysteine, the twenty-first amino acid (**figure 13.32a**). Pyrrolysine, the twenty-second amino acid, can be found in the proteins of several methanogens and at least one bacterium (**figure 13.32b**). Genomic analysis indicates that pyrrolysine might also exist in many other bacteria and some eukaryotes. Selenocysteine is inserted at certain UGA codons, whereas pyrrolysine is inserted at UAG codons.

(a) Base pairing of one glycine tRNA with two codons due to wobble

Glycine mRNA codons: GGU, GGC, GGA, GGG (5' → 3')

Glycine tRNA anticodons: CCG, CCU, CCC (3' → 5')

(b) Glycine codons and anticodons

Figure 13.31 Wobble and Coding. The use of wobble in coding for the amino acid glycine. (a) Because of wobble, G in the 5' position of the anticodon can pair with either C or U in the 3' position of the codon. Thus two codons can be recognized by the same tRNA. (b) Because of wobble, only three tRNA anticodons are needed to translate the four glycine (Gly) codons.

| Table 13.4 Some Exceptions to the Universal Genetic Code | | |
|--|---------------------|---|

MICRO INQUIRY For each of the above codons, determine what it normally encodes. Choose one of the variants and suggest how it might have evolved.

Figure 13.32 Selenocysteine and Pyrrolysine. These unusual amino acids are not coded for by DNA but are inserted in response to specific stop codons and stem-loop structures in mRNA.

Translation involves decoding mRNA and covalently linking amino acids together to form a polypeptide; this occurs at the ribosome. Translation begins when a ribosome binds mRNA and is positioned properly so that translation will yield the correct amino acid sequence in the polypeptide chain. Transfer RNA molecules carry amino acids to the ribosome so that they can be added to the polypeptide chain as the ribosome moves down the mRNA molecule. Just as DNA and RNA synthesis proceeds in one direction, so too does protein synthesis. Polypeptide synthesis begins with the amino acid at the end of the chain with a free amino group (the N-terminal) and moves in the C-terminal direction. Thus translation is said to occur in the amino terminus to carboxyl terminus direction. Protein synthesis is accurate and very rapid. In *E. coli*, synthesis occurs at a rate of at least 900 amino acids added per minute; eukaryotic translation is slower, about 100 amino acids residues per minute. ▶▶ *Translation in eukaryotes (section 15.4)*

Cells that grow quickly must use each mRNA with great efficiency to synthesize proteins at a sufficiently rapid rate. The two subunits of the ribosome (the 50S subunit and the 30S subunit in bacteria and archaea; 60S and 40S in eukaryotes) are free in the cytoplasm if protein is not being synthesized. They come together to form the complete ribosome complexed with mRNA only when translation occurs. Frequently mRNAs are simultaneously complexed with several ribosomes, each ribosome reading the mRNA message and synthesizing a polypeptide. At maximal rates of mRNA use, there may be a ribosome every 80 nucleotides along the mRNA or as many as 20 ribosomes simultaneously reading an mRNA that codes for a 50,000 dalton polypeptide. A complex of mRNA with several ribosomes is called a **polyribosome** or polysome (figure 13.33). Polysomes are present in all organisms. Bacteria and archaea can further increase the efficiency of gene expression by coupling transcription and translation (figure 13.33b). While RNA polymerase is synthesizing an mRNA, ribosomes can already be attached to the mRNA so that transcription and translation occur simultaneously. Coupled transcription and translation is possible in bacterial and archaeal cells because a nuclear envelope does not separate the translation machinery from DNA, as it does in eukaryotes. 🌺 *How Translation Works; Protein Synthesis*

13.7 Translation in Bacteria

After reading this section, you should be able to:

- Relate the general structure of a tRNA molecule to its role in amino acid activation and translation
- Summarize the formation of a translation initiation complex
- Describe the structure of bacterial ribosomes
- State the initiator tRNA used by bacteria
- Outline the events that occur at the A, P, and E sites of the bacterial ribosome during the elongation phase of translation

Transfer RNA and Amino Acid Activation

For translation to occur, a ready supply of tRNA molecules bearing the correct amino acid must be available. Thus a preparatory step for protein synthesis is **amino acid activation**, the process in which amino acids are attached to tRNA molecules. Before we discuss this process, we need to examine the structure of tRNA molecules.

Transfer RNA molecules are about 70 to 95 nucleotides long and possess several characteristic structural features. These features become apparent when the tRNA is folded so that base pairing within the tRNA strand is maximized. When represented two-dimensionally, this base pairing causes the

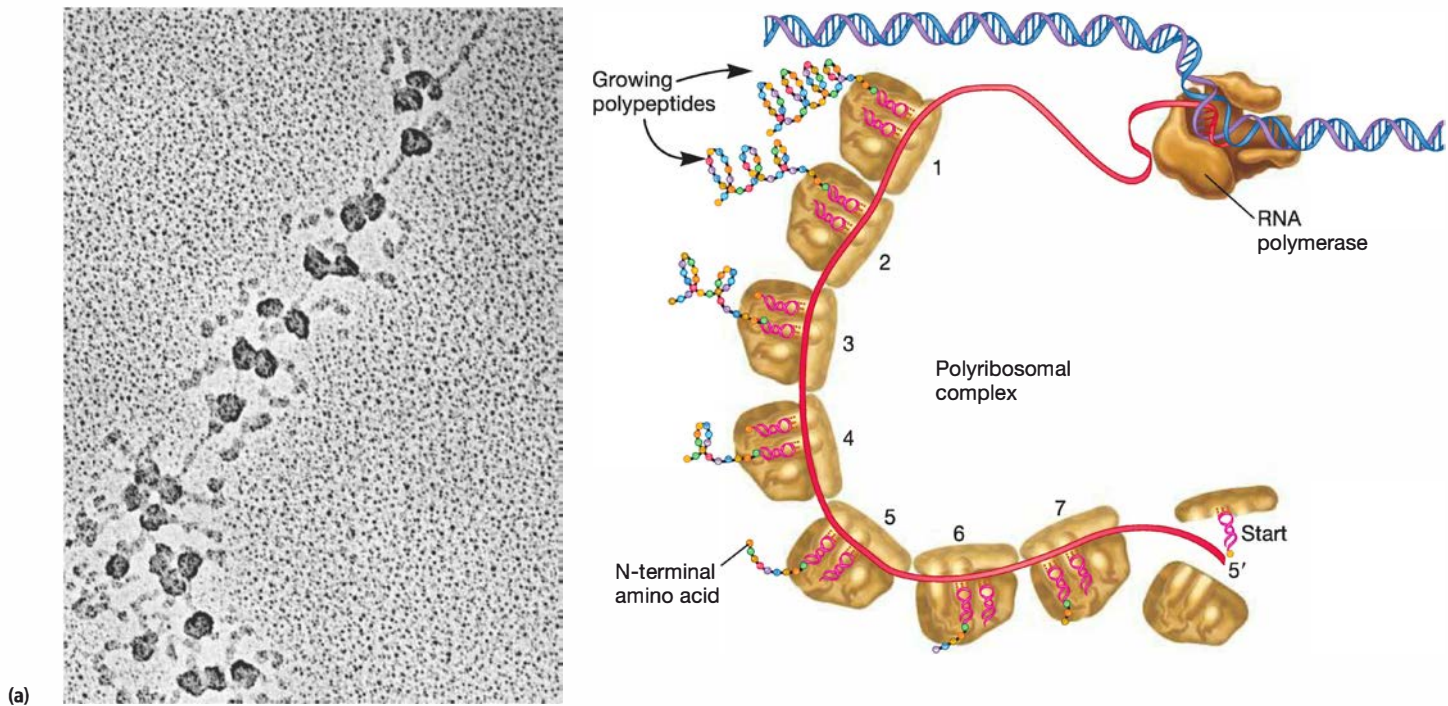

Figure 13.33 Coupled Transcription and Translation in Bacteria. (a) A transmission electron micrograph showing a polyribosome. (b) A schematic representation of coupled transcription and translation. As the DNA is transcribed, ribosomes bind the free 5' end of the mRNA. Thus translation is started before transcription is completed. Note that there are multiple ribosomes bound to the mRNA, forming a polyribosome. The ribosomes are shown at different points in the translation process. Ribosomes 1, 2, 5, and 7 have completed the transpeptidation reaction, but translocation has not yet occurred. Ribosomes 3 and 4 have an A site containing an incoming aminoacyl-tRNA. Transpeptidation has not occurred. Ribosome 6 shows elongation upon completion of both transpeptidation and translocation. The tRNA bearing the growing polypeptide is in the P site and the empty tRNA is in the E site.

MICRO INQUIRY Why is simultaneous transcription and translation impossible in eukaryotes?

tRNA to assume a cloverleaf conformation (**figure 13.34a**). However, the three-dimensional structure looks like the letter L (**figure 13.34b**). One important feature of tRNAs is the acceptor stem, which holds the activated amino acid. The 3' end of all tRNAs has the same —C—C—A sequence, and in all cases, the amino acid is attached to the terminal adenylic acid (A). Another important feature of the tRNA is the **anticodon**. The anticodon is complementary to the mRNA codon and is located on the anticodon arm (**figure 13.34a**).

Enzymes called **aminoacyl-tRNA synthetases** catalyze amino acid activation (**figure 13.35**). As is true of DNA and RNA synthesis, the reaction is driven to completion when ATP is hydrolyzed to release pyrophosphate. The amino acid is attached to the 3'-hydroxyl of the terminal adenylic acid on the tRNA by a high-energy bond. The storage of energy in this bond provides the fuel needed to generate the peptide bond when the amino acid is added to the growing peptide chain.

There are at least 20 aminoacyl-tRNA synthetases, each specific for a single amino acid and its tRNAs (cognate tRNAs).

It is critical that each tRNA attach the corresponding amino acid because if an incorrect amino acid is attached to a tRNA, it will be incorporated into a polypeptide in place of the correct amino acid. The protein synthetic machinery recognizes only the anticodon of the aminoacyl-tRNA and cannot tell whether the correct amino acid is attached. Some aminoacyl-tRNA synthetases proofread just like DNA polymerases do. If the wrong amino acid is attached to tRNA, the enzyme hydrolyzes the amino acid from the tRNA, rather than release the incorrect product.

Aminoacyl-tRNA Structure

Ribosome Structure

Protein synthesis takes place on ribosomes that serve as workbenches, with mRNA acting as the blueprint. Recall that ribosomes are formed from two subunits, the large subunit and the small subunit, and each contains one or more rRNA molecules and numerous polypeptide chains. A bacterial ribosome and its components are shown in **figure 13.36**. The

(a)

(b)

Figure 13.34 tRNA Structure. (a) The two-dimensional cloverleaf structure for tRNA. In addition to the anticodon arm, three other arms are readily observed: the D or DHU arm, the T or TΨC arm, and the variable arm. The D and T arms are named because of the presence of unusual nucleotides. The variable arm is of different lengths depending on the tRNA; the other arms are fairly constant in size. Bases found in all tRNAs are in diamonds; purine and pyrimidine positions in all tRNAs are labeled Pu and Py, respectively. (b) The three-dimensional structure of tRNA. The various regions are distinguished with different colors.

region of the ribosome directly responsible for translation is called the translational domain. Both subunits contribute to this domain. The growing peptide chain emerges from the large subunit at the exit domain (figure 13.36d).

Ribosomal RNA is thought to have three roles. (1) It contributes to ribosome structure. (2) The 16S rRNA of the 30S subunit is needed for the initiation of protein synthesis because its

MICRO INQUIRY What would be the outcome if an aminoacyl-tRNA synthetase added the wrong amino acid to a tRNA (i.e., the anticodon specified a different amino acid than that added to the 3' end of the tRNA)?

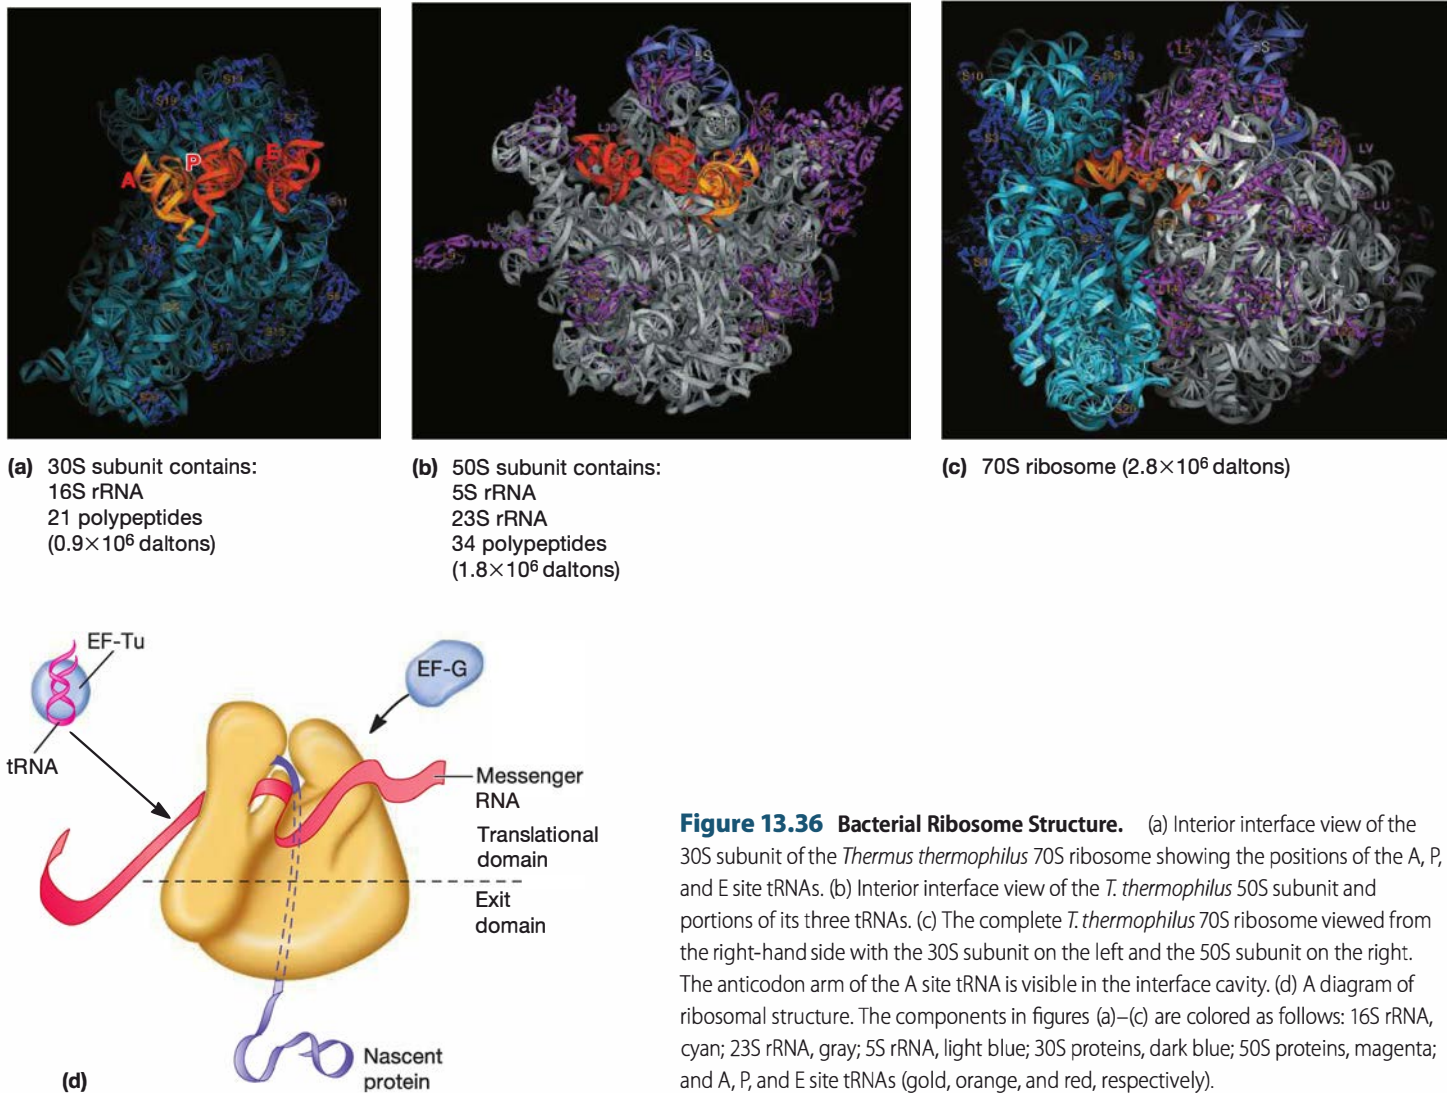

Figure 13.36 Bacterial Ribosome Structure. (a) Interior interface view of the 30S subunit of the *Thermus thermophilus* 70S ribosome showing the positions of the A, P, and E site tRNAs. (b) Interior interface view of the *T. thermophilus* 50S subunit and portions of its three tRNAs. (c) The complete *T. thermophilus* 70S ribosome viewed from the right-hand side with the 30S subunit on the left and the 50S subunit on the right. The anticodon arm of the A site tRNA is visible in the interface cavity. (d) A diagram of ribosomal structure. The components in figures (a)–(c) are colored as follows: 16S rRNA, cyan; 23S rRNA, gray; 5S rRNA, light blue; 30S proteins, dark blue; 50S proteins, magenta; and A, P, and E site tRNAs (gold, orange, and red, respectively).

3' end binds to a site on the leader of the mRNA called the Shine-Dalgarno sequence; thus the Shine-Dalgarno sequence is part of the **ribosome-binding site (RBS)**. This helps position the mRNA on the ribosome. The 16S rRNA also binds a protein needed to initiate translation (initiation factor 3) and the 3' CCA end of amino-acyl-tRNA. (3) The 23S rRNA is a ribozyme that catalyzes peptide bond formation.

Initiation of Protein Synthesis

Like transcription and DNA replication, protein synthesis is divided into three stages: initiation, elongation, and termination. The initiation of protein synthesis is very elaborate. Apparently the complexity is necessary to ensure that the ribosome does not start synthesizing a polypeptide chain in the middle of a gene—a disastrous error.

Bacteria begin protein synthesis with a modified aminoacyl-tRNA, *N*-formylmethionyl-tRNA^{fMet} (fMet-tRNA), which is

coded for by the start codon AUG (**figure 13.37**). The amino acid of the initiator tRNA has a formyl group covalently

Figure 13.37 *N*-formylmethionyl-tRNA^{fMet} Is the Initiator tRNA Used by Bacteria. The formyl group is in color. Archaea and eukaryotes use methionyl-tRNA for initiation.

MICRO INQUIRY Why would it be impossible for fMet-tRNA to initiate peptide bond formation with another amino acid? (Hint: Examine figure 13.40 closely.)

bound to the amino group and can be used only for initiation because of the presence of the formyl group. When methionine is to be added to a growing polypeptide chain (i.e., at an AUG codon in the middle of the mRNA), a normal methionyl-tRNA^{Met} is employed. Although bacteria start protein synthesis with *N*-formylmethionine, the formyl group is not retained but is hydrolytically removed. In fact, one to three amino acids may be removed from the amino terminal end of the polypeptide after synthesis.

The initiation stage is crucial for the translation of mRNA into the correct polypeptide (**figure 13.38**). In bacteria, it begins when initiator fMet-tRNA binds to a free 30S ribosomal subunit.

The 16S rRNA within the 30S subunit then binds the Shine-Dalgarno sequence in the leader sequence of the mRNA. By aligning the Shine-Dalgarno sequence with the 16S rRNA, the **initiator codon** (AUG or sometimes GUG, though GUG is not as good an initiator) specifically binds with the fMet-tRNA anticodon. This ensures that the codon for the initiator fMet-tRNA will be translated first. When the 50S subunit of the ribosome binds to the 30S subunit-mRNA, an active ribosome-mRNA complex is formed, with the fMet-tRNA positioned at the peptidyl or P site (see description of the elongation cycle). This complex is referred to as the initiation complex. Three protein initiation factors (IF-1, IF-2, and IF-3) are required for formation

Figure 13.38 Initiation of Protein Synthesis in Bacteria. IF-1, IF-2, and IF-3 stand for initiation factors 1, 2, and 3; initiator tRNA is *N*-formylmethionyl-tRNA^{fMet}. The ribosomal locations of initiation factors are depicted for illustration purposes only. They do not represent the actual initiation factor binding sites.

of the initiation complex, and GTP is hydrolyzed during the association of the 50S and 30S subunits (figure 13.38). Eukaryotes and archaeal cells require more initiation factors. **►► Translation and protein maturation and localization (section 15.4)**

Elongation of the Polypeptide Chain

Every addition of an amino acid to a growing polypeptide chain is the result of an elongation cycle composed of three phases: aminoacyl-tRNA binding, the transpeptidation reaction, and translocation. The process is aided by proteins called **elongation factors (EF)**. In each turn of the cycle, an amino acid corresponding to the proper mRNA codon is added to the C-terminal end of the polypeptide chain as the ribosome moves down the mRNA in the 5' to 3' direction.

The ribosome has three sites for binding tRNAs: (1) the **peptidyl or donor site (P site)**, (2) the **aminoacyl or acceptor site (A site)**, and (3) the **exit site (E site)**. At the beginning of an elongation cycle, the P site is filled with either fMet-tRNA or a tRNA bearing a growing polypeptide chain (peptidyl-tRNA), and the A and E sites are empty (figure 13.39). Messenger RNA is bound to the ribosome in such a way that the proper codon interacts with the P site tRNA (e.g., an AUG codon for fMet-tRNA). The next codon is located within the A site and is ready to accept an aminoacyl-tRNA.

The first phase of the elongation cycle is the aminoacyl-tRNA binding phase. The aminoacyl-tRNA corresponding to the codon in the A site is inserted so its anticodon is aligned with the codon on the mRNA. In bacterial cells, this is aided by two elongation factors and requires the expenditure of one GTP (figure 13.39). Aminoacyl-tRNA binding to the A site initiates the second phase of the elongation cycle, the transpeptidation reaction (figure 13.39 and figure 13.40). Transpeptidation is catalyzed by the **peptidyl transferase** activity of the 23S rRNA ribozyme, which is part of the 50S ribosomal subunit. In this reaction, the amino group of the A site amino acid reacts with the carboxyl group of the C-terminal amino acid on the P site tRNA (figure 13.40). This results in the transfer of the peptide chain from the tRNA in the P site to the tRNA in the A site, as a peptide bond is formed between the peptide chain and the incoming amino acid. No extra energy source is required for peptide bond formation because the bond linking an amino acid to tRNA is high in energy (figure 13.35).

The final phase in the elongation cycle is **translocation**. Three things happen simultaneously: (1) the peptidyl-tRNA moves from the A site to the P site; (2) the ribosome moves one codon along mRNA so that a new codon is positioned in the A site; and (3) the empty tRNA moves from the P site to the E site and subsequently leaves the ribosome. Translocation occurs by a ratcheting mechanism brought about by conformational changes in constituents of the ribosome and rotations of the 30S and 50S subunits relative to each other. This intricate process requires the participation of an elongation factor and GTP hydrolysis. **► Translation Elongation**

Insertion of Selenocysteine and Pyrrolysine

Insertion of the unusual amino acids selenocysteine and pyrrolysine during translation occurs by two distinctive mechanisms. Selenocysteine is synthesized from serine after it has been attached to certain tRNAs. The enzyme catalyzing the conversion is selenocysteine synthase. Once formed, the amino acid is recognized by a specific elongation factor and is incorporated when a UGA stop codon is encountered in association with nucleotide sequences called *cis-acting selenocysteine insertion sequence elements (SECIS)*. In bacteria, SECIS are found immediately after the UGA stop codon. In archaea and eukaryotes, SECIS are located in the 3' untranslated region of the mRNA.

Pyrrolysine insertion differs from that of selenocysteine in several ways. Pyrrolysine is synthesized from lysine before being attached to a tRNA. Organisms that use pyrrolysine make an unusual tRNA with a CUA anticodon; the pyrrolysine is attached by a specific aminoacyl-tRNA synthetase. Pyrrolysine is inserted at UAG stop codons located near a sequence element called *pyrrolysine insertion sequence (PYLIS)*. Both SECIS and PYLIS form stem-loop structures that prevent cessation of translation.

Termination of Protein Synthesis

Protein synthesis stops when the ribosome reaches one of three stop codons: UAA, UAG, and UGA (figure 13.41). The stop codon is found on the mRNA immediately before the trailer. Three release factors (RF-1, RF-2, and RF-3) aid the ribosome in recognizing these codons. Because there is no cognate tRNA for a stop codon, the ribosome halts. Peptidyl transferase hydrolyzes the bond linking the polypeptide to the tRNA in the P site, and the polypeptide and the empty tRNA are released. GTP hydrolysis occurs during this sequence of events. Next the ribosome dissociates from its mRNA and separates into 30S and 50S subunits. IF-3 binds the 30S subunit, which prepares it for the next round of protein synthesis. The termination of archaeal and eukaryotic protein synthesis is similar except that only one release factor appears to be active. **► Translation Termination**

Protein synthesis is a very expensive process. Three GTP molecules probably are used during each elongation cycle, and two ATP high-energy bonds are required for amino acid activation (ATP is converted to AMP, rather than to ADP). Therefore five high-energy bonds are required to add one amino acid to a growing polypeptide chain. GTP also is used in initiation and termination of protein synthesis (figures 13.38 and 13.41). Presumably this large energy expenditure is required to ensure the fidelity of protein synthesis. Fidelity can be ensured both before and after formation of the peptide bond. When an aminoacyl-tRNA enters the A site, correct pairing of the anticodon and codon causes conformational changes in components of the ribosome such that the aminoacyl-tRNA is "locked into place" in a manner that facilitates peptide bond

Figure 13.39 The Elongation Cycle of Protein Synthesis. The ribosome possesses three sites, a peptidyl or donor site (P site), an aminoacyl or acceptor site (A site), and an exit site (E site). The arrow to the right of the ribosome in the translocation step shows the direction of ribosome movement.

Figure 13.40 Transpeptidation. The peptidyl transferase reaction catalyzed by the 23S rRNA ribozyme. The peptide grows by one amino acid and is transferred to the A site.

MICRO INQUIRY What provides the energy to fuel this reaction?

formation. On rare occasions, the incorrect aminoacyl-tRNA is selected, and a peptide bond is formed between the growing polypeptide and the wrong amino acid. The ribosome is able to detect its error; how it does so is not clear. However, the presence of an incorrect amino acid is recognized by release factors. This leads to hydrolysis of the aberrant polypeptide from the tRNA, its release from the ribosome, and termination of translation.

Figure 13.41 Termination of Protein Synthesis in Bacteria. Although three different nonsense codons can terminate chain elongation, UAA is most often used. Three release factors (RF) assist the ribosome in recognizing nonsense codons and terminating translation and GTP is hydrolyzed. Binding of IF-3 to the 30S subunit prepares it for the next round of translation initiation. Transfer RNAs are in pink.

Retrieve, Infer, Apply

1. In which direction are polypeptides synthesized? What is a polyribosome and why is it useful?
2. Briefly describe the structure of transfer RNA and relate this to its function. How are amino acids activated for protein synthesis, and why is the specificity of the aminoacyl-tRNA synthetase reaction so important?
3. What are the translational and exit domains of the ribosome? What roles do ribosomal RNAs have?
4. Tabulate the nature and function of the following: fMet-tRNA, initiator codon, elongation cycle, peptidyl and aminoacyl sites, transpeptidation reaction, peptidyl transferase, translocation, nonsense codon, and release factors.
5. How many ATP and GTP molecules would be hydrolyzed in the synthesis of a 125 amino acid protein? Explain why this is a good argument for careful regulation of gene expression (especially considering that most proteins are larger than 125 amino acids).

13.8 Protein Maturation and Secretion

After reading this section, you should be able to:

- Discuss the role of molecular chaperones in protein folding, and list some important examples of chaperones
- Describe the role of protein splicing in protein maturation
- Distinguish translocation of proteins from protein secretion
- List bacterial translocation systems, and indicate whether they function in Gram-positive, Gram-negative, or both types of bacteria

As a polypeptide emerges from a ribosome, it is not yet ready to assume its cellular functions. Protein function depends on its three-dimensional shape. Proteins must be properly folded and in some cases associated with other protein subunits to generate a functional enzyme (e.g., DNA and RNA polymerases are multimeric proteins). In addition, proteins must be delivered to the proper subcellular or extracellular site. We now discuss these posttranslational events.

Protein Folding and Molecular Chaperones

Although the amino acid sequence of a polypeptide determines its final conformation, helper proteins aid the newly formed or nascent polypeptide in folding to its proper functional shape. These proteins, called **molecular chaperones** or simply chaperones, recognize only unfolded polypeptides or partly denatured proteins and do not bind to normal, functional proteins. Their role is essential because the cytoplasm is filled with new polypeptide chains. Under such conditions, it is possible for polypeptides to fold improperly and aggregate to form nonfunctional complexes. Molecular chaperones suppress incorrect folding and may reverse any incorrect folding that has already taken place. They are so important that chaperones are present in all cells.

Several chaperones and cooperating proteins aid proper protein folding in *E. coli*: chaperones DnaK, DnaJ, GroEL, and GroES; and the stress protein GrpE. After a sufficient length of nascent polypeptide extends from the ribosome, a series of reactions involving DnaJ and DnaK fold the protein into its native conformation. This requires the expenditure of ATP (figure 13.42). Sometimes the polypeptide does not reach its native conformation

Figure 13.42 Chaperones and Polypeptide Folding. The involvement of bacterial chaperones in the proper folding of a newly synthesized polypeptide chain is depicted in this diagram. Three possible outcomes of a chaperone reaction cycle are shown. A native protein may result, the partially folded polypeptide may bind again to DnaK and DnaJ, or the polypeptide may be transferred to GroEL and GroES to complete folding.

in one series of reactions, and the folding process may be repeated. Alternatively, the partially folded protein may be transferred to chaperones GroEL and GroES, which complete the folding. This chaperone system also expends ATP as it folds the protein into its proper conformation.

Chaperones were first discovered because they dramatically increase in concentration when cells are exposed to high temperatures, metabolic poisons, and other stressful conditions that cause protein denaturation. Thus many chaperones are called **heat-shock proteins**. When an *E. coli* culture is switched from 30 to 42°C, the concentrations of some 20 different heat-shock proteins increase greatly within about 5 minutes. If the cells are exposed to a lethal temperature, the heat-shock proteins are still synthesized but most other proteins are not. Thus chaperones protect the cell from thermal damage and other stresses as well as promote the proper folding of new polypeptides. For example, DnaK protects *E. coli* RNA polymerase from thermal inactivation in vitro. In addition, DnaK reactivates thermally inactivated RNA polymerase, especially if ATP, DnaJ, and GrpE are present. GroEL and GroES also protect intracellular proteins from aggregation.

Protein Splicing

A further level of complexity in the formation of proteins has been discovered in microbes belonging to all three domains of life. Some microbial proteins are spliced after translation. In protein splicing, a part of the polypeptide is removed before the polypeptide folds into its final shape. Self-splicing proteins begin as larger precursor proteins composed of an internal intervening sequence called an **intein** (about 130 to 600 amino acids in length) flanked by external sequences called **exteins** (figure 13.43). Inteins remove themselves from the precursor protein. When the splicing is completed, two proteins have been formed: the intein protein and the protein formed by splicing the two exteins together.

Protein Translocation and Secretion in Bacteria

It has been estimated that almost one-third of the proteins synthesized by cells leave the cytoplasm to reside in membranes, the periplasmic space of bacterial and archaeal cells, or the external environment. It is not surprising then that over 15 different systems for moving proteins out of the cytoplasm have evolved. Some of these systems are found in all domains of life. Others are unique to bacterial cells, and others are observed only in Gram-negative bacteria. When proteins are moved from the cytoplasm to the membrane or to the periplasmic space, the movement is called translocation. Protein secretion refers to the movement of proteins from the cytoplasm to the external environment. Many of the secretion pathways are designated with numbers (e.g., type I secretion system, type II secretion system, etc.).

Why are so many proteins moved out of the cytoplasm? Many important proteins are located in membranes. These include transport proteins that bring needed materials into the cell and take wastes out of the cell. They also include proteins

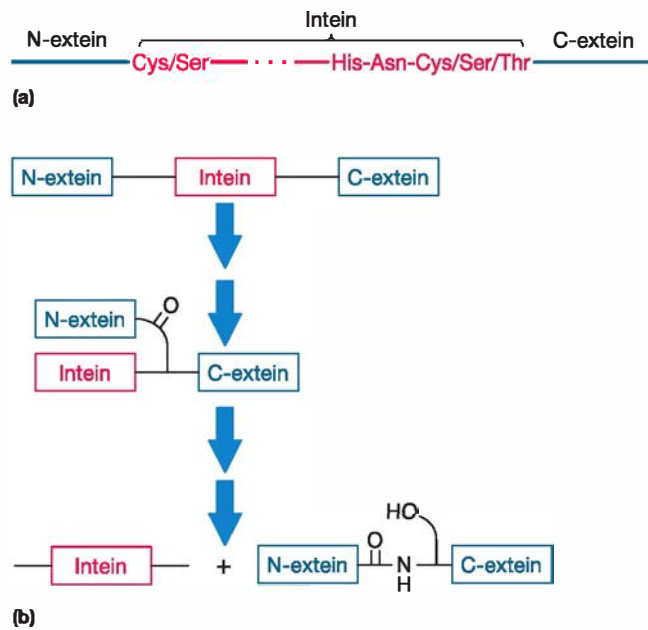

Figure 13.43 Protein Splicing. (a) A generalized illustration of intein structure. The amino acids that are commonly present at each end of the inteins are shown. Note that many are thiol- or hydroxyl-containing amino acids. (b) A simplified overview of splicing.

involved in electron transport. In Gram-negative bacteria, the periplasmic space is loaded with proteins such as chemotaxis proteins, enzymes involved in cell wall synthesis, and periplasmic components of nutrient uptake systems. Many organisms secrete hydrolytic enzymes into the external environment. These enzymes break down macromolecules into monomers that are more easily brought into the cell. The protein subunits of external structures such as flagella and fimbriae must also be moved out of the cell and assembled on its external surface. Pathogenic microbes often release toxins that are important in the infection process.

Protein secretion poses different difficulties, depending on the structure of the cell envelope. For Gram-positive bacteria to secrete proteins, the proteins must be translocated across the plasma membrane. Once across the plasma membrane, the protein either passes through the relatively porous peptidoglycan into the external environment or becomes embedded in or attached to the peptidoglycan. Gram-negative bacteria have more hurdles to jump when they secrete proteins. They, too, must transport the proteins across the plasma membrane, but to complete secretion, the proteins must be transported across the outer membrane.

Common Translocation and Secretion Systems

The major pathway for translocating proteins across the plasma membrane is the Sec (secretion) pathway (figure 13.44). In Gram-negative bacteria, proteins can be transported across the outer membrane by several different mechanisms, some of which bypass the Sec system, moving proteins directly from the cytoplasm

Figure 13.44 Posttranslational Translocation by the Sec System.

to the outside of the cell (**figure 13.45**). All protein translocation and secretion pathways described here require the expenditure of energy at some step in the process. The energy is usually supplied by the hydrolysis of high-energy molecules such as ATP and GTP. However, the proton motive force also sometimes plays a role. **Active transport** (section 3.3); **ATP** (section 10.2); **Electron transport and oxidative phosphorylation** (section 11.6)

The **Sec system**, sometimes called the general secretion pathway, is highly conserved, having been identified in all three domains of life (figure 13.44). It translocates unfolded proteins across the plasma membrane or integrates them into the membrane itself. It does so either posttranslationally or cotranslationally. In posttranslational translocation, the protein is synthesized and released from the ribosome as a preprotein; the amino acid sequence at its amino terminus is called a **signal peptide**. The signal peptide is recognized and bound by chaperone proteins (e.g., SecB). This helps delay protein folding, thereby helping the preprotein reach the Sec transport machinery in the conformation needed for transport. The chaperone protein “delivers” the preprotein to the Sec system. Certain Sec proteins (SecY, SecE, and SecG) form a

Figure 13.45 Some Protein Secretion Systems of Gram-Negative Bacteria. Five of the six secretion systems of Gram-negative bacteria are shown. The type VI secretion system is not shown. The Sec and Tat pathways deliver proteins from the cytoplasm to the periplasmic space and also are found in archaea and Gram-positive bacteria. Type II, type V, and sometimes type IV secretion systems complete the secretion process begun by the Sec system. The Tat system appears to deliver proteins only to the type II pathway. Type I and type III secretion systems bypass the Sec and Tat pathways, moving proteins directly from the cytoplasm, through the outer membrane, to the extracellular space. The type IV secretion system can work either with the Sec system or alone to transport proteins to the extracellular space. Type IV systems are also observed in Gram-positive bacteria, where they function in DNA transfer only. Proteins translocated by the Sec system posttranslationally or secreted by the type III secretion system are delivered to those systems by chaperone proteins.

MICRO INQUIRY What are two distinguishing features of protein translocation via the Tat system as compared to that using the Sec system?

channel in the membrane through which the preprotein passes. Another protein (SecA) binds to the SecYEG proteins and acts as a motor, using the energy released from ATP hydrolysis to translocate the preprotein. Recent studies suggest that two other proteins (SecDF) use the proton motive force to help fuel translocation through the plasma membrane. When the preprotein emerges from the plasma membrane, free from chaperones, an enzyme called signal peptidase removes the signal peptide. The protein then folds into the proper shape.

Cotranslational movement of proteins by the Sec system is mediated by a complex of RNA and protein called the **signal recognition particle (SRP)**. It is thought that SRP binds a signal sequence (not the same as the signal peptide) in the protein as it leaves the ribosome and directs the protein together with the translating ribosome to SecYEG. As translation continues, the protein is threaded into the SecYEG channel (see figure 15.12) and inserted into the plasma membrane, often with the aid of a protein called YidC. This process is similar to the cotranslational translocation that occurs in the eukaryotic Sec system that moves proteins across the membranes of the endoplasmic reticulum. ►► *Protein localization and secretion in eukaryotes (section 15.4)*

In bacteria and some archaea, another translocation system called the **Tat system** can move proteins across the plasma membrane. This system is distinguished from the Sec pathway by the nature of the protein transported. The Sec pathway translocates unfolded proteins; the Tat pathway translocates folded proteins. Furthermore, the Tat pathway only moves proteins that feature two, or “twin,” arginine residues in their signal sequence—in fact, *Tat* stands for *twin arginine translocase*. In Gram-negative bacteria, proteins translocated by the Tat pathway are delivered to a type II secretion system for transport across the outer membrane.

Type I secretion systems are ubiquitous in Gram-positive and Gram-negative bacteria, as well as in members of *Archaea* (figure 13.45). Type I systems are members of a protein superfamily defined by the ABC transporters described in chapter 3. In pathogenic Gram-negative bacteria, type I secretion systems are involved in the secretion of toxins (α -hemolysin), as well as proteases, lipases, and specific peptides. Secreted proteins usually contain C-terminal secretion signals that help direct the newly synthesized protein to the type I machinery. In Gram-negative bacteria, the type I machinery spans the plasma membrane, the periplasmic space, and the outer membrane. These systems move proteins in one step across both membranes, bypassing the Sec system.

Type IV secretion systems are unique in that they are used to secrete proteins as well as to transfer DNA from a donor bacterium to a recipient during a process called bacterial conjugation. These systems are observed in both Gram-positive and Gram-negative bacteria; however, in Gram-positive bacteria, they only function in DNA transfer. The type IV systems of Gram-negative bacteria are best studied. They are composed of many different proteins and are described in more detail in chapter 16.

Protein Secretion in Gram-Negative Bacteria

Currently six protein secretion systems (types I to VI) have been identified in Gram-negative bacteria (figure 13.45; the type VI system is not shown). Some of these systems have already been described as they are present in both Gram-negative and Gram-positive bacteria (type I and type IV secretion systems). All others are unique to Gram-negative bacteria. Most are used to secrete virulence factors produced by plant and animal pathogens. Gram-negative bacteria use the **type II** and **type V** systems to transport proteins across the outer membrane after the protein has first been translocated across the plasma membrane by the Sec system. The type I, III, and VI systems do not transport proteins with the help of the Sec system, so they are said to be Sec-independent. The type IV pathway sometimes is linked to the Sec pathway but usually functions on its own.

Three of the systems (III, IV, and VI) form a needlelike structure that extends beyond the outer membrane and can make contact with other cells (figure 13.45; also see figure 39.9). The **type III secretion system** is best studied because it injects virulence factors directly into the plant and animal host cells that these pathogens attack. Its needle, called the **injectisome**, delivers virulence factors, including toxins, phagocytosis inhibitors, stimulators of cytoskeleton reorganization in the host cell, and promoters of host cell suicide (apoptosis). Type III systems also transport other proteins, including (1) some of the proteins from which the system is built, (2) proteins that regulate the secretion process, and (3) proteins that aid in the insertion of secreted proteins into target cells. In addition to *E. coli*, important examples of bacterial genera having members with type III systems are *Salmonella*, *Yersinia*, *Shigella*, *Bordetella*, *Pseudomonas*, and *Erwinia*. The participation of type III systems in bacterial virulence is further discussed in chapter 39.

Type V and VI secretion systems also warrant comment. Type V systems employ proteins called autotransporters because after being translocated across the plasma membrane by the Sec pathway, the proteins are able to transport themselves across the outer membrane. Autotransporters have three domains. One is recognized by the Sec system, and another forms a pore in the outer membrane through which the third domain (a virulence factor) is transported. Type VI systems are of interest because they are similar to the injection systems used by some bacteriophages to “push” their genomes into the cytoplasm of their bacterial hosts. ►► *Bacteriophage T4 (section 27.2)*

1. What are molecular chaperones and heat-shock proteins? Describe their functions.
2. Give the major characteristics and functions of the protein secretion systems described in this section.
3. Which secretion system is most widespread?
4. What is a signal peptide? Why do you think a protein's signal peptide is not removed until after the protein is translocated across the plasma membrane?

Key Concepts

13.1 DNA as Genetic Material

- DNA is composed of only four different building blocks (nucleotides). Therefore it was originally thought to be too simple to function as an organism's genetic material.
- The knowledge that DNA is the genetic material for cells came from studies on transformation by Griffith and Avery and from experiments on T2 phage by Hershey and Chase (figures 13.1–13.3).

13.2 Nucleic Acid and Protein Structure

- DNA differs in composition from RNA in having deoxyribose and thymine, rather than ribose and uracil.
- DNA is double stranded, with complementary AT and GC base pairing between the strands. The strands run antiparallel and are twisted into a right-handed double helix (figure 13.5).
- RNA is normally single stranded, although it can coil upon itself and base pair to form hairpin structures.
- Proteins are polymers of amino acids (figure 13.6) linked by peptide bonds (figure 13.7).

13.3 DNA Replication in Bacteria

- Circular bacterial DNAs have a single origin of replication. They are copied by two replication forks moving around the circle to form a theta-shaped (θ) figure (figure 13.9).
- The replisome is a huge complex of proteins and is responsible for DNA replication (figures 13.11 and 13.12).
- DNA polymerase enzymes catalyze the synthesis of DNA in the 5' to 3' direction while reading the DNA template in the 3' to 5' direction. The double helix is unwound by helicases with the aid of topoisomerases such as DNA gyrase. DNA binding proteins keep the strands separate (figures 13.10, 13.12, and 13.13).
- DNA polymerase III holoenzyme, the replicative DNA polymerase in bacteria, synthesizes a complementary DNA copy beginning with a short RNA primer made by the enzyme primase. The leading strand is replicated continuously, whereas DNA synthesis on the lagging strand is discontinuous and forms Okazaki fragments (figures 13.13 and 13.14). DNA polymerase I excises the RNA primers and fills in the resulting gap. DNA ligase then joins the fragments together (figures 13.14 and 13.15).
- The linear chromosomes of *Borrelia burgdorferi* have hairpin ends and an origin of replication in the middle of the chromosome. DNA replication proceeds bidirectionally from the origin, but only leading strand synthesis occurs at each fork. The resulting molecule is a dimer that is then cut into the single linear molecules as hairpin ends are formed (figure 13.18).

13.4 Bacterial Gene Structure

- A gene may be defined as a nucleic acid sequence that codes for a polypeptide, tRNA, or rRNA.
- The template strand of DNA carries genetic information and directs the synthesis of an RNA transcript.
- A gene also contains a promoter, a coding region, and a terminator; it may have a leader and a trailer (figure 13.20).
- The genes for tRNA and rRNA often code for a precursor that is subsequently processed to yield several products (figure 13.21).

13.5 Transcription in Bacteria

- Genes of related function are often organized into a transcriptional unit called an operon. A single promoter directs transcription of the operon, yielding a polycistronic mRNA. Each coding region in the polycistronic mRNA has its own start and stop codons and gives rise to a single polypeptide (figure 13.22).
- RNA synthesis is catalyzed by enzymes called RNA polymerases. Bacterial RNA polymerases are composed of several protein subunits (figure 13.23).
- The transcription cycle (figure 13.24) includes initiation, elongation, and termination.
- A protein called sigma factor directs RNA polymerase to a promoter during transcription initiation. Sigma recognizes certain sequences in the promoter (figure 13.25). Once bound, RNA polymerase unwinds a short stretch of DNA (figure 13.26). It then begins moving down the template strand (figure 13.27), synthesizing RNA in a 5' to 3' direction (elongation). Termination of transcription is brought about by two mechanisms: factor-independent and factor-dependent termination (figures 13.28 and 13.29).

13.6 The Genetic Code

- Genetic information is carried in the form of 64 nucleotide triplets called codons (table 13.3); 61 sense codons direct amino acid incorporation, and three stop codons terminate translation. The code is degenerate; that is, there is more than one codon for most amino acids.
- Some proteins contain two rare amino acids: selenocysteine and pyrrolysine (figure 13.32).

13.7 Translation in Bacteria

- In translation, ribosomes attach to mRNA and synthesize a polypeptide beginning at the N-terminal end. A polysome or polyribosome is a complex of mRNA with several ribosomes (figure 13.33).
- Amino acids are activated for protein synthesis by attachment to the 3' end of transfer RNAs. Activation requires ATP, and the reaction is catalyzed by aminoacyl-tRNA synthetases (figure 13.35).

- Ribosomes are large, complex organelles composed of rRNAs and many polypeptides. Amino acids are added to a growing peptide chain at the translational domain of the ribosome (**figure 13.36**).
- Protein synthesis begins with the binding of fMet-tRNA (**figure 13.37**) to a start codon on mRNA and to the two ribosomal subunits. This involves the participation of protein initiation factors (**figure 13.38**).
- In the elongation cycle, the proper aminoacyl-tRNA binds to the A site (**figure 13.39**). Then the transpeptidation reaction is catalyzed by peptidyl transferase (**figure 13.40**). Finally, during translocation, the peptidyl-tRNA moves to the P site and the ribosome moves down the mRNA by one codon. The empty tRNA leaves the ribosome by way of the exit site.
- Protein synthesis stops when a stop codon is reached. Bacteria require three release factors for codon recognition and ribosome dissociation from the mRNA (**figure 13.41**).

13.8 Protein Maturation and Secretion

- Chaperone proteins help ensure that proteins fold properly or are delivered to their destination site (**figure 13.42**).
- Some proteins are self-splicing and excise portions of themselves before folding into their final shape (**figure 13.43**).
- Many proteins must be transported across the plasma membrane of cells. The most commonly used mechanism is the Sec system, which is found in all organisms (**figure 13.44**). Type I secretion systems are observed in many bacteria and archaea. Type IV secretion systems are observed in both Gram-positive and Gram-negative bacteria (**figure 13.45**).
- Gram-negative bacteria have evolved additional systems for moving proteins across the outer membrane of the cell wall. These include type II, III, V, and VI secretion systems.

Compare, Hypothesize, Invent

1. *Streptomyces coelicolor* has a linear chromosome. Interestingly, there are no genes that encode essential proteins near the ends of the chromosome in this bacterium. Why do you think this is the case?
2. You have isolated several *E. coli* mutants:
 Mutant #1 has a point mutation in the -10 region of the promoter of a structural gene encoding an enzyme needed for synthesis of the amino acid serine.
 Mutant #2 has a mutation in the -35 region in the promoter of the same gene.
 Mutant #3 is a double mutant with mutations in both the -10 and -35 region of the promoter of the same gene.
 Only Mutant #3 is unable to make serine. Why do you think this is so?
3. DNA polymerase I (Pol I) of *E. coli* consists of three functional parts (domains): an N-terminal domain with 5' to 3' exonuclease activity required for removal of the RNA primer, a central domain responsible for 3' to 5' exonuclease proofreading, and a C-terminal domain with

polymerase activity. Pol I is thought to simultaneously remove RNA primers and fill in the gaps that result (**figure 13.14**). A group of proteins known as RNaseH also have 5' to 3' exonuclease activity and can thus remove RNA primers. However, they lack the other two functions observed for Pol I. Predict the ability of the following mutants to replicate DNA: (1) a strain with a mutant gene encoding Pol I such that it no longer has polymerase activity (but retains both types of nuclease activities); (2) a strain without RNaseH proteins; (3) a strain with a mutant gene encoding Pol I such that it no longer has 5' to 3' exonuclease activity (but retains 3' to 5' nuclease and polymerase activities); (4) a strain with the mutant Pol I described in (3) and a strain lacking all RNaseH proteins. Explain your reasoning for each.

Regulation of Bacterial Cellular Processes

Letting Go

Treatment of diseases such as cancer often requires the placement of intravenous catheters for the long-term delivery of medications through the bloodstream. The catheters stay in the vein between chemotherapy sessions and are rinsed with anticoagulant solutions after each use. Unfortunately, the catheters and the solutions used to rinse them can be a source of danger, rather than a critical part of the treatment plan. Such was the case in December 2004 when an anticoagulant solution contaminated with the bacterium *Pseudomonas fluorescens* was used to rinse the intravenous catheters of patients. Thirty-six patients in four different states developed blood infections from the contaminated solution. The Centers for Disease Control and Prevention (CDC) investigated the outbreak, and by the end of January 2005, the U.S. Food and Drug Administration had alerted the nation and all existing bottles of contaminated solution were recalled. Problem solved? Unfortunately not.

In March 2005 the CDC was again alerted that 28 cancer patients developed bloodstream infections caused by *P. fluorescens*. Investigations determined that the infections were caused by the same *P. fluorescens* strain isolated from the cancer patients in 2004. These new patients had been exposed to the contaminated solution many months earlier but did not become ill. Thus they were not identified in the 2004 outbreak. Why was their illness so delayed? Subsequent CDC investigations showed that the catheters in the new patients had a *P. fluorescens* biofilm. The CDC hypothesized that the biofilm enabled the bacterium to reproduce, increasing its numbers from that in the original contaminating solution. Much after this initial exposure, the bacterial cells in the biofilm were dislodged when the catheters were flushed with sterile solutions. The dislodged cells were the cause of the blood infections.

For these patients, physical forces released the cells from the biofilms, but it has long been known that bacteria have mechanisms for “deciding” when to establish a biofilm and when to “let go” and escape the biofilm. This involves sensing their environment and then altering cellular processes

Intravenous catheters such as this are often used to deliver drugs. However, they can also serve as a portal of entry for pathogenic bacteria and as a site for biofilm formation.

to make the switch. Switching back and forth between free-swimming (planktonic) and biofilm (sessile) growth is an example of a regulated behavior. Importantly, understanding how the change is made is critical to developing strategies for controlling biofilm formation and dissolution.

A series of experiments culminating in a 2011 report have begun to reveal the mechanism for letting go, at least in one situation. The model includes an adhesion molecule located in the outer membrane (LapA), another protein (LapG), and describes how they work to control cells leaving a biofilm when phosphate levels are low.

Why phosphate? Phosphate is needed for synthesis of nucleic acids. No phosphate, no DNA replication or transcription, dead cell. When phosphate is abundant, *P. fluorescens* cells want to stay put. They do so by sticking to a surface with LapA, the adhesion protein. Biofilm building then commences. However, when phosphate levels wane, if the cells are to survive, they must escape the biofilm and hunt for a location with more phosphate. They accomplish this with LapG, a periplasmic protease that cleaves LapA, removing it from the outer membrane. Without LapA holding them to the surface, the bacterial cells are free to leave the biofilm.

The capacity of *P. fluorescens* to stay or leave a biofilm is just one example of the many “decisions” microbes make. Bacteria are constantly detecting changes in their environment and responding accordingly. Cells use two general approaches to regulate cellular processes. (1) They can alter the activity of enzymes and other proteins. This type of regulation occurs after the protein is synthesized and is called posttranslational control. (2) They can change the rate of synthesis of enzymes and other proteins. This type of regulation is often called regulation of gene expression. Posttranslational control acts rapidly to adjust metabolic activity and other processes from moment to moment. The control of gene expression occurs over longer intervals. For example, the *Escherichia coli* chromosome can code for about 4,500 polypeptides, yet only a fraction are synthesized at any one time. Regulation of gene expression conserves energy and raw materials, maintains the balance between the amounts of various cell proteins, and enables microbes to acclimate to long-term environmental change. Thus control of gene expression complements

posttranslational control. Both types of regulatory mechanisms are illustrated in this chapter. ◀◀ *Posttranslational regulation of enzyme activity (section 10.7)*

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Describe the mechanisms often used to regulate enzyme activity (section 10.7)
- ✓ Discuss genome structure and organization of genetic information in bacterial cells (chapter 13)
- ✓ Summarize the events that occur during the three phases of transcription and translation (sections 13.5 and 13.7)
- ✓ Describe the phosphoenolpyruvate: sugar phosphotransferase system (section 3.3)

14.1 Levels of Regulation

After reading this section, you should be able to:

- List when, during the flow of genetic information, bacterial cells can regulate gene expression
- Speculate why microbial geneticists for many years focused almost exclusively on the regulation of transcription initiation

Figure 14.1 summarizes the steps leading from the information coded in DNA to a functional protein. As we discuss in chapter 13, the process begins with transcription of the gene, followed by translation of the mRNA to yield a protein. Regulation that occurs by controlling the processes of transcription and translation is often called regulation of gene expression. When gene expression is regulated by controlling mRNA synthesis, it is said to be “at the level of transcription” or at the “transcriptional level.” Likewise, when gene expression is governed by controlling protein synthesis, it is said to be “at the level of translation” or at the “translational level.” Translation yields a protein that may or may not be functional. The activity level of proteins may be altered by posttranslational modification.

Although the overall processes of transcription and translation are similar for all organisms, some differences affect gene expression. Thus regulation of gene expression is somewhat different for members in each domain. Our focus in this chapter is on well-understood bacterial regulatory processes.

Regulation at the level of transcription has been the focus of microbial geneticists for many years and is well understood. Transcription can be regulated by governing its initiation or its elongation, and these topics are covered in sections 14.2 and 14.3, respectively. We begin our discussion by introducing two phenomena: induction of enzyme synthesis and repression of enzyme synthesis. Induction and repression provided the first models for gene regulation. These models involve the action of regulatory proteins, and the notion that gene expression is regulated solely by proteins persisted for many years. Eventually it was demonstrated that RNA molecules also have regulatory functions.

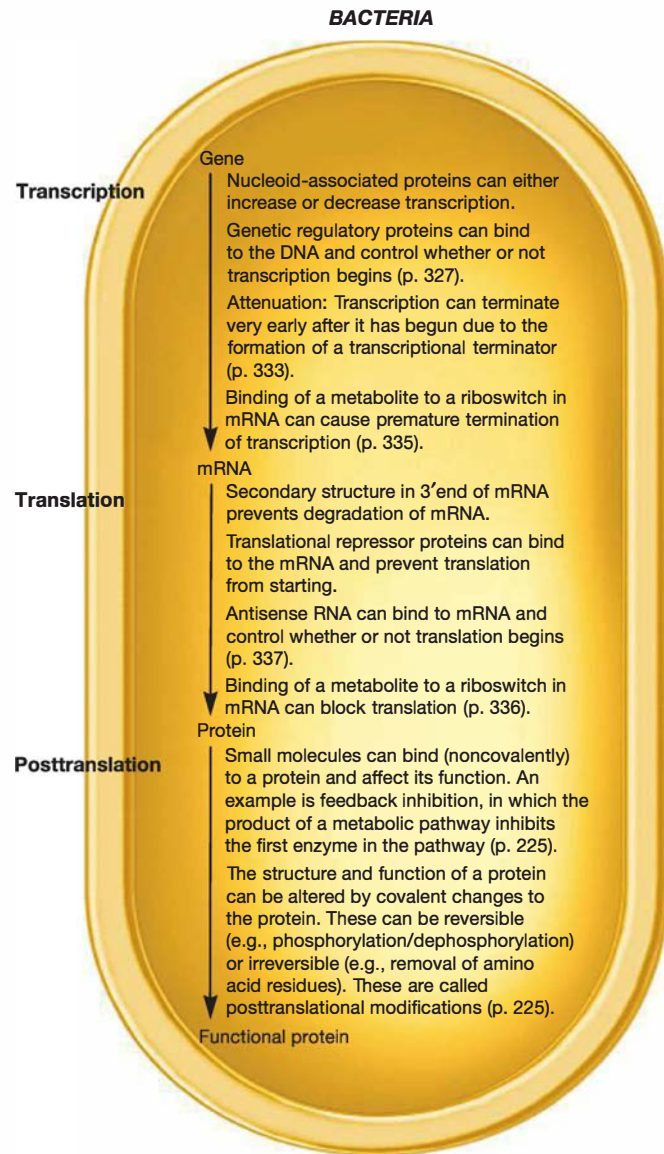

Figure 14.1 Gene Expression and Common Regulatory Mechanisms in Bacteria.

14.2 Regulation of Transcription Initiation

After reading this section, you should be able to:

- Compare and contrast housekeeping, constitutive, inducible, and repressible genes
- Describe two common motifs in DNA-binding proteins
- Summarize how negative transcriptional control and positive transcriptional control can be used to regulate both inducible and repressible genes
- Outline the regulatory “decisions” made by cells

Induction and repression are historically important, as they were the first regulatory processes for gene expression to be understood in any detail. In this section, we first describe these phenomena and then examine the underlying regulatory mechanisms.

Induction and Repression of Enzyme Synthesis

Just as an automobile or a refrigerator does not work forever and eventually must be replaced, so too enzymes remain functional only for a certain time. The “old” enzymes are eventually degraded by proteasomes and other protein-degrading systems. This degradation not only removes enzymes that may not be functioning properly but also recycles amino acids so that they can be used to synthesize new proteins. Despite the value of this, it also creates a problem for a cell because many enzymes catalyze reactions that are needed almost all the time (e.g., enzymes of the central metabolic pathways). Their functions are often referred to as “housekeeping functions,” and the genes that encode them are often called **housekeeping genes**. To maintain the proper amount of housekeeping enzymes, many housekeeping genes are expressed continuously by the cell. Those housekeeping genes that are expressed continuously are said to be **constitutive genes**. Other enzymes are only needed at certain times and in certain environments. The genes encoding these enzymes are expressed only when needed; therefore their expression is regulated. The β -galactosidase gene is an example of a regulated gene.

The enzyme β -galactosidase catalyzes hydrolysis of the disaccharide sugar lactose to glucose and galactose (figure 14.2). When *E. coli* grows with lactose as its only carbon source, each cell contains about 3,000 β -galactosidase molecules, but it has less than three molecules in the absence of lactose. β -galactosidase is an

inducible enzyme; that is, its level rises in the presence of a small effector molecule called an **inducer** (in this case, the lactose derivative allolactose). Likewise, the genes that encode inducible enzymes such as β -galactosidase are referred to as **inducible genes**.

β -galactosidase is an enzyme that functions in a catabolic pathway, and many catabolic enzymes are inducible enzymes. On the other hand, the genes for enzymes involved in biosynthetic pathways are often called **repressible genes**, and their products are called repressible enzymes. For instance, an amino acid present in the surroundings may inhibit the formation of enzymes responsible for its biosynthesis. This makes sense because the microorganism does not need the biosynthetic enzymes for a particular substance if it is already available. Generally, repressible enzymes are necessary for synthesis and are present unless the end product of their pathway is available. Inducible enzymes, in contrast, are required only when their substrate is available; they are missing in the absence of the inducer.

Control of Transcription Initiation by Regulatory Proteins

Regulatory proteins are often responsible for induction and repression. Many of these regulatory proteins are DNA-binding proteins that form dimers and attach to short, inverted sequences of bases in the DNA called palindromes. Only a small portion of the proteins actually interacts with the palindromes, and these are referred to as DNA-binding domains. Examination of numerous regulatory proteins has led to the recognition of two common motifs in DNA-binding domains: helix-turn-helix and zinc fingers.

Figure 14.2 The Reactions of β -Galactosidase. The main reaction catalyzed by β -galactosidase is the hydrolysis of lactose, a disaccharide, into the monosaccharides galactose and glucose. The enzyme also catalyzes a minor reaction that converts lactose to allolactose. Allolactose acts as the inducer of β -galactosidase synthesis.

Helix-turn-helix DNA-binding domains are often observed in bacterial regulatory proteins (e.g., *lac* repressor, *trp* repressor, and CAP; pp. 330, 331, and 341, respectively). The helix-turn-helix domains are generally about 20 amino acids in length and are folded into two α -helices (see figure A1.14) separated by a β -turn. One of the helices protrudes from the surface of the protein and is often positioned in the major groove of the DNA. Thus when the regulatory protein forms a dimer, two α -helices, one from each protein subunit, interact with the major groove of the DNA.

Zinc finger DNA-binding domains have been observed in some bacterial regulatory proteins but are most common in eukaryotic regulatory proteins. Zinc fingers are long loops formed by about 30 amino acids. The loop is stabilized by an interaction between certain amino acids in the loop and a Zn^{2+} ion. Regulatory proteins often have more than one zinc finger, each of which interacts with DNA. However, the function of each finger can differ. For instance, one finger may bind DNA nonspecifically, whereas another is important for recognition of a particular sequence in the DNA.

Regulatory proteins can exert either negative or positive control. **Negative transcriptional control** occurs when the binding of the protein to DNA inhibits initiation of transcription. Regulatory proteins that act in this fashion are called **repressor proteins**. **Positive transcriptional control** occurs when the binding of the protein to DNA promotes transcription initiation. These proteins are called **activator proteins**. 🌀 *Regulatory Proteins*

Repressor and activator proteins usually act by binding DNA at specific sites. In bacteria, repressor proteins attach to a region called the **operator**, which usually overlaps or is downstream of the promoter (i.e., closer to the coding region) (figure 14.3a,b). When bound, the repressor protein either blocks binding of RNA polymerase to the promoter or prevents its movement. Activator proteins attach to **activator-binding sites** (figure 14.3c,d). These are often upstream of the promoter (i.e., farther away from the coding region). Binding of an activator to its regulatory site generally facilitates RNA polymerase binding.

Repressor and activator proteins must exist in both active and inactive forms if transcription initiation is to be controlled appropriately. The activity of regulatory proteins is usually modified by small effector molecules, most of which bind the regulatory protein noncovalently (i.e., allosteric regulation). Figure 14.3 shows the four basic ways in which the interactions of an effector and a regulatory protein can affect transcription. (1) For negatively controlled inducible genes (e.g., those encoding enzymes needed for catabolism of a sugar), the repressor protein is active and prevents transcription when the substrate of the pathway is not available (figure 14.3a). It is inactivated by the inducer (e.g., the substrate of the pathway). (2) For negatively controlled repressible genes (e.g., those encoding enzymes needed for the synthesis of an amino acid), an inactive repressor protein, called the **aporepressor**, is initially synthesized. It is activated by the **corepressor** (figure 14.3b). For repressible enzymes that function in a biosynthetic pathway, the corepressor is often the product of the pathway (e.g., an amino acid). (3) The activator of a positively regulated inducible gene is

activated by the inducer (figure 14.3c), whereas (4) the activator of a positively regulated repressible gene is inactivated by an inhibitor (figure 14.3d). ◀◀ *Allosteric regulation (section 10.7)*

Before we continue our discussion, we must consider two general aspects of regulation. The first is that gene expression is rarely an all-or-nothing phenomenon; it is a continuum. Inhibition of transcription usually does not mean that genes are “turned off” (though this terminology is frequently used). Rather it means the level of mRNA synthesis is decreased significantly and in most cases is occurring at very low levels. In other words, many promoters of regulated genes and operons are considered “leaky” in that there is always some low, basal level of transcription. The second aspect of regulation is the “decision-making” process used by microbial cells. Although cells do not have thought processes, it is convenient to think of regulation in this way. Consider the regulatory “decisions” made by an *E. coli* cell. It need only synthesize the enzymes of a specific catabolic pathway if the substrate of the pathway is present in the environment and a preferred carbon and energy source (e.g., glucose) is not (figure 14.4; also see figure 22.4). Preferred carbon and energy sources usually are more easily catabolized or yield more energy. Thus it is to the cell’s advantage to use the preferred source before another source. Conversely, synthesis of enzymes for biosynthetic pathways is inhibited when the end product of the pathway is present.

Recall that functionally related bacterial and archaeal genes are often transcribed from a single promoter. The **structural genes**—the genes coding for nonregulatory polypeptides (e.g., enzymes)—are simply lined up together on the DNA, and a single, polycistronic mRNA carries all the messages (see figure 13.22). The sequence of bases coding for one or more polypeptides, together with the promoter and operator or activator-binding sites, is called an **operon**. Many operons have been discovered and studied. Three well-studied operons are discussed next. They demonstrate different ways that regulatory proteins can be used to control gene expression at the level of transcription initiation.

Lactose Operon: Negative Transcriptional Control of Inducible Genes

In the late 1930s Jacques Monod began examining bacterial growth and its regulation. He chose *E. coli* as a model bacterium and eventually focused his attention on genes involved in the growth of *E. coli* on lactose. He was joined in his studies about 15 years later by François Jacob. Together they developed the concept of an operon, and as a result of their studies, the lactose (*lac*) operon of *E. coli* is probably the best-studied negative control system.

The *lac* operon contains three structural genes controlled by the *lac* repressor, which is encoded by *lacI* (figure 14.5). One gene codes for β -galactosidase; a second gene directs the synthesis of β -galactoside permease, the protein responsible for lactose uptake. The third gene codes for the enzyme β -galactoside transacetylase, whose function still is uncertain. The presence of the first two genes in the same operon ensures that the rates of lactose uptake and breakdown will vary together.

Figure 14.3 Action of Bacterial Regulatory Proteins. Bacterial regulatory proteins have two binding sites, one for a small effector molecule and one for DNA. The binding of the effector molecule changes the regulatory protein's ability to attach to DNA. (a) In the absence of an inducer, the repressor protein blocks transcription. The presence of an inducer prevents the repressor from binding DNA and transcription occurs. (b) In the absence of a corepressor, the repressor is unable to bind DNA and transcription occurs. When the corepressor interacts with the repressor, the repressor is able to attach to DNA and transcription is blocked. (c) The activator protein is only able to bind DNA and activate transcription when it interacts with the inducer. (d) The activator binds DNA and promotes transcription unless the inhibitor is present. When the inhibitor is present, the activator undergoes a conformational change that prevents it from binding DNA; this inhibits transcription.

MICRO INQUIRY In what way is an inducer molecule that binds a repressor protein similar to an inhibitor molecule that binds an activator protein?

Lactose is one of many organic molecules *E. coli* can use as a carbon and energy source. It is wasteful to synthesize enzymes of the *lac* operon when lactose is not available. Therefore the cell expresses this operon at high levels when lactose is available and a preferred carbon and energy source is not; the *lac* repressor is responsible for inhibiting transcription when there is no lactose.

The *lac* repressor is composed of four identical subunits (i.e., it is a tetramer), each with a helix-turn-helix DNA-binding domain. The tetramer is formed when two dimers interact. When lactose catabolism is not required, each dimer recognizes and tightly binds one of three different *lac* operator sites: O_1 , O_2 , and O_3 (figure 14.6a). O_1 is the main operator site and must be bound by the repressor if transcription is to be inhibited. When one dimer is at O_1 and another is at one of the two other operator sites,

the dimers bring the two operator sites close together, with a loop of DNA forming between them. Attachment of the *lac* repressor is a two-step process. First, it binds nonspecifically to DNA. Then it rapidly slides along the DNA until it reaches an operator site. Two α -helices of the repressor fit into the major groove of operator-site DNA (figure 14.6b).

How does the repressor inhibit transcription? The *lac* promoter is located near the *lac* operator sites. When there is no lactose, the repressor binds O_1 and one of the other operator sites, bending the DNA in the promoter region. This prevents initiation of transcription either because RNA polymerase cannot access the promoter or because it is blocked from moving into the coding region (figure 14.7a). When lactose is available, it is brought into the cell by lactose permease. Once inside the cell, β -galactosidase converts

lactose to allolactose, the inducer of the operon (figure 14.2). This occurs because there is always a low level of permease and β -galactosidase synthesis. Allolactose noncovalently interacts with the *lac* repressor and causes the repressor to change to an inactive shape that is unable to bind any operator sites. The inactivated repressor leaves the DNA and transcription of the operon occurs (figure 14.7b).

Close examination of figures 14.5 and 14.6 clearly shows that regulation of the *lac* operon is not as simple as has just been described. That is because the *lac* operon is regulated by a second regulatory protein called catabolite activator protein (CAP). CAP functions in a global regulatory network that allows *E. coli* to use glucose preferentially over all other carbon and energy sources by a mechanism called catabolite repression. The use of two different regulatory proteins to control the expression of an operon illustrates another important point about regulatory processes—there are often layers of regulation. In the case of the lactose operon, the lactose repressor regulates gene

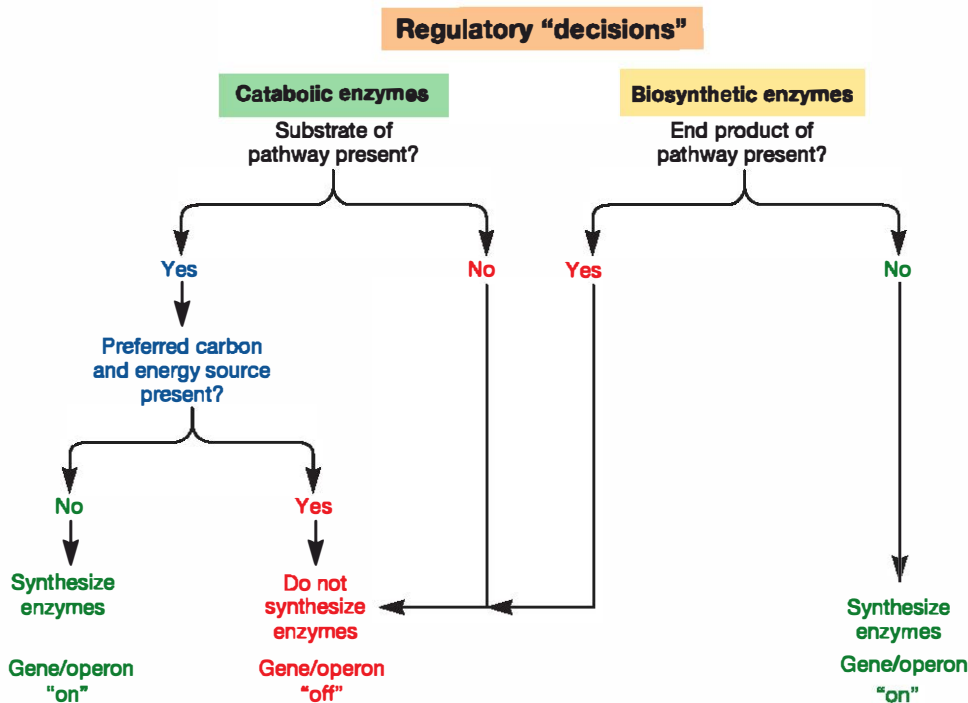

Figure 14.4 Examples of Regulatory “Decisions” Made by Cells.

Figure 14.5 The *lac* Operon. The *lac* operon consists of three structural genes—*lacZ*, *lacY*, and *lacA*—that are transcribed as a single unit from the *lac* promoter. The operon is regulated both negatively and positively. Negative control is brought about by the *lac* repressor, which is the product of the *lacI* gene. The operator is the site of *lac* repressor binding. Positive control results from the action of CAP. CAP binds the CAP site located just upstream from the *lac* promoter. CAP is partly responsible for a phenomenon called catabolite repression, an example of a global control network, in which numerous operons are controlled by a single protein (section 14.5). For simplicity, the operator is represented as a single region. In reality, the *lac* operator consists of three distinct sites, as shown in figure 14.6.

(a) Possible DNA loops caused by the binding of the lac repressor

(b) Proposed model of the *lac* repressor binding to O_1 and O_3 (red) based on crystallography studies

Figure 14.6 The *lac* Operator Sites. The *lac* operon has three operator sites: O_1 , O_2 , and O_3 (a). As shown in (a) and (b), the *lac* repressor (violet) binds O_1 and one of the other operator sites, forming a DNA loop. The DNA loop contains the -35 and -10 binding sites (green) recognized by RNA polymerase holoenzyme. Thus these sites are inaccessible and transcription is blocked. The DNA loop also contains the CAP binding site, and CAP (blue) is shown bound to the DNA (b). When the *lac* repressor is bound to the operator, CAP is unable to activate transcription.

expression in response to the presence or absence of lactose. CAP regulates the operon in response to the presence or absence of glucose. As described in section 14.5, the use of two regulatory proteins generates a continuum of expression levels. The highest levels of transcription occur when lactose is available and glucose is not; the lowest levels occur when lactose is not available and glucose is. For almost all of the examples described in this chapter, regulation occurs by more than one mechanism. 🌀 *The lac Operon*

Tryptophan Operon: Negative Transcriptional Control of Repressible Genes

The tryptophan (*trp*) operon of *E. coli* consists of five structural genes that encode enzymes needed for synthesis of the amino acid tryptophan (figure 14.8). It is regulated by the *trp* repressor, which is encoded by the *trpR* gene. Because the enzymes encoded by the *trp* operon function in a biosynthetic pathway, it is wasteful to make the enzymes needed for tryptophan synthesis when tryptophan is readily available. Therefore the operon functions only when tryptophan is not present and must be made de novo from precursor molecules (figure 14.4). To accomplish this regulatory goal, the *trp* repressor is synthesized in an inactive form that cannot bind the *trp* operator as long as tryptophan levels are low (figure 14.8a). When tryptophan levels increase, tryptophan acts as a corepressor, binding the repressor and activating it. The repressor-corepressor complex then attaches to the operator, blocking transcription initiation (figure 14.8b).

Like the *lac* operon, the *trp* operon is subject to another layer of regulation. In addition to being controlled at the level of

transcription initiation by the *trp* repressor, expression of the *trp* operon is also controlled at the level of transcription elongation by a process called attenuation. This mode of regulation is discussed in section 14.3. 🌀 *Tryptophan Repressor*

Arabinose Operon: Transcriptional Control by a Protein That Acts Both Positively and Negatively

The regulation of the *E. coli* arabinose (*ara*) operon illustrates how the same protein can function either positively or negatively, depending on the environmental conditions. The *ara* operon encodes enzymes needed for catabolism of arabinose to xylulose 5-phosphate, an intermediate of the pentose phosphate pathway. The *ara* operon is regulated by AraC, which can interact with three different regulatory sequences: *araO*₂, *araO*₁, and *araI* (figure 14.9). When arabinose is not present, one molecule of AraC binds *araI* and another binds *araO*₂. The two AraC proteins interact, causing the DNA to bend. This prevents RNA polymerase from binding to the *ara* promoter, thereby blocking transcription. In these conditions, AraC acts as a repressor (figure 14.9a). However, when arabinose is present, it binds AraC and prevents AraC molecules from interacting. This breaks the DNA loop. Furthermore, binding of two AraC-arabinose complexes to *araI* promotes transcription. Thus when arabinose is available, AraC acts as an activator (figure 14.9b). The *ara* operon, like the *lac* operon, is also subject to catabolite repression (section 14.5). 🏠 *Pentose phosphate pathway (section 11.4)*

**(b) Lactose present****Figure 14.7 Regulation of the *lac* Operon by the *lac* Repressor.**

(a) The *lac* repressor is active and can bind the operator when allolactose is not present. Binding of the repressor to the operator inhibits transcription of the operon by RNA polymerase. (b) When lactose is available, some of it is converted to allolactose by β -galactosidase. When sufficient amounts of allolactose are present, it binds and inactivates the *lac* repressor. The repressor leaves the operator and RNA polymerase is free to initiate transcription.

MICRO INQUIRY Is allolactose a corepressor or inducer molecule? Explain your answer.

Retrieve, Infer, Apply

- Many genes and operons are regulated at the level of transcription initiation. What do you think are the advantages to regulating proteins before they are made, rather than during or after translation?

**(a) Low tryptophan levels, transcription of the entire *trp* operon occurs****(b) High tryptophan levels, repression occurs****Figure 14.8 Regulation of the *trp* Operon by Tryptophan and the *trp* Repressor.**

The *trp* repressor is inactive when first synthesized and therefore is unable to bind the operator. It is activated by the binding of tryptophan, which serves as the corepressor. (a) When tryptophan levels are low, the repressor is inactive and transcription occurs. The enzymes encoded by the operon catalyze the reactions needed for tryptophan biosynthesis. (b) When tryptophan levels are sufficiently high, it binds the repressor. The repressor-corepressor complex binds the operator, and transcription of the operon is inhibited.

- What are induction and repression? How do bacteria use them to respond to changing nutrient supplies?
- Using figure 14.4 as a guide, trace the “decision-making” pathway of an *E. coli* cell that is growing in a medium containing arabinose but lacking tryptophan.
- Suppose synthesis of an amino acid was accomplished by four enzymes encoded by four genes that formed an operon. Draw a model of the operon showing how it would be controlled by positive regulation of transcription initiation.

(a) Operon inhibited in the absence of arabinose

(b) Operon activated in the presence of arabinose

Figure 14.9 Regulation of the *ara* Operon by the AraC Protein. The AraC protein can act both as a repressor and as an activator, depending on the presence or absence of arabinose. (a) When arabinose is not available, the protein acts as a repressor. Two AraC proteins are involved. One binds *araI* and the other binds *araO₂*. The two proteins interact in such a way that the DNA between the two sites is bent, making it inaccessible to RNA polymerase. (b) When arabinose is present, it binds AraC, disrupting the interaction between the two AraC proteins. Subsequently, two AraC proteins, each bound to arabinose, form a dimer, which binds to *araI*. The AraC dimer functions as an activator and transcription occurs.

14.3 Regulation of Transcription Elongation

After reading this section, you should be able to:

- Describe in general terms how the *trp* operon of *E. coli* is regulated by attenuation
- Compare and contrast regulation of transcription elongation by attenuation and riboswitches
- Explain why the coupling of transcription and translation in bacterial cells is important to the regulatory mechanisms they use

In addition to regulating transcription initiation, bacteria can also regulate transcription termination. In this type of regulation, transcription is initiated but prematurely stopped depending on the environmental conditions and the needs of the organism. Attenuation was the first example of this kind of regulation. It was discovered by Charles Yanofsky in his 1970s studies of the *trp* operon. More recently riboswitches have been discovered. These regulatory sequences in the leader of an mRNA both sense and respond to environmental conditions by either prematurely terminating transcription or blocking translation. Both attenuation and riboswitches are described in this section.

Attenuation: Ribosome Behavior Influences Transcription

As noted in section 14.2, the tryptophan (*trp*) operon of *E. coli* is under the control of a repressor protein, and excess tryptophan inhibits transcription of operon genes by acting as a corepressor and activating the repressor protein. Although the operon is regulated mainly by repression, the continuation of transcription also is controlled. That is, there are two decision points involved in transcriptional control: the initiation of transcription and the continuation of transcription into the operon's structural genes. This additional level of control serves to adjust transcription in a more subtle fashion, such that the two systems of control can decrease transcription more than either one alone. When the repressor protein is not active, RNA polymerase begins transcription of the leader. However, it often does not progress to the first structural gene in the operon. Instead, transcription is terminated within the leader; this is called **attenuation**. **◀ Bacterial gene structure (section 13.4)**

The ability to attenuate transcription is based on two things: the nature of the leader and the fact that transcription and translation are coupled in bacteria (see figure 13.33). The *trp* operon leader contains a sequence of nucleotides called *trpL*. Interestingly, a small portion of *trpL* is transcribed and translated, giving rise to a small peptide called the leader peptide. The leader peptide has never been isolated, presumably because it is rapidly degraded. In addition to encoding the leader peptide, *trpL* contains **attenuator** sequences (figure 14.10). When transcribed, these sequences form stem-loop secondary structures in the newly formed mRNA. We define these sequences numerically (regions 1, 2, 3, and 4). When regions 1 and 2 pair with one another (1:2; figure 14.10a), they form a secondary structure called the pause loop, which causes RNA polymerase to slow down. The pause loop forms just prior to the formation of the terminator loop, which is made when regions 3 and 4 base-pair (3:4; figure 14.10a). A poly-U sequence follows the 3:4 terminator loop, just as it does in factor-independent transcriptional terminators (see figure 13.28). However, in this case, the terminator is in the leader, rather than at the end of the operon. Another stem-loop structure can be formed in the mRNA by the pairing of regions 2 and 3 (2:3; figure 14.10b). The formation of this antiterminator loop prevents the generation of both the 1:2 pause and 3:4 terminator loops.

How do these various loops control transcription termination? Three scenarios describe the process. In the first, translation is not coupled to transcription because protein synthesis is not occurring. In other words, no ribosome is associated with the mRNA. In this scenario, the pause and terminator loops form, stopping transcription before RNA polymerase reaches the *trpE* gene (figure 14.10a).

In the next two scenarios, translation and transcription are coupled; that is, a ribosome initiates synthesis of the leader peptide. The interaction between RNA polymerase and the nearest ribosome determines which stem-loop structures are formed. As a ribosome translates the mRNA, it follows the RNA polymerase.

(a) No translation occurring

(b) Translation occurring, low tryptophan levels, 2:3 forms → transcription continues

(c) Translation occurring, high tryptophan levels, 3:4 forms → transcription is terminated

Among the first several nucleotides of region 1 are two tryptophan (*trp*) codons; this is unusual because normally there is only one tryptophan residue per 100 amino acids in *E. coli* proteins. If tryptophan levels are low, there will not be enough charged tRNA^{trp} to fill the A site of the ribosome when the ribosome encounters the two *trp* codons, and it will stall (figure 14.10b). Meanwhile RNA polymerase continues to transcribe mRNA, moving away from the stalled ribosome. The presence of the ribosome on region 1 prevents region 1 from base-pairing with region 2. As RNA polymerase continues, region 3 is transcribed, enabling the generation of the 2:3 antiterminator loop. This prevents the formation of the 3:4 terminator loop. Because the terminator loop is not present, RNA polymerase is not ejected from the DNA and transcription continues into the *trp* structural genes. If, on the other hand, there is plenty of tryptophan in the cell, there will be an abundance of charged tRNA^{trp}, and the ribosome will translate the two *trp* codons in the leader peptide sequence without hesitation. Thus the ribosome remains close to the RNA polymerase. As RNA polymerase and the ribosome continue through *trpL*, regions 1 and 2 are transcribed and readily form a pause loop. Then regions 3 and 4 are transcribed, the terminator loop forms, and RNA polymerase is ejected from the DNA template. Finally, the presence of a UGA stop codon between regions 1 and 2 (i.e., the end of the leader peptide-coding region) causes termination of translation (figure 14.10c). ◀ The genetic code (section 13.6)

How is attenuation useful to *E. coli*? If the bacterium is deficient in an amino acid other than tryptophan, protein synthesis will slow and tryptophanyl-tRNA^{trp} (trp-tRNA) will accumulate. Transcription of the tryptophan operon will be inhibited by attenuation. When the bacterium begins to synthesize protein rapidly,

Figure 14.10 Attenuation of the *trp* Operon.

(a) When protein synthesis has slowed, transcription and translation are not tightly coupled. Under these conditions, the most stable form of the mRNA occurs when region 1 hydrogen bonds to region 2 (RNA polymerase pause loop) and region 3 hydrogen bonds to region 4 (transcription terminator or attenuator loop). The formation of the transcription terminator causes transcription to stop within *trpL*. (b) When protein synthesis is occurring, transcription and translation are coupled, and the behavior of the ribosome on *trpL* influences transcription. If tryptophan levels are low, the ribosome pauses at the *trp* codons in *trpL* because of insufficient amounts of charged tRNA^{trp}. This blocks region 1 of the mRNA, so that region 2 can hydrogen bond only with region 3. Because region 3 is already hydrogen bonded to region 2, the 3:4 terminator loop cannot form. Transcription proceeds and the *trp* biosynthetic enzymes are made. (c) If tryptophan levels are high, translation of *trpL* progresses to the stop codon, blocking region 2. Regions 3 and 4 can hydrogen bond and transcription terminates.

MICRO INQUIRY How does this attenuation respond to rates of protein synthesis in addition to the intracellular level of tryptophan?

tryptophan may be scarce and the concentration of trp-tRNA may be low. This would reduce attenuation activity and stimulate operon transcription, resulting in larger quantities of the tryptophan biosynthetic enzymes. Acting together, repression and attenuation can coordinate the rate of synthesis of amino acid biosynthetic enzymes with the availability of amino acid end products and with the overall rate of protein synthesis. When tryptophan is present at high concentrations, any RNA polymerases not blocked by the activated repressor protein probably will not get past the attenuator sequence. Repression decreases transcription about 70-fold and attenuation slows it another eight- to ten-fold; when both mechanisms operate together, transcription can be slowed about 600-fold.

Attenuation is important in regulating at least five other operons that encode amino acid biosynthetic enzymes. In all cases, the leader peptide sequences resemble the tryptophan system in organization. For example, the leader peptide sequence of the histidine operon codes for seven histidines in a row and is followed by an attenuator that is a terminator sequence.

Riboswitches: Effector Molecule–mRNA Interaction Regulates Transcription

Regulation by riboswitches (also called sensory RNAs) is a specialized form of transcription attenuation that involves mRNA folding but not ribosome behavior. In this case, if the leader of an mRNA is folded one way, transcription continues; if folded another, transcription is terminated. The leader is called a **riboswitch** because it is analogous to a light switch turning lights on or off, depending on whether the switch is in the on position (one folding pattern of the mRNA) or the off position (another folding pattern of the mRNA). What makes riboswitches unique and exciting is that the mRNA folding pattern is determined by binding of an effector molecule directly to the mRNA—a capability previously thought confined to proteins.

The riboswitch that regulates the riboflavin (*rib*) biosynthetic operon of *Bacillus subtilis* serves as an example (figure 14.11). The production of riboflavin biosynthetic enzymes is repressed by flavin mononucleotide (FMN), which is derived from riboflavin. When transcription of the *rib* operon begins, sequences in the leader of the mRNA fold into a structure called the RFN-element. This element binds FMN and in doing so alters the folding of the leader, creating a terminator that stops transcription.

Controlling transcription with sensory RNAs is an important method used by Gram-positive bacteria to regulate amino acid-related genes. As with the *rib* operon, the leaders of these mRNAs contain a regulatory element. In this case, the region is called the T box. T box sequences give rise to competing terminator and antiterminator loops. The development of either a terminator or an antiterminator is determined by the binding of an uncharged tRNA corresponding to the relevant amino acid. For instance, expression of a tyrosyl-tRNA synthetase gene (i.e., a gene that encodes the enzyme that links tyrosine to a tRNA molecule) is governed by the presence of tRNA^{Tyr}. When the level of charged tRNA^{Tyr} falls, the anticodon of an uncharged tRNA binds directly to the “specifier sequence” codon in the leader of the mRNA. At the same time, the antiterminator loop is stabilized by base-pairing between sequences in the loop and the acceptor end of the tRNA, which normally binds the amino acid. This prevents formation of the terminator structure, and transcription of the tyrosyl-tRNA synthetase gene continues. Genomic analysis suggests that the T box mechanism may be involved in regulating over 300 genes and operons.

Some other genes that bear sensory RNAs in their leaders are listed in table 14.1. In addition, some riboswitches bind cyclic dimeric GMP (c-di-GMP; p. 339), the second messenger described in the chapter opening story. Finally, some riboswitches have been shown to function at the level of translation. They are described in section 14.4.

Figure 14.11 Riboswitch Control of the Riboflavin (*rib*) Operon of *Bacillus subtilis*. The *rib* operon produces enzymes needed for the synthesis of riboflavin, a component of flavin mononucleotide (FMN). Binding of FMN to the *rfn* (rifampin) box in the leader of *rib* mRNA causes the formation of a transcription terminator and cessation of transcription.

Table 14.1 Regulation of Gene Expression by Riboswitches

| System | Microbe(s) | Target genes encode: | Effector and Regulatory Response |
|---------------------------------|---|--|---|
| T box | Many Gram-positive bacteria | Amino acid biosynthetic enzymes | Uncharged tRNA; anticodon base-pairs to 5' end of mRNA, preventing formation of transcriptional terminator. |
| Vitamin B ₁₂ element | <i>E. coli</i> | Cobalamine biosynthetic enzymes | Adenosylcobalamine (AdoCbl) binds to <i>btuB</i> mRNA and blocks translation. |
| THI box | <i>Rhizobium etli</i> <i>E. coli</i> <i>Bacillus subtilis</i> | Thiamine (vitamin B ₁) biosynthetic and transport proteins | Thiamine pyrophosphate (TPP) causes either premature transcriptional termination (<i>R. etli</i> , <i>B. subtilis</i>) or blocks ribosome binding (<i>E. coli</i>). |
| RFN-element | <i>B. subtilis</i> | Riboflavin biosynthetic enzymes | Flavin mononucleotide (FMN) causes premature transcriptional termination. |
| S box | Low G + C Gram-positive bacteria | Methionine biosynthetic enzymes | S-adenosylmethionine (SAM) causes premature transcriptional termination. |

14.4 Regulation of Translation

After reading this section, you should be able to:

- Distinguish translational riboswitches from transcriptional riboswitches
- Discuss regulation of translation by antisense RNAs

It appears that in general, the riboswitches found in Gram-positive bacteria function by transcriptional termination, whereas the riboswitches discovered in Gram-negative bacteria regulate the translation of mRNA. Translation is usually regulated by blocking its initiation. In addition, some small RNA molecules can control translation initiation of target mRNAs. Both riboswitch and small RNA regulatory mechanisms are described now.

Regulation of Translation by Riboswitches

Similar to the riboswitches described in section 14.3, riboswitches that function at the translational level contain effector-binding elements at the 5' end of the mRNA. Binding of the effector molecule affects the folding pattern of the mRNA leader, which often results in occlusion of the Shine-Dalgarno sequence and other elements of the ribosome-binding site. This inhibits ribosome binding and initiation of translation (figure 14.12). An example of this type of regulation is observed for the thiamine biosynthetic operons of numerous bacteria and some archaea. The leaders of thiamine operons contain a structure called the THI-element, which can bind thiamine pyrophosphate. Association of thiamine pyrophosphate with the THI-element causes a conformational change in the leader that sequesters the Shine-Dalgarno sequence and blocks translation initiation.

Regulation of Translation by Small RNA Molecules

A large number of RNA molecules have been discovered that do not function as mRNAs, tRNAs, or rRNAs. Microbiologists often refer to them as **small RNAs (sRNAs)** or as noncoding RNAs

(ncRNAs). In *E. coli*, there are thought to be about 100 sRNAs, ranging in size from around 40 to 400 nucleotides. Eukaryotes may have hundreds to thousands of ncRNAs with lengths from 21 to over 10,000 nucleotides. Although some sRNAs have been

Figure 14.12 Regulation of Translation by a Riboswitch. In the absence of a relevant metabolite, an effector binding site is formed in the leader of the mRNA (red) when complementary sequences (orange box and green box) hydrogen bond. This folding pattern exposes important sequences in the ribosome-binding site (e.g., the Shine-Dalgarno sequence; blue box) and translation occurs. When the appropriate effector molecule is present, it binds the leader, creating a structure containing the ribosome-binding site. Thus the ribosome-binding site becomes inaccessible and translation is blocked.

implicated in the regulation of DNA replication and transcription, many function at the level of translation.

In *E. coli*, most sRNAs regulate translation by base-pairing to the leader region of a target mRNA. Thus they are complementary to the mRNA and are called **antisense RNAs**. It seems intuitive that by binding to the leader, antisense RNAs would block ribosome attachment and inhibit translation. Indeed, many antisense RNAs work in this manner. However, some antisense RNAs actually promote translation upon binding to the mRNA. Whether inhibiting or activating, most *E. coli* antisense RNAs work with a protein called Hfq to regulate their target RNAs. Hfq is an RNA chaperone; that is, it interacts with RNA to promote changes in its structure. In addition, Hfq may promote RNA-RNA interactions.

The regulation of synthesis of the OmpF porin protein provides an example of translation control by an antisense RNA. Recall that the outer membrane of Gram-negative bacteria contains channels made of porin proteins (see figure 3.27). The two most important porins in *E. coli* are OmpF and OmpC (Omp for outer membrane protein). OmpC pores are slightly smaller and are made when the bacterium grows at high osmotic pressures. It is the dominant porin when *E. coli* is in the intestinal tract. The larger OmpF pores are favored when *E. coli* grows in a dilute environment; OmpF allows solutes (e.g., nutrients) to diffuse into the cell more readily. The cell must maintain a constant level of porin protein in the membrane, with the relative levels of the two porins corresponding to the osmolarity of the medium. Expression of the *ompF* gene is regulated by an antisense RNA called MicF RNA, the product of the *micF* gene (*mic* for mRNA-interfering complementary RNA). The MicF RNA is complemen-

Figure 14.13 Regulation of Translation by Antisense RNA.

The *ompF* mRNA encodes the porin OmpF. Translation of this mRNA is regulated by the antisense RNA MicF, the product of the *micF* gene. MicF is complementary to the *ompF* mRNA and, when bound to it, prevents translation.

MICRO INQUIRY How does the inhibition of translation by antisense RNA differ from translational inhibition by riboswitches?

tary to *ompF* mRNA at the translation initiation site (figure 14.13). Therefore, when MicF RNA base-pairs with *ompF* mRNA, translation is repressed. MicF RNA is produced under conditions such as high osmotic pressure or the presence of some toxic material, both of which favor *ompC* expression. Production of MicF RNA helps ensure that OmpF protein is not produced at high levels at the same time as OmpC protein. Some other antisense RNAs are listed in table 14.2. In addition to being regulated by an antisense RNA, *ompF* (and *ompC*) is regulated by a two-component signal transduction system, as we describe in section 14.5.

Table 14.2 Regulation of Gene Expression by Small Regulatory RNAs

| Small RNA | Size | Bacterium | Function |
|--------------|--------------------|--|---|
| RhyB | 90 nt ¹ | <i>E. coli</i> | Represses translation of mRNAs encoding iron-containing proteins when iron availability is low |
| Spot 42 | 109 nt | <i>E. coli</i> | Inhibits translation of <i>galK</i> mRNA (encodes galactokinase) |
| Rpr A | 105 nt | <i>E. coli</i> | Promotes translation of <i>rpoS</i> mRNA (encodes σ^s , a stationary phase sigma factor); antisense repressor of global negative regulator H-NS (involved in stress responses) |
| MicF | 109 nt | <i>E. coli</i> | Inhibits <i>ompF</i> mRNA translation |
| OxyS | 109 nt | <i>E. coli</i> | Inhibits translation of transcriptional regulator <i>fnrA</i> mRNA and <i>rpoS</i> mRNA |
| DsrA | 85 nt | <i>E. coli</i> | Increases translation of <i>rpoS</i> mRNA |
| CsrB | 366 nt | <i>E. coli</i> | Inhibits CsrA, a translational regulatory protein that positively regulates flagella synthesis, acetate metabolism, and glycolysis |
| RNAIII | 512 nt | <i>Staphylococcus aureus</i> | Activates genes encoding secreted proteins (e.g., α -hemolysin); represses genes encoding surface proteins |
| RNA α | 650 nt | <i>Vibrio anguillarum</i> | Decreased expression of fat, an iron-uptake protein |
| RsmB' | 259 nt | <i>Erwinia carotovora</i> subsp. <i>carotovora</i> | Stabilizes mRNA of virulence proteins (e.g., cellulases, proteases, pectinolytic enzymes) |

1 nt: nucleotides

Retrieve, Infer, Apply

1. What are the functions of *trpL* and the ribosome in attenuation?
2. Describe how attenuation would change in *E. coli* from its inoculation into a tryptophan-rich medium to one that is tryptophan deficient.
3. What are translational riboswitches? How are they similar to attenuation as described for the *trp* operon? How do they differ? How do translational riboswitches differ from sRNAs?
4. Suggest a mechanism by which *micF* transcription might be regulated.

14.5 Regulating Complex Cellular Processes

After reading this section, you should be able to:

- Compare and contrast two-component signal transduction systems with phosphorelay signal transduction systems
- List the nucleotides that are used by bacteria as second messengers
- Explain how alternate sigma factors can be used to initiate transcription of distinct sets of operons
- Summarize how CAP, cAMP, and the *lac* repressor work together to cause diauxic growth as well as other outcomes related to regulation of the lactose operon
- Hypothesize how other operons encoding catabolic enzymes might be regulated by catabolite repression
- Outline how the proteins of the *E. coli* chemotaxis system function to control flagellar rotation in the presence of a chemoattractant
- Predict the events that would occur if *E. coli* cells were in a gradient of a chemorepellent
- Differentiate quorum sensing observed in *Vibrio fischeri* from that in *Vibrio harveyi*
- Describe the stringent response
- Outline the regulatory mechanisms used by *Bacillus subtilis* to control endospore formation

Thus far, we have considered the function of isolated operons. It is usually possible to regulate all the genes of a metabolic pathway in a single operon. However, this is not possible for more complex cellular processes that involve too many genes to be accommodated in a single operon. For example, the machinery required for protein synthesis is composed of 150 or more gene products, and coordination requires a regulatory network that controls many separate operons. Regulatory systems that affect many genes, operons, and pathways simultaneously are called **global regulatory systems**. In this section, we consider some ways bacteria control complex processes using global regulation. We begin by introducing some common “themes” in global regulation. We then provide several examples that illustrate the use of these common mechanisms.

Mechanisms Used for Global Regulation

Bacteria have several tools in their regulatory tool belts that enable them to control processes such as chemotaxis, translation,

quorum sensing, and endospore formation. Perhaps the simplest approach is to use a single **global regulatory protein** to alter the expression of multiple operons (or genes). In some cases, the global repressor or activator is the only mechanism of control for the operons. In this case, the collection of genes and operons is referred to as a **regulon**. Usually the operons are associated with a single pathway or function (e.g., the catabolism of glycerol). A somewhat more complex situation is seen with a **modulon**. This is an operon network under the control of a common global regulatory protein but whose constituent operons also are controlled separately by their own regulators. A good example of a modulon is catabolite repression, which is discussed on p. 340. Global regulatory proteins can also function in stimulons. A stimulon is a regulatory system in which all operons respond together in a coordinated way to an environmental stimulus. It may contain several regulons and modulons, and some of these may not share regulatory proteins, or they may be controlled by other mechanisms such as those described next.

Another approach to global regulation is used in response to environmental conditions that do not produce a metabolite that can interact directly with a regulatory protein (e.g., as we saw for the *lac* repressor, *trp* repressor, and AraC; pp. 330, 331, and 331, respectively). These conditions include temperature, osmolarity, oxygen levels, and other environmental conditions. Responses to these external changes are controlled by regulatory proteins that make up **two-component signal transduction systems**. These systems link events occurring outside the cell to gene expression inside the cell.

Two-component signal transduction systems have been identified in members of all three domains of life and are named after the two proteins that govern the regulatory pathway. The first is a **sensor kinase** that spans the plasma membrane so that part of it is exposed to the extracellular environment (periplasm in Gram-negative bacteria), while another part is exposed to the cytoplasm. In this way, the sensor kinase can detect specific changes in the environment and communicate information to the cell's interior. The second component is the **response regulator**. There are two types of response regulators. Most are DNA-binding proteins that, when activated by the sensor kinase, can act as either activators or repressors of transcription initiation. Other response regulators function posttranslationally to control the activity of enzymes or other proteins in the global network. An example of this type of system is chemotaxis, which is described on p. 342.

The EnvZ/OmpR system is an excellent example of a two-component signal transduction system that functions at the level of transcription; it is used to control porin production in *E. coli*. As we introduce in section 14.4, *E. coli* uses an antisense RNA to control OmpF production. In addition, regulation of the ratio of OmpF and OmpC porin proteins is controlled by a sensor kinase EnvZ (Env for cell *envelope*) and a response regulator OmpR. EnvZ is a homodimeric protein that is an integral membrane protein anchored to the membrane by two membrane-spanning domains. EnvZ is looped through the membrane such that a central domain protrudes into the periplasm, while the amino and carboxyl termini are exposed to the cytoplasm (**figure 14.14**).

Figure 14.14 Two-Component Signal Transduction System and the Regulation of Porin Proteins. In this system, the sensor kinase protein EnvZ loops through the cytoplasmic membrane so that both its C- and N-termini are in the cytoplasm. When EnvZ senses an increase in osmolarity, it autophosphorylates a histidine residue at its C-terminus. EnvZ then passes the phosphoryl group to the response regulator OmpR, which accepts it on an aspartic acid residue located in its N-terminus. This activates OmpR so that it is able to bind DNA and repress *ompF* expression and enhance that of *ompC*.

MICRO INQUIRY Relative to each promoter, where would you predict phosphorylated OmpR would bind the *ompC* and *ompF* genes?

The response regulator OmpR is a soluble, cytoplasmic protein that controls transcription of the *ompF* and *ompC* structural genes. The N-terminal end of OmpR is called the receiver domain because it possesses a specific aspartic acid residue that accepts the signal (a phosphoryl group) from the sensor kinase. Upon receipt of the signal, the C-terminal end of OmpR is able to regulate transcription by binding DNA. When EnvZ senses high osmolarity, it phosphorylates itself (autophosphorylation) on a specific histidine residue. This phosphoryl group is quickly transferred to the N-terminus of OmpR. Once OmpR is phosphorylated, it is able to regulate transcription of the porin genes so that *ompF* transcription is repressed and *ompC* transcription is activated.

Homologues of OmpR have been identified in other enterobacteria in addition to *E. coli*. In these organisms, OmpR regulates expression of *ompF* and *ompC* but has other functions as well. For instance, it also controls synthesis of a type of fimbriae in *E. coli* called curli fimbriae. In various *Salmonella* species, it regulates virulence genes, including some located in a pathogenicity island. ◀◀ *Bacterial pili and fimbriae* (section 3.7); ▶▶ *Pathogenicity islands* (section 35.2)

Two-component signal transduction systems involve a simple phosphorelay where the sensor kinase transfers a phosphoryl group directly to the response regulator. However, there are

instances when more proteins participate in the transfer of phosphoryl groups. These more complex pathways are called **phosphorelay systems**. Phosphorelays are important control measures observed in quorum-sensing by *Vibrio harveyi* (p. 347) and endospore formation by *B. subtilis* (p. 349). The effectiveness of two-component phosphorelay systems is illustrated by their abundance. Most bacterial and archaeal cells use a variety of these systems to respond to an array of environmental stresses. For example, members of the soil bacterial genus *Streptomyces* have at least 80 such systems.

Many bacteria use **second messengers** in their global control systems. Second messengers are small molecules produced within a cell in response to a signal (i.e., the first messenger) that is outside the cell. Two bacterial second messengers were discovered many years ago: cyclic adenosine monophosphate (cAMP) and guanosine tetraphosphate (ppGpp). One of the newest additions to the bacterial second messenger family is **cyclic dimeric GMP (c-di-GMP; figure 14.15a)**. The role of cAMP in catabolite repression and that of ppGpp in the stringent response are discussed on pages 341 and 348, respectively. Here we consider c-di-GMP.

The second messenger c-di-GMP is synthesized by enzymes called diguanylate cyclases (DGCs). Once formed, c-di-GMP functions until it is destroyed by enzymes called phosphodiesterases

Figure 14.15 Cyclic Dimeric GMP. (a) Structure of cyclic dimeric GMP (c-di-GMP). This second messenger consists of two GMP molecules linked together by their phosphates. (b) The two enzymes that control levels of c-di-GMP in cells. Diguanylate cyclases form c-di-GMP and phosphodiesterases degrade c-di-GMP.

(PDEs; figure 14.15b). Each type of enzyme has a characteristic sequence of amino acids: GGDEF for DGCs, and EAL (or HD-GYP) for PDEs (see table 13.3). C-di-GMP was discovered in the 1980s but drew relatively little interest until the annotation of many bacterial genomes led to the discovery that an unexpectedly large number of proteins contained the characteristic GGDEF and EAL sequences. When the expression of these proteins was increased by genetic manipulation, a host of important and complex behaviors were affected. These included biofilm formation, motility, and production of virulence factors. Interestingly, if a GGDEF-containing protein was overexpressed and affected a particular behavior, then overexpression of an EAL-containing protein had the opposite effect on the same behavior.

Only recently have scientists begun to unravel the mechanism of action of c-di-GMP. Both DGCs and PDEs have at least one sensory domain that can detect environmental signals such as oxygen levels, decreasing nutrients, and light. When a DGC detects its signal, it catalyzes formation of c-di-GMP. When PDE receives its signal, it degrades c-di-GMP. When c-di-GMP is available, it interacts with an effector. Most effectors thus far identified are proteins, but as we note in section 14.3, some are riboswitches. Upon interacting with c-di-GMP, the effector is able to influence the activity of its target. Some effectors are transcriptional regulatory proteins and thus control transcription. Others act posttranslationally, directly changing the activity of enzymes.

Recall from this chapter's opening story that *P. fluorescens* is able to “decide” whether to stay in or flee a biofilm. How is this accomplished? The answer is an “inside-out” signaling pathway where c-di-GMP plays a central role as a second messenger communicating phosphate levels to an effector called LapD. The DGC and PDE involved sense phosphate levels (the signal) and respond accordingly. When phosphate levels are high, DGC activity is high and PDE activity is low. Thus, c-di-GMP levels are high. It enters a pocket in a cytoplasmic domain in LapD, a protein embedded in the plasma membrane.

LapD (the effector) also has a domain that extends into the periplasmic space. When c-di-GMP is in the pocket, LapD assumes a shape that promotes interaction with the protease LapG (the target), sequestering it. LapG is unable to cleave LapA, and cells form or remain in a biofilm. When phosphate levels decrease, PDE activity increases, and the enzyme destroys c-di-GMP. With no c-di-GMP in the LapD pocket, LapD undergoes a conformational change and LapG is released. It cleaves LapA, and the cell is free to leave the biofilm.

The final mechanism we introduce is unique to bacteria: the use of **alternate sigma factors**, which can immediately change expression of many genes as they direct RNA polymerase to specific subsets of bacterial genes. This is possible because RNA polymerase core enzyme needs the assistance of a sigma factor to bind a promoter and initiate transcription. Each sigma factor

recognizes promoters that differ in sequence (see table 13.2).

◀ Transcription in bacteria (section 13.5)

E. coli synthesizes several sigma factors (table 14.3). Under normal conditions, a sigma factor called σ^{70} directs RNA polymerase activity. (The superscript number or letter indicates the size or function of the sigma factor; 70 stands for 70,000 daltons.) When flagella and chemotactic proteins are needed, *E. coli* produces σ^F (σ^{28}). σ^F then binds its consensus sequences in promoters of genes whose products are needed for flagella biosynthesis and chemotaxis. If the temperature rises too high, σ^H (σ^{32}) is produced and stimulates the formation of about 17 heat-shock proteins that protect the cell from thermal destruction. Importantly, each sigma factor has its own set of promoter consensus sequences to which it binds (see table 13.2).

In the remainder of this section, we explore several examples of global control networks. As you examine these examples, notice that many involve multiple mechanisms of control that function at different levels (e.g., transcriptionally or posttranslationally). Remember that these examples were chosen because they are relatively well studied and are important model systems for understanding the regulation of even more complex networks. We encourage you to imagine how these models might help elucidate the control of the cell cycle, developmental processes such as fruiting body formation by *Myxococcus* spp., or the expression of virulence factors by pathogenic bacteria. We begin these discussions by returning to the “grand daddy” of operons, the lactose operon and its regulation by catabolite repression. ▶▶ Order Myxococcales (section 22.4)

Catabolite Repression in *E. coli*

If *E. coli* grows in a medium containing both glucose and lactose, it uses glucose preferentially until the sugar is exhausted. Then after a shortlag, growth resumes at a slower rate with lactose as the carbon source (figure 14.16). This allows glucose, the more easily catabolized and more energy-yielding molecule, to be used first, followed by other energy sources that may be more difficult to degrade or yield less energy. This biphasic growth pattern is called

Table 14.3 *E. coli* Sigma Factors

| Sigma Factor | Genes Transcribed |
|------------------------------|---|
| σ^{70} | Genes needed during exponential growth |
| σ^S | Genes needed during the general stress response and during stationary phase |
| σ^E | Genes needed to restore membrane integrity and the proper folding of membrane proteins |
| σ^H (σ^{32}) | Genes needed to protect against heat shock and other stresses, including genes encoding chaperones that help maintain or restore proper folding of cytoplasmic proteins and proteases that degrade damaged proteins |
| FecI σ | Genes that encode the iron citrate transport machinery in response to iron starvation and the availability of iron citrate |
| σ^F (σ^{28}) | Genes involved in flagellum assembly |
| σ^{60} | Genes involved in nitrogen metabolism |

diauxic growth. The cause of diauxic growth is complex and not completely understood, but **catabolite repression** plays a part. The enzymes for glucose catabolism are constitutive. However, operons that encode enzymes required for the catabolism of carbon sources that must first be modified before entering glycolysis (e.g., the *lac* operon) are regulated by catabolite repression. These include the *ara*, *mal* (maltose), and *gal* (galactose) operons, as well as the *lac* operon. Collectively, these can be called catabolite operons, and their expression is coordinately repressed when glucose is plentiful.

Figure 14.16 **Diauxic Growth.** The diauxic growth curve of *E. coli* grown with a mixture of glucose and lactose. Glucose is first used, then lactose. A short lag in growth is present while the bacteria synthesize the enzymes needed for lactose use.

MICRO INQUIRY For what other compounds would you also see this kind of diauxic growth?

The coordinated regulation of catabolite operons is brought about by **catabolite activator protein (CAP)**, which is also called **cyclic AMP receptor protein (CRP)**. CAP exists in two states. It is active when the small cyclic nucleotide **3', 5'-cyclic adenosine monophosphate (cAMP; figure 14.17)** is bound, and it is inactive

Figure 14.17 **Cyclic Adenosine Monophosphate (cAMP).** The phosphate extends between the 3' and 5' hydroxyls of the ribose sugar. The enzyme adenyl cyclase forms cAMP from ATP.

when it is free of cAMP. The levels of cAMP are controlled by the enzyme adenyl cyclase, which converts ATP to cAMP and PP_i . Adenyl cyclase is active only when little or no glucose is available. Thus the level of cAMP varies inversely with that of glucose. When glucose is unavailable and the catabolism of another sugar might be needed, the amount of cAMP in the cell increases, allowing cAMP to bind to and activate CAP.

All catabolite operons contain a CAP recognition site, and CAP must be bound to this site before RNA polymerase can begin transcription. Upon binding, CAP bends the DNA within two helical turns, which stimulates transcription (figure 14.6b and figure 14.18). Thus all catabolite operons are controlled by two regulatory proteins: the regulatory protein specific to each operon (e.g., *lac* repressor and AraC protein) and CAP. In the case of the *lac* operon, if glucose is absent and lactose is present, the inducer allolactose will bind to and inactivate the *lac* repressor protein, CAP will be in the active form (with cAMP attached), and transcription will proceed (figure 14.19a). However, if glucose and lactose are both in short supply, even though CAP binds to its site on the DNA, transcription will be inhibited by the presence of the repressor protein, which remains bound to the operator in the absence of inducer (figure 14.19c). Dual control ensures that the *lac* operon is expressed only when lactose catabolic genes are needed.

We have seen how CAP controls catabolite operons; now let's turn our attention to the regulation of the levels of cAMP. The decrease in cAMP levels that occurs when glucose is present is due to the effect of the phosphoenolpyruvate:sugar phosphotransferase system (PTS) on the activity of adenyl cyclase (figure 14.20). Recall from chapter 3 that in the PTS, a phosphoryl group is transferred by a series of proteins from phosphoenolpyruvate (PEP) to glucose, which then enters the cell as glucose 6-phosphate (see figure 3.14). When glucose is present, enzyme IIA transfers the phosphoryl group to enzyme IIB, which phosphorylates glucose. However, when glucose is absent, the phosphoryl groups from PEP are transferred to enzyme IIA but are not transferred to enzyme IIB. The phosphorylated form of enzyme IIA accumulates. This form of the enzyme activates adenyl cyclase, stimulating cAMP production.

◀◀ Group translocation (section 3.3) 🔗 Combination of Switches: The *lac* Operon

Catabolite repression is of considerable advantage to *E. coli*. It will use the most easily catabolized sugar (glucose) first, rather than synthesize the enzymes necessary for catabolism of another carbon and energy source. Catabolite repression is used by a variety of bacteria to regulate numerous metabolic pathways.

Chemotaxis in *E. coli*

Recall from chapter 3 that bacteria are able to sense chemicals in their environment and move either toward them or away from them, depending on whether the chemical is an attractant or a repellent. For simplicity, we only concern ourselves with movement toward an attractant. The best-studied chemotactic system

(b)

Figure 14.18 CAP Structure and DNA Binding. (a) The CAP dimer binding to DNA at the *lac* operon promoter. The recognition helices fit into two adjacent major grooves on the double helix. (b) A model of the *E. coli* CAP-DNA complex derived from crystal structure studies. The cAMP-binding domain is in blue and the DNA-binding domain, in purple. The cAMP molecules bound to CAP are in red. Note that the DNA is bent when complexed with CAP.

is that of *E. coli*, which, like many other peritrichously flagellated bacteria, exhibits two movement modalities: a smooth swimming motion called a run, which is interrupted by the second type of movement called a tumble. A run occurs when the flagellum rotates in a counterclockwise direction (CCW), and a tumble occurs when the flagellum rotates clockwise

Figure 14.19 Regulation of the *lac* Operon by the *lac* Repressor and CAP. A continuum of *lac* mRNA synthesis is brought about by the action of CAP, an activator protein, and the *lac* repressor. (a) When lactose is available and glucose is not, the repressor is inactivated and cAMP levels increase. Cyclic AMP binds CAP, activating it. CAP binds the CAP binding site near the *lac* promoter and facilitates binding of RNA polymerase. Under these conditions, transcription occurs at maximal levels. (b) When both lactose and glucose are available, both CAP and the *lac* repressor are inactive. Because RNA polymerase cannot bind the promoter efficiently without the aid of CAP, transcription levels are low. (c) When neither glucose nor lactose is available, both CAP and the *lac* repressor are active. In this situation, both proteins are bound to their regulatory sites. CAP binding enhances the binding of RNA polymerase to the promoter. However, the repressor blocks transcription. Transcription levels are low. (d) When glucose is available and lactose is not, CAP is inactive and the *lac* repressor is active. Thus RNA polymerase binds inefficiently, and those polymerase molecules that do bind are blocked by the repressor. This condition results in the lowest levels of transcription observed for the *lac* operon.

Figure 14.20 Activation of Adenyl Cyclase by the Phosphoenolpyruate: Sugar Phosphotransferase System (PTS). PEP is phosphoenolpyruvate. EI and EII are enzymes I and II of the PTS, respectively. EII is composed of three subunits: A, B, and C. HPr stands for heat-stable protein. A factor called factor x is also involved in activating the adenyl cyclase enzyme (not shown). It has never been isolated, and its nature is not known.

(CW) (see figures 3.46 and 3.51). The cell alternates between these two types of movements, with the tumble establishing the direction of movement in the run that follows.

When *E. coli* is in an environment that is homogenous—that is, the concentration of all chemicals in the environment is the same throughout its habitat—the cell moves about randomly, with no apparent direction or purpose; this is called a random walk. However, if a chemical gradient exists in its environment, the frequency of tumbles decreases as long as the cell is moving toward the attractant. In other words, the length of time spent moving toward the attractant is increased, and eventually the cell gets closer to the attractant. The process is not perfect, and the cell must continually readjust its direction through a trial-and-error process that is mediated by tumbling. When one examines the path taken by the cell, it is similar to a random walk but is biased toward the attractant.

For many decades, scientists have been dissecting this complex behavior in order to understand how *E. coli* senses the presence of an attractant, how it switches from a run to a tumble and back again, and how it “knows” it is heading in the correct direction. These studies reveal that the chemotactic response of *E. coli* involves a phosphorelay system and covalent modification of chemotaxis receptors. As we noted previously, most phosphorelay systems are used to regulate transcription initiation (p. 338).

However, some regulate enzyme activity. This is the case for chemotaxis.

For chemotaxis to occur, *E. coli* must determine if an attractant is present and then modulate the activity of the phosphorelay system that dictates the rotational direction of the flagellum (i.e., either run or tumble). *E. coli* senses chemicals in its environment when they bind to chemoreceptors (figure 14.21). Numerous che-

moreceptors have been identified. Here we focus on one class of receptors called methyl-accepting chemotaxis proteins (MCPs). The phosphorelay system that controls direction of flagellar rotation consists of the sensor kinase CheA and the response regulator CheY. When activated, CheA phosphorylates itself using ATP (figure 14.21c). The phosphoryl group is then quickly transferred to CheY. Phosphorylated CheY diffuses through the cytoplasm to

Figure 14.21 Proteins and Signaling Pathways of the Chemotaxis Response in *E. coli*. (a) The methyl-accepting chemotaxis proteins (MCPs) form clusters associated with the CheA and CheW proteins. CheA is a sensor kinase that, when activated, phosphorylates CheB, a methylesterase, or CheY. Phosphorylated CheY interacts with the FliM protein of the flagellar motor, causing rotation of the flagellum to switch from counterclockwise (CCW) to clockwise (CW). This results in a switch from a run (CCW rotation) to a tumble (CW rotation). (b) MCPs, CheW, and CheA complexes form large clusters of receptors at either end of the cell, as shown in this electron micrograph of *E. coli*. Gold-tagged antibodies were used to label the receptor clusters, which appear as black dots (encircled). (c) The chemotactic signaling pathways of *E. coli*. The pathways that increase the probability of CCW rotation are shown in red. CCW rotation is the default rotation. It is periodically interrupted by CW rotation, which causes tumbling. The pathways that lead to CW rotation are shown in green. Molecules shown in gray are unphosphorylated and inactive. Note that MCP, CheA, and CheZ are homodimers. CheW, CheB, CheY, and CheR are monomers.

the flagellar motor. Upon interacting with the motor, the direction of rotation is switched from CCW to CW, and a tumble ensues. When CheA is inactive, the flagellum rotates in its default mode (CCW), and the cell moves forward in a smooth run.

As implied by the preceding discussion, the state of the MCPs must be communicated to the CheA/CheY phosphorelay system. How is this accomplished? The MCPs are embedded in the plasma membrane with different parts exposed on each side of the membrane (figure 14.21c). The periplasmic side of each MCP has a binding site for one or more attractant molecules. The cytoplasmic side of an MCP interacts with two proteins, CheW and CheA. The CheW protein associates with the MCP and helps attach the CheA protein. Together with CheW and CheA, the MCP receptors form large receptor clusters at one or both poles of the cell (figure 14.21b). It is thought that smaller aggregations of the MCPs, CheA, and CheW function as signaling teams and are the building blocks of the receptor clusters. The number of each of these molecules in the signaling team is not clear, but it has been suggested that each team includes three receptors, often of different types, two CheW molecules, and one CheA dimer (figure 14.22). The signaling teams become interconnected by an unknown mechanism to form the receptor clusters visible at the poles of the cell.

No matter what the precise stoichiometry or architecture of the receptor clusters, evidence exists that the MCPs in each signaling team work cooperatively to modulate CheA activity. When any one of the MCPs in the signaling team is bound to an attractant, CheA autophosphorylation is inhibited, the flagellum continues rotating CCW, and the cell continues in its run. Because of this cooperation, the cell can respond to very low concentrations of attractant. Furthermore, it can integrate signals from all receptors in the team (figure 14.22). On the other hand, if attractant levels decrease, so that the level of attractant bound to the MCPs in a signaling team decreases, CheA is stimulated to autophosphorylate, the phosphorelay is set into motion, and the cell begins to tumble. However, tumbling does not continue indefinitely. About 10 seconds after the switch to CW rotation occurs, the phosphoryl group is removed from CheY by the CheZ protein, and CCW rotation is resumed.

But how does *E. coli* measure the concentration of attractant in its environment, and how does it know when it is moving toward the attractant? *E. coli* measures the concentration of an attractant every few seconds and determines if the concentration is increasing or decreasing over time. As long as the concentration increases, the cell continues a run. If the concentration decreases, a tumble is triggered. To compare concentrations of the attractant over time, *E. coli* must have a mechanism for “remembering” the previous concentration. *E. coli* accomplishes this by using covalent modification, specifically methylation of the MCPs. *E. coli* compares the overall methylation level of the MCPs (on the cytoplasmic side) with the overall amount of attractant bound (on the periplasmic face). The cytoplasmic portion of each MCP has four to six glutamic acid residues that can be methylated. As long as the

Figure 14.22 The Methyl-Accepting Chemotaxis Proteins of *E. coli*

The attractants sensed by each methyl-accepting chemotaxis protein (MCP) are shown. Some are sensed directly, when the attractant binds the MCP (solid lines). Others are sensed indirectly (dashed lines). The attractants maltose, dipeptides, galactose, and ribose are detected by their interaction with periplasmic binding proteins. Oxygen is detected indirectly by the Aer chemoreceptor, which differs from other MCPs in that it lacks a periplasmic sensing domain. Instead, the cytoplasmic domain has a binding site for FAD. FAD is an important electron carrier found in many electron transport systems. The redox state of the MCP-bound FAD molecule is used to monitor the functioning of the electron transport system. This in turn mediates a tactic response to oxygen.

MICRO INQUIRY Why doesn't the Aer receptor need a periplasmic domain?

concentration of the attractant keeps increasing, the number of MCPs bound to attractant remains high, and the MCP methylation level remains high. However, if the attractant concentration decreases, the level of methylation will exceed the level of attractant bound. This disparity in methylation level and MCP-bound attractant stimulates CheA to autophosphorylate. As a result, the phosphorelay signal for CW flagellar rotation is initiated, and the cell tumbles in an attempt to reorient itself in the gradient so that it is moving up the gradient (toward the attractant), rather than down the gradient (away from the attractant). At the same time, some of the methyl groups are removed from the MCPs by the methyl-erastase CheB, establishing a methylation level that is commensurate with the number of MCPs bound to the attractant. A few seconds later, the number of MCPs bound to attractant will be compared to this new methylation level. Based on the correspondence of the two, the cell will determine if it is again moving up the gradient. If it is, tumbling will be suppressed and the run will continue.

1. What are global regulatory systems and why are they necessary? Briefly differentiate between regulons, modulons, and stimulons.
2. What is diauxic growth? Explain how catabolite repression causes diauxic growth.
3. Describe the events that occur with *E. coli* in each of the following growth conditions: in a medium containing glucose but not lactose; in a medium containing both sugars; in a medium containing lactose but no glucose; and in a medium containing neither sugar.
4. *E. coli* has two phosphate uptake systems (one with a high affinity for phosphate, the other with a low affinity). Describe how a two-component regulatory system might be used by *E. coli* to regulate phosphate transport.
5. Describe the MCP-CheW-CheA receptor complex. What two proteins are phosphorylated by CheA? What is the role of each?
6. How does an MCP regulate the rate of CheA autophosphorylation? How does this mediate chemotaxis?

Quorum Sensing by *Vibrio* spp.

Cell-to-cell communication among bacterial cells often occurs by the exchange of chemicals often termed signals or signaling molecules. The exchange of signaling molecules is essential in the coordination of gene expression in microbial populations. Quorum-sensing mechanisms vary among microbes. Here we focus on two of the best-studied systems.

The marine bioluminescent bacterium *Vibrio fischeri* uses quorum sensing to regulate light production; cells produce light only if cells are at a high density. Since the discovery of *V. fischeri* signaling, it has become clear that intercellular communication plays an essential role in the regulation of genes whose products are needed for the establishment of virulence, symbiosis, biofilm

production, plasmid transfer, and morphological differentiation in a wide range of bacteria. Here we describe how signals that are secreted by a group of cells can regulate the genetic expression of that population. Our focus is on the regulation of a single operon. However, it should be kept in mind that **quorum sensing** regulates multiple genes and operons. ◀◀ *Cell-cell communication within microbial populations (section 7.4)*

Quorum sensing in *V. fischeri* and many other Gram-negative bacteria uses an ***N*-acylhomoserine lactone (AHL)** signal (figure 14.23). Synthesis of this small molecule is catalyzed by an enzyme called AHL synthase, the product of the *luxI* gene. The *luxI* gene is subject to positive autoregulation; that is, transcription of *luxI* increases as AHL accumulates in the cell. This is accomplished through the transcriptional activator LuxR, which is active only when AHL binds to it. Thus a simple feedback loop is created. Without AHL-activated LuxR, the *luxI* gene is transcribed only at basal levels. Small amounts of AHL freely diffuse out of the cell and accumulate in the environment. As cell density increases, the concentration of AHL outside the cell eventually exceeds that inside the cell, and the concentration gradient is reversed. As AHL flows back into the cell, it binds and activates LuxR. LuxR can now activate high-level transcription of *luxI* and the genes whose products are needed for bioluminescence (*luxCDABEG*). Quorum sensing is often called **autoinduction**, and the AHL signal is termed the **autoinducer (AI)** to reflect the autoregulatory nature of this system. 🌀 *Quorum Sensing*

Another kind of quorum sensing depends on an elaborate phosphorelay signal transduction system. It is found in both Gram-negative and Gram-positive bacteria, including *Staphylococcus aureus*, *Ralstonia solanacearum*, *Salmonella enterica*, *Vibrio cholerae*, and *E. coli*. It has been best studied in the bioluminescent bacterium *Vibrio harveyi*.

Figure 14.23 Quorum Sensing in *V. fischeri*. The AHL signaling molecule (AI) diffuses out of the cell; when cell density is high, AHL diffuses back into the cell, where it binds to and activates the transcriptional regulator LuxR. Active LuxR then stimulates transcription of the gene coding for AHL synthase (*luxI*), as well as the genes encoding proteins needed for light production.

Unlike *V. fischeri*, *V. harveyi* responds to three autoinducer molecules: HAI-1, AI-2, and CAI-1. HAI-1 (harveyi autoinducer-1) is a homoserine lactone, and its synthesis depends on the *luxM* gene. AI-2 (autoinducer-2) is furanosylborate, a small molecule that contains a boron atom—quite an unusual component in an organic molecule (see figure 7.18). Its synthesis relies on the product of the *luxS* gene. CAI-1 (cholerae autoinducer-1) is the product of the enzyme CqsA. The structure of CAI-1 was recently determined and is 3-hydroxytridecan-4-one. As shown in figure 14.24,

HAI-1, AI-2, and CAI-1 are secreted by cells, which then use separate proteins called LuxN, LuxPQ, and CqsS, respectively, to detect their presence. LuxN, LuxQ, and CqsS are sensor kinases. At low cell density in the absence of any autoinducer, the three sensor kinases autophosphorylate and converge on a single phosphotransferase protein called LuxU. LuxU accepts phosphates from each sensor kinase and then phosphorylates the response regulator LuxO. Phosphorylated LuxO in turn activates the transcription of genes encoding several small RNAs that destabilize

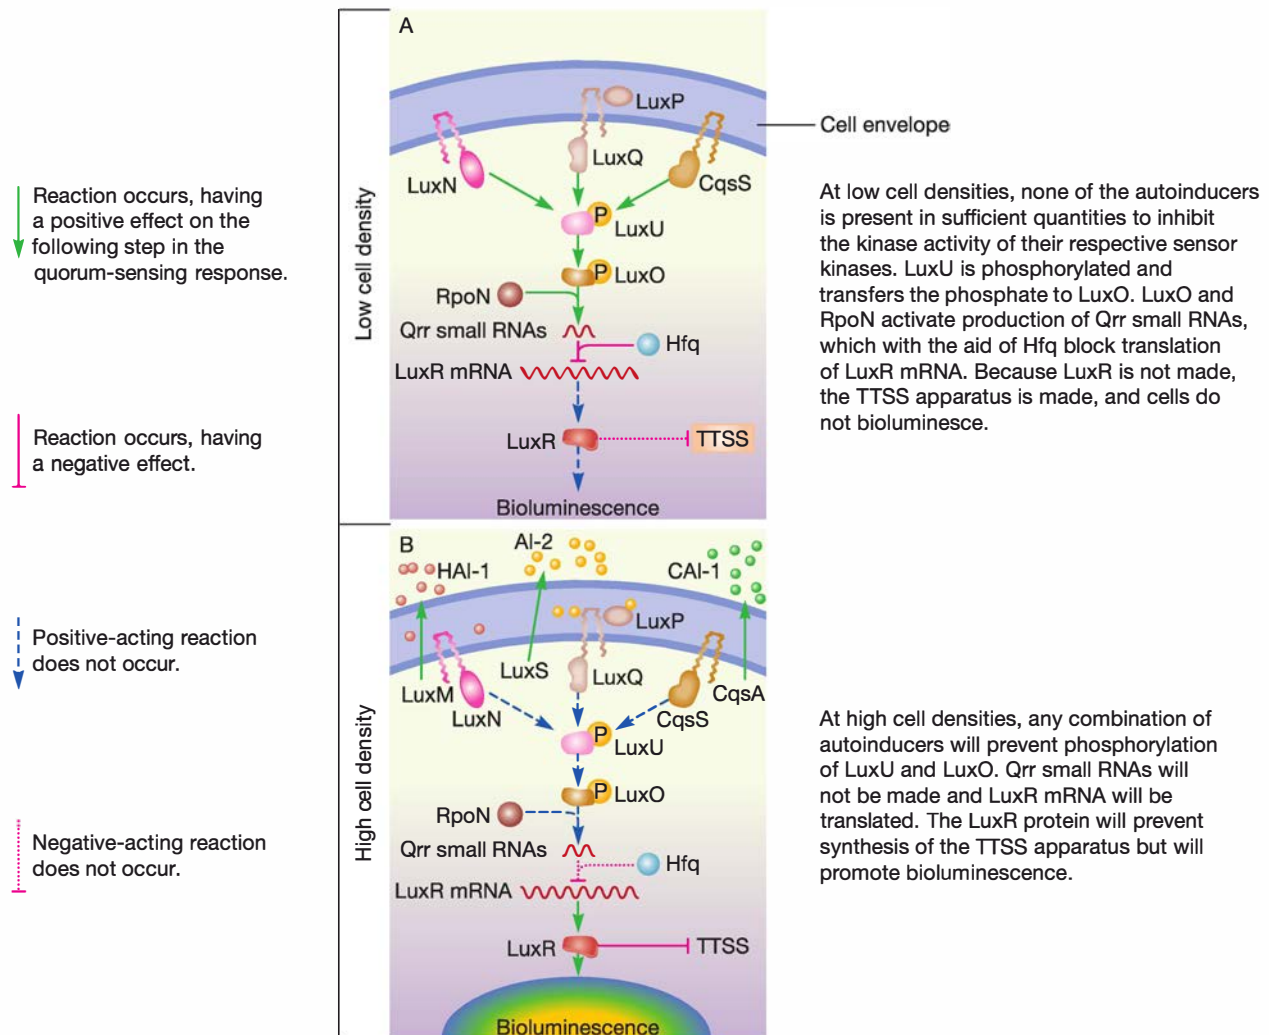

Figure 14.24 Quorum Sensing in *V. harveyi*. Three autoinducing signals—HAI-1, AI-2, and CAI-1—are detected. HAI-1 is only produced by *V. harveyi* and one other closely related species. AI-2 is produced by many Gram-negative and Gram-positive bacteria. CAI-1 is produced by many members of the genus *Vibrio*. Thus *V. harveyi* not only “measures” the density of its own population but that of other bacteria as well. LuxN, LuxA, and CqsA are sensor kinases involved in detecting HAI-1, AI-2, and CAI-1, respectively. Their kinase activity is inhibited by the presence of their respective autoinducer. All three quorum-sensing signals converge at LuxU, which when phosphorylated transfers the phosphate to LuxO. LuxO working with the sigma factor RpoN activates transcription of the *qrr* (quorum regulatory RNA) genes. The products of these genes are small RNAs that block translation of the mRNA encoding the protein LuxR. This is accomplished in conjunction with a small protein, Hfq, which is an RNA chaperone that helps RNA molecules bind each other or aids in their folding. Lux R is a regulatory protein that represses transcription of genes encoding components of a type III secretion system (TTSS) and activates transcription of genes required for bioluminescence.

MICRO INQUIRY Why does *V. harveyi* make three separate signaling molecules?

luxR mRNA. This is accomplished with the aid of the RNA chaperone Hfq (p. 337). LuxR is a transcriptional activator of the operon *luxCDABE*, which encodes proteins needed for bioluminescence. Because *luxR* mRNA is not translated, LuxR protein is not made. Therefore cells do not make light at low cell density.

An interesting thing happens as the density of any one of these autoinducers increases: LuxN binds HAI-1, LuxPQ binds AI-2, and CqsS binds CAI-1. When this happens, the proteins switch from functioning as kinases to phosphatases, proteins that dephosphorylate, rather than phosphorylate, their substrates. The flow of phosphates is now reversed; LuxO is inactivated by dephosphorylation, the small RNAs are not made, and *luxR* mRNA is translated. LuxR now activates transcription of *luxCDABE* and light is produced. Careful inspection of figure 14.24 reveals that another set of genes is controlled by the quorum-sensing system of *V. harveyi*. In this microbe, genes for a type III protein secretion system (TTSS) are controlled in the opposite manner as those for bioluminescence.

At this point, we should pause and ask an important question: Why does *V. harveyi* need three different autoinducers? It appears that these molecules allow the bacterium to carry out three different kinds of conversations. HAI-1 is specific to *V. harveyi* (and one other closely related species). Thus it is thought to allow *V. harveyi* to communicate with members of its own species. In essence, this autoinducer conveys the message, “There are many *V. harveyi* nearby.” AI-2 is made by many Gram-negative and Gram-positive bacteria. Thus its message is thought to be, “There are many bacteria nearby.” Finally, CAI-1 is produced by other members of the genus *Vibrio*, including *V. cholerae*, for which it is named. Its message is thought to be, “There are many *Vibrio* species nearby.” As might be expected, each autoinducer has a different signal strength. HAI-1 is the

strongest and CAI-1 is the weakest. The presence of all three autoinducers maximizes expression of the bioluminescence genes and fully represses expression of the type III secretion system genes.

Stringent Response in *E. coli*

The **stringent response** occurs when bacterial cells are starved for amino acids and is regulated by the second messenger **guanosine tetraphosphate (ppGpp; figure 14.25)**. The stringent response is observed in many bacterial species but is best studied in *E. coli*. When *E. coli* cells are growing in a nutrient-rich environment, many of the RNA polymerase molecules in the cell are transcribing tRNA and rRNA genes, providing a ready supply of these molecules for protein synthesis. When cells are starved for amino acids, protein synthesis cannot proceed as it does in nutrient-rich conditions. Therefore it is wasteful for the cell to keep synthesizing large quantities of tRNA and rRNA. Instead, the cell decreases synthesis of these molecules and increases transcription of the appropriate amino acid biosynthetic genes. Eventually the cell “resets” its level of metabolic activity to one commensurate with the nutrients available in its environment.

The mechanism by which these changes are brought about has become increasingly clear over the 40 years this phenomenon has been studied. When *E. coli* is starved for one or more amino acids, tRNA molecules cannot become attached to their cognate amino acids. Thus during translation, there are no charged tRNAs to enter the A site of the ribosome, and the ribosome stalls (figure 14.26). However, an uncharged tRNA eventually enters the A site of the stalled ribosome. This triggers an enzyme called RelA to catalyze the formation of ppGpp from GDP and ATP (figure 14.25b). RelA also catalyzes a reaction between GTP and ATP, generating guanosine pentaphosphate (pppGpp), which is quickly converted to ppGpp.

ppGpp then interacts with RNA polymerase and downregulates synthesis of tRNA and rRNA, while simultaneously upregulating transcription of amino acid biosynthetic genes. However, ppGpp does not act alone. Instead, it exerts its effects with the help of the protein DksA. Together they destabilize open complexes (see figure 13.26) formed during transcription initiation of the downregulated genes and enhance the rate of open complex formation of the upregulated genes (figure 14.27).

An important question for understanding the stringent response is how the cell knows which promoters to downregulate and which to upregulate. Comparisons of the promoters of rRNA genes and amino acid synthetic genes have answered this question. Recall that sigma factor (σ) positions RNA polymerase core enzyme properly on the promoter. The enzyme then melts the two strands of DNA, forming an open complex. In ppGpp-regulated genes, there is a region between the -10 site of the promoter and the $+1$ nucleotide that is important for controlling transcription initiation. In downregulated

Figure 14.25 Guanosine Tetraphosphate. (a) The structure of ppGpp. (b) The two processes that generate ppGpp. In the stringent response, these reactions are catalyzed by the enzyme RelA.

genes (i.e., rRNA and tRNA genes), this region is GC rich, whereas in amino acid biosynthetic genes, it is AT rich (figure 14.27). The GC-rich regions form unstable open complexes during transcription initiation. DksA and ppGpp further destabilize the open complexes, lowering transcription levels. The AT-rich regions of the upregulated genes form much more stable open complexes and are not destabilized by DksA and ppGpp. Instead, these two

molecules increase the rate of formation of open complexes, increasing transcription.

More recently, ppGpp has been shown to function as an “alarm,” signaling that changes in transcription must be made to protect the cell from a number of stresses in addition to amino acid starvation. These include deprivation for other nutrients (e.g., phosphorus, iron, fatty acids). In these situations, production of ppGpp is catalyzed by a different enzyme, called SpoT. Despite being an area of intensive research for many years, many of the details of this global response to stress are still being explored.

Sporulation in *B. subtilis*

As we discuss in chapter 3, endospore formation is a complex process that involves asymmetric division of the cytoplasm to yield a large mother cell and a smaller forespore, engulfment of the forespore by the mother cell, and construction of additional layers of spore coverings (figures 14.28a and 3.54). Sporulation takes approximately 8 hours. Numerous bacterial species form endospores, including *B. subtilis*, which has served for many years as the model organism for understanding sporulation.

In *B. subtilis*, sporulation is controlled by phosphorelay, post-translational modification of proteins, numerous transcription initiation regulatory proteins, and alternate sigma factors. The latter are particularly important. When growing vegetatively, *B. subtilis* RNA polymerase uses sigma factors σ^A and σ^H to recognize genes for normal survival. However, when cells sense a starvation signal, a cascade of events is initiated that results in the production of alternative sigma factors that are differentially expressed in the developing endospore and mother cell.

Initiation of sporulation is controlled by the protein Spo0A, a response regulator protein that is part of a phosphorelay system (figure 14.28b). Sensor kinases associated with this system detect environmental stimuli that trigger sporulation. One of the most important sensor kinases is KinA, which senses nutrient starvation. When *B. subtilis* finds its nutrients are depleted, KinA auto-phosphorylates a specific histidine residue. The phosphoryl group

Figure 14.26 Activation of RelA in Response to Amino Acid Starvation.

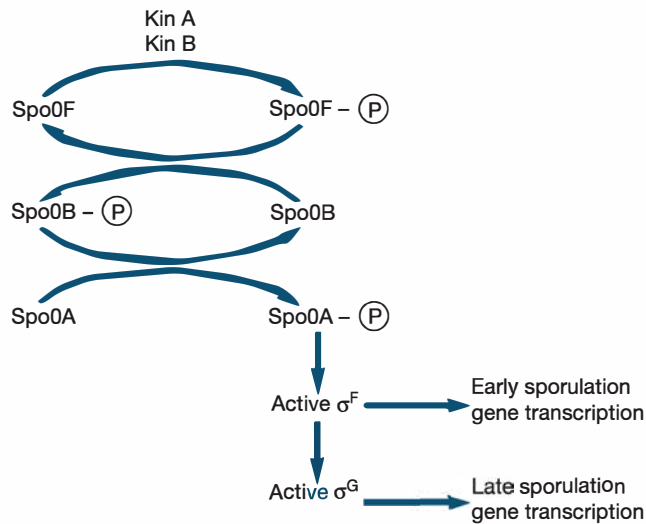

Figure 14.27 Effects of ppGpp and DksA on Transcription. Genes encoding tRNA and rRNA have a region between the -10 site of the promoter and the $+1$ nucleotide of the coding region that is GC rich. This region interacts with sigma factor as it positions the RNA polymerase core enzyme at the promoter. The presence of the GC region destabilizes open complexes formed during initiation. During the stringent response, ppGpp working with DksA further destabilizes the open complexes, thus lowering the rate of transcription. Elsewhere in the genome are genes encoding enzymes needed for amino acid biosynthesis. The promoters for these genes are rich for AT base-pairs in the same area of the promoter. These regions do not destabilize open complex formation. The interaction of ppGpp and DksA promotes open complex formation, and transcription is increased for these genes.

MICRO INQUIRY Why would having many GC pairs in the -10 to $+1$ region of the promoter make it more difficult to maintain an open complex?

(a)

(b)

Figure 14.28 Genetic Regulation of Sporulation in *B. subtilis*.

(a) The initiation of sporulation is governed in part by the activities of two spatially separated sigma factors. σ^F is located in the forespore, while σ^E is confined to the mother cell. These sigma factors direct the initiation of transcription of genes whose products are needed for early events in sporulation. Later, σ^G and σ^K are localized to the developing endospore and mother cell, respectively. They control the expression of genes whose products are involved in later steps of sporulation. (b) The activation of σ^F is accomplished through a phosphorelay system that is triggered by the activation of the sensor kinase protein KinA. When KinA senses starvation, it autophosphorylates a specific histidine residue. The phosphoryl group is then passed in relay fashion from Spo0F to Spo0B and finally to Spo0A.

MICRO INQUIRY Compartmentation—the spatial localization of proteins as a means of regulation—is usually considered in the context of eukaryotic cells. How is the process of sporulation an example of compartmentation?

is then transferred to an aspartic acid residue on Spo0F. However, Spo0F cannot directly regulate gene expression; instead, Spo0F donates the phosphoryl group to a histidine on Spo0B. Spo0B in turn relays the phosphoryl group to Spo0A. Phosphorylated Spo0A positively controls genes needed for sporulation and negatively controls genes that are not needed. In response to Spo0A, the expression of over 500 genes is altered. This has earned Spo0A the name “master regulator.” Among the genes whose expression is stimulated by Spo0A is *sigF*, the gene encoding sigma factor σ^F , and *spoIIGB*, the gene encoding an inactive form of σ^E (pro- σ^E).

When sporulation starts, the chromosome has replicated, with one copy remaining in the mother cell and another to be partitioned in the forespore. Shortly after the formation of the spore septum, σ^F is found in the forespore, and pro- σ^E is localized to the mother cell. Pro- σ^E is cleaved by a protease to form active σ^E . The two sigma factors, σ^F and σ^E , bind to the promoters of genes needed in the forespore and mother cell, respectively. There they direct the expression of genes encoding products needed for the early steps of endospore formation. These genes are primarily responsible for the engulfment process. Another gene regulated by σ^F is one that encodes the sigma factor, σ^G , which will replace σ^F in the developing endospore. Likewise, σ^E directs the transcription of a mother-cell-specific sigma factor, σ^K . Like σ^E , σ^K is first produced in an inactive form, pro- σ^K . Upon activation of pro- σ^K by proteolysis, σ^K ensures that genes encoding late-stage sporulation products are transcribed. These include genes for synthesis of the cortex and coat layers of the endospore. Overall, temporal regulation is achieved because σ^F and σ^E direct transcription of genes that are needed early in the sporulation process, whereas σ^G and σ^K are needed for the transcription of genes whose products function later. In addition, spatial control of gene expression is accomplished because σ^F and σ^G are located in the forespore and developing endospore, whereas σ^E and σ^K are found only in the mother cell.

3. Why is the stringent response typically active during nitrogen starvation but not in response to carbon sources?
4. Briefly describe how a phosphorelay system and sigma factors are used to control sporulation in *B. subtilis*. Give one example of posttranslational modification as a means to regulate this process.

Key Concepts

14.1 Levels of Regulation

- Regulation of gene expression can be controlled at many levels, including transcription initiation, transcription elongation, translation, and posttranslation (figure 14.1).

- The three domains of life differ in terms of their genome structure and the steps required to complete gene expression. These differences affect the regulatory mechanisms they use.

14.2 Regulation of Transcription Initiation

- Induction and repression of enzyme levels are two important regulatory phenomena. They usually occur because of the activity of regulatory proteins.
- Regulatory proteins are DNA-binding proteins. When bound to DNA, they can either inhibit transcription (negative control) or promote transcription (positive control). Their activity is modulated by small effector molecules called inducers, corepressors, and inhibitors (**figure 14.3**).
- Repressors are responsible for negative control. They block transcription by binding an operator and interfering with the binding of RNA polymerase to its promoter or by blocking the movement of RNA polymerase after it binds DNA.
- Activator proteins are responsible for positive control. They bind DNA sequences called activator-binding sites and, in doing so, promote binding of RNA polymerase to its promoter.
- The *lac* operon of *E. coli* is an example of a negatively controlled inducible operon. When there is no lactose in the surroundings, the *lac* repressor is active and transcription is blocked. When lactose is available, it is converted to allolactose by the enzyme β -galactosidase. Allolactose acts as the inducer of the *lac* operon by binding the repressor and inactivating it. The inactive repressor cannot bind the operator and transcription occurs (**figure 14.7**).
- The *trp* operon of *E. coli* is an example of a negatively controlled repressible operon. When tryptophan is not available, the *trp* repressor is inactive and transcription occurs. When tryptophan levels are high, tryptophan acts as a corepressor and binds the *trp* repressor, activating it. The *trp* repressor binds the operator and blocks transcription (**figure 14.8**).
- The *ara* operon of *E. coli* is an example of an inducible operon that is regulated by the dual-function regulatory protein AraC. AraC functions as a repressor when arabinose is not available. It functions as an activator when arabinose, the inducer, is available (**figure 14.9**).

14.3 Regulation of Transcription Elongation

- In the tryptophan operon, a region called *trpL* lies between the operator and the first structural gene (**figure 14.10**). It codes for synthesis of a leader peptide and contains an attenuator, a factor-independent termination site. Synthesis of the leader peptide by a ribosome while RNA polymerase is transcribing *trpL* regulates transcription. Therefore the tryptophan operon is expressed only when insufficient tryptophan is available. This mechanism of transcription control is called attenuation.
- The 5' ends (leaders) of some mRNA molecules can bind metabolites that act as effector molecules. Binding of the metabolite to the mRNA causes a change in the leader structure, which can terminate transcription. This regulatory mechanism is called a riboswitch (**figure 14.11**).

14.4 Regulation of Translation

- Some riboswitches regulate gene expression at the level of translation. For these riboswitches, the binding of a small molecule to specific sequences in the leader region of the mRNA alters leader structure and prevents ribosome binding (**figure 14.12**).
- Translation can also be controlled by antisense RNAs. These small RNA molecules are noncoding. They base-pair to the mRNA and usually inhibit translation (**figure 14.13**).

14.5 Regulating Complex Cellular Processes

- Some cellular processes are so complex they require the action of multiple operons that must be simultaneously controlled. Such operon networks are global regulatory systems.
- Global regulatory systems often involve many layers of regulation. Mechanisms such as global regulatory proteins, two-component signal transduction systems, phosphorelay systems, second messengers, and alternate sigma factors are often used.
- Expression of the porin genes *ompF* and *ompC* is controlled by a two-component signal transduction system. These systems have a sensor kinase that detects an environmental change. The sensor kinase transduces the environmental signal to the response-regulator protein by transferring a phosphoryl group to it. The response regulator then activates genes needed to adapt to the new environmental conditions and inhibits expression of those genes that are not needed (**figure 14.14**).
- Cyclic dimeric GMP (c-di-GMP) is a recently discovered second messenger. Its level in bacterial cells depends on the activity of enzymes called diguanylate cyclases (DGCs), which synthesize c-di-GMP, and phosphodiesterases (PDEs), which degrade c-di-GMP (**figure 14.15**). The DGCs and PDEs have sensory domains that detect environmental signals. Their response to the signal determines the level of c-di-GMP. C-di-GMP interacts with effector molecules that affect a target, bringing about the appropriate response to the environmental signal.
- Diauxic growth is observed when *E. coli* is cultured in the presence of glucose and another sugar such as lactose (**figure 14.16**). This growth pattern is the result of catabolite repression, where glucose is used preferentially over other sugars. Operons that are part of the catabolite repression system are regulated by the activator protein CAP. CAP activity is modulated by the second messenger cAMP, which is produced only when glucose is not available (**figure 14.20**). Thus when there is no glucose, CAP is active and promotes transcription of operons needed for the catabolism of other sugars (**figure 14.19**).
- Chemotaxis in *E. coli* is regulated by covalent modification of chemoreceptor proteins and a phosphorelay system that controls the direction of flagellar rotation (**figure 14.21**). Methylation is used to measure the amount of a

chemoattractant encountered over time. In this way, *E. coli* can determine if it is moving toward or away from an attractant.

- Quorum sensing is a type of cell-to-cell communication mediated by small signaling molecules such as *N*-acylhomoserine lactone (AHL). Quorum sensing couples cell density to regulation of transcription. Well-studied quorum-sensing systems include the regulation of bioluminescence in *Vibrio* spp. (figures 14.23 and 14.24). *V. harveyi* quorum sensing is another example of a phosphorelay signal transduction pathway.

- The stringent response occurs when bacteria are starved for amino acids. It is mediated by the second messenger guanosine tetraphosphate (ppGpp). The stringent response results in a decrease in transcription of tRNA and rRNA genes and increased transcription of amino acid biosynthetic genes (figures 14.25–14.27).
- Endospore formation in *B. subtilis* is regulated by a phosphorelay system that is important in initiation of sporulation and the use of alternate sigma factors (figure 14.28).

Compare, Hypothesize, Invent

1. Attenuation affects anabolic pathways, whereas repression affects either anabolic or catabolic pathways. Provide an explanation for this.
2. Describe the phenotype of the following *E. coli* mutants when grown in two different media: glucose only and lactose only. Explain the reasoning behind your answer.
 - a. A strain with a mutation in the gene encoding the *lac* repressor; the mutant repressor cannot bind allolactose.
 - b. A strain with a mutation in the gene encoding CAP; the mutant form of CAP binds but cannot release cAMP.
 - c. A strain in which the Shine-Dalgarno sequence has been deleted from the gene encoding adenyl cyclase.
3. What would be the phenotype of an *E. coli* strain in which the tandem *trp* codons in the leader region were mutated so that they coded for serine instead?
4. What would be the phenotype of a *B. subtilis* strain whose gene for σ^G has been deleted? Consider the ability of the mutant to survive in nutrient-rich versus nutrient-depleted conditions.
5. Propose a mechanism by which a cell might sense and respond to levels of Na^+ in its environment.
6. The extracytoplasmic sigma factor (ECF) σ^F is required for full virulence in *Mycobacterium tuberculosis*, which causes tuberculosis. Many stimuli induce σ^F production, including

detergent stress to the cell surface, alkaline pH, heat shock, and oxidative stress. Unlike most ECF sigma factors, σ^E does not regulate its own transcription. Because it is so important in *M. tuberculosis* pathogenicity, microbiologists want to understand what controls σ^E production. They have discovered that at least three different types of regulation are in play. (1) A two-component regulatory system consisting of MprA and MprB (signal kinase and response regulator, respectively) activates transcription of the σ^E structural gene *sigE* in response to cell surface stress and increases in pH. (2) The *M. tuberculosis* heat-shock sigma factor, σ^H , activates transcription of *sigE* in response to heat shock and oxidative stress, and (3) an antisigma factor RsrA binds to and inactivates σ^E .

Sketch this regulatory network using arrows to represent induction and cross-hatched lines to indicate repression. How might RsrA be regulated so that it is not always bound to σ^E ? Suggest an explanation for why *M. tuberculosis* uses three different regulatory mechanisms to control *sigE* expression. Is this type of regulatory layering unusual in bacterial cells? Explain your answer.

Eukaryotic and Archaeal Genome Replication and Expression

Plastics: Brought to You by Microbes

The next time you discard a plastic water bottle, consider this: that plastic bottle will take thousands of years to be converted back into the smaller chemical molecules from which it was made, assuming it ever degrades. Also consider that each year 140 million tons of equally recalcitrant plastics are purchased (and usually discarded). And what is often forgotten is that to make all that plastic, 150 million tons of fossil fuels must be processed each year, contributing additional waste, diversion of the fuels from refineries and power plants, and exacerbating geopolitical problems centered on oil and other fossil fuels. Could microbes solve this problem? Microbiologists have been trying for years to answer that question.

You may be asking how microbiologists could even suggest microbes as a solution to the plastics problem. This is how. Plastics are organic polymers, such as polyurethane, polystyrene, polyethylene, and polyester. Microbiologists have known for decades that many bacteria and archaea produce poly- β -hydroxybutyrate (PHB) and other polyhydroxyalkanoates (PHAs) as intracellular inclusions that store carbon. PHAs are polyesters; thus bacteria and archaea have evolved to synthesize a type of plastic. And even more important, because PHA-producing bacteria and archaea have evolved a means to use the PHA when carbon is in short supply, they produce the enzymes needed for PHA degradation.

For many years, microbiologists have worked to optimize production of PHAs by bacteria such as *Ralstonia eutropha*, and they have succeeded—up to 80% of cellular dry weight is produced by some strains. However, the cost of feeding these chemoorganoheterotrophic bacteria so that they produce PHAs makes the plastics they produce very expensive. Therefore, although some companies manufacture bioplastics, their share of the market is minuscule relative to that produced each year by chemical means.

“If expense arises from feeding a chemoorganotroph,” scientists thought, “why not move the bacterial genes encoding PHB-synthesizing

Approximately 140 million tons of plastics, such as those shown here, are purchased each year. Most are discarded.

enzymes into an organism that feeds itself?” The logical autotrophs were plants such as thale cress (*Arabidopsis thaliana*) and tobacco (*Nicotiana tabacum*). Though successful, scientists were then faced with another dilemma: the use of land to “grow” plastics rather than to grow food.

Once again, microbes may provide a solution. In 2011 several German microbiologists reported they had introduced the genes for PHB synthesis into a microalga, the diatom *Phaeodactylum tricornutum*. The advantages of an alga-based system are that these photoautotrophs need only be provided with sunlight and CO₂, and they can be grown in areas (e.g., a desert) that are not used for food production. This greatly decreases cost and avoids the ethical problems associated with plant-based systems.

Although the 2011 report did nothing to maximize PHB production by the diatom, it was a “proof of concept” experiment. It showed that an alga-based system for plastic production may be successful. The next step is to maximize PHB production in a cost-effective manner. This will require that microbiologists take into account the differences between gene expression in bacteria and eukaryotes. They will need to modify the PHB-synthesis genes such that they are transcribed at a high rate in the diatom, producing mRNA molecules that are recognized and translated by eukaryotic ribosomes. Fortunately, microbiologists have the wealth of information provided by geneticists and molecular biologists studying plant systems and eukaryotic microbes such as the yeast *Saccharomyces cerevisiae* to guide them. What these geneticists and molecular biologists have learned is the focus of this chapter.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Discuss bacterial genome structure and the organization of genetic information (sections 13.3 and 13.4)
- ✓ Describe the events that occur during the three phases of DNA replication and how the components of the bacterial replisome participate (section 13.3)

- ✓ Describe the structure of a typical bacterial RNA polymerase holoenzyme and how it functions during the three phases of transcription (section 13.5)
- ✓ List the major features of the universal genetic code and comment on any deviations from it (section 13.6)
- ✓ Describe the events that occur during the three phases of translation and the structure of bacterial ribosomes, and identify the initiator tRNA used by bacteria (section 13.7)
- ✓ Summarize the posttranslational events that result in a properly folded protein in its appropriate location within or outside a bacterial cell (section 13.8)
- ✓ Trace the movement of materials via the endocytic and secretory pathways of eukaryotic cells (section 5.4)
- ✓ Describe the structure of mitochondria and chloroplasts (section 5.6)
- ✓ Outline the steps of the eukaryotic cell cycle

15.1 Why Consider Eukaryotic and Archaeal Genetics Together?

If it looks like a duck, walks like a duck, and quacks like a duck, it must be a duck. The logic of this saying fails when applied to archaea. For many years, microbiologists thought they looked like bacteria, did the things bacteria do, and therefore were just another group of bacteria. And why not? Archaea have prokaryotic cell architecture; thus they look like bacteria. Archaeal energy-conserving and biosynthetic pathways and enzymes are similar to those of bacteria; thus archaea did the things bacteria do. However, archaea were never exactly like bacteria (which are often called eu- or true bacteria). Archaeal cell walls and membrane lipids are very different. Archaea are often described as being extremophiles, and they are alone in their ability to carry out methanogenesis. A clear distinction between archaea and bacteria was made in the 1970s when Carl Woese compared rRNA molecules of numerous bacteria and archaea. This was soon followed by comparisons of other components of their genome replication and expression systems. These studies led to the realization that the archaeal machinery for genetic information processing is more similar to that of eukaryotes than of bacteria.

Evidence clearly demonstrates that the evolutionary history of archaea and eukaryotes is intertwined, though the details have yet to be fully revealed. In this chapter, our goal is to accomplish three things: (1) to illustrate the similarities of archaea and eukaryotes with respect to how they replicate and express the information in their genomes, (2) to point out those aspects of the archaeal machinery that are distinct, and (3) to draw comparisons among the members of the three domains of life. To that end, we organize the chapter with sections that parallel the flow of genetic information in cells. We begin each section with a brief summary of the most salient information about each process as it occurs in bacteria. We then describe the process in eukaryotes and finally consider archaea. As you will see, archaea are an interesting mix of bacterial and eukaryotic characteristics. It is this mix that has prompted further studies to elucidate the evolutionary history of microorganisms.

15.2 DNA Replication

After reading this section, you should be able to:

- Create a table or concept map that illustrates the differences in eukaryotic, archaeal, and bacterial genome structure and organization
- Distinguish the replicons of eukaryotes and archaeal cells from bacterial replicons
- Compare and contrast the replisomes of eukaryotes, archaeal cells, and bacterial cells
- Construct a model to demonstrate the role of telomerase in the replication of eukaryotic chromosomes

DNA replication is similar in all cellular organisms. It is accomplished by a huge complex of proteins called the **replisome**. Central to the functioning of the replisome are the DNA polymerases responsible for leading and lagging strand replication. All known DNA polymerases catalyze the synthesis of DNA in the 5' to 3' direction using a template to synthesize a complementary DNA strand and a primer to provide a free 3'-hydroxyl group to which nucleotides can be added (*see figure 13.10*).

Recall from chapter 13 that the DNA of most bacteria is circular and replication begins at a single point, the origin of replication (*see figure 13.9*). The bacterial replicative DNA polymerase (DNA polymerase III; *see figure 13.11*) is recruited to the origin only after the initiator protein DnaA begins assembly of the bacterial replisome, which is composed of at least 30 proteins. The replication forks move bidirectionally from the origin until the entire circular chromosome is replicated. We now compare this to what occurs in eukaryotes.

DNA Replication in Eukaryotes

The distinctive features of eukaryotic DNA replication arise from differences in chromosome structure and the replication machinery. Eukaryotes have multiple chromosomes, each of which is usually much larger than a typical bacterial chromosome. The DNA in eukaryotic chromosomes is linear, which means that a mechanism for replicating chromosome ends is needed. Finally, eukaryotic DNA is wound around histones. These must associate with the newly synthesized strand of DNA.

Initiation of DNA Replication

Replication of the large chromosomes of eukaryotes is initiated at multiple origins of replication (**figure 15.1**). This allows the chromosome to be replicated much faster than it could be if there were only one origin per chromosome. Two replication forks move outward from each origin until they encounter replication forks that formed at adjacent origins. Thus eukaryotic chromosomes consist of multiple **replicons**, rather than the single replicon (i.e., the entire chromosome) observed in bacteria.

In eukaryotes, origins of replication are “marked” by a complex of proteins called the **origin recognition complex (ORC)**, which remains bound to the origins throughout much of the cell

Figure 15.1 Eukaryotic Chromosomes Are Replicated from Multiple Origins of Replication. (a) Drawing of a eukaryotic chromosome being replicated. (b) Schematic of chromosome III from the yeast *Saccharomyces cerevisiae*. It has 180 genes and is replicated from nine origins of replication.

cycle (table 15.1). Six different ORC proteins have been identified (Orc1 to Orc6), and these are combined in a species-specific manner to form the ORC. For instance, the ORC of the yeast *Schizosaccharomyces pombe* consists of six ORC proteins, two each of Orc1 (origin-recognition-complex protein 1), Orc2, and Orc4. ORC serves as a platform on which other proteins assemble in a cell cycle-dependent fashion. The first two proteins to associate with ORC are Cdc6 (cell-division-cycle protein 6) and

Cdt1 (Cdc10-dependent-transcript 1 protein). The two proteins bind ORC in the late M/early G1 phases of the cell cycle. Together, ORC, Cdc6, and Cdt1 recruit a set of proteins called the MCM complex to the origin, thereby forming the pre-replicative complex (pre-RC). Pre-RCs are activated as the cell cycle transitions from the G1 phase to the S phase by phosphorylation of Cdc6. Cdc6 and Cdt1 are then replaced by numerous other proteins, forming the complete replication machinery (table 15.1). At this point, MCM, which has helicase activity, begins unwinding DNA and replication begins.

Eukaryotic Primases and DNA Polymerases

DNA polymerases from many organisms have been analyzed and sorted into seven families based on their amino acid sequence and structure. As shown in table 15.2, eukaryotic DNA polymerases are found in different families than are the bacterial enzymes. In eukaryotes, three DNA polymerases are responsible for DNA replication: DNA polymerases α -primase, ϵ , and δ . Synthesis of the leading and lagging strands begins with the formation of a primer in all organisms, regardless of domain. However, among eukaryotes, this is accomplished with a bifunctional enzyme called DNA polymerase α -primase (often called simply Pol α -primase). This interesting enzyme consists of four subunits: two catalyze DNA synthesis (Pol α), and two catalyze RNA synthesis (primase). The primer is made in two steps: the primase component of the enzyme makes a short RNA strand (~10 nucleotides), which is then transferred to the active site of Pol α . Pol α adds an additional 20 or so deoxyribonucleotides to the RNA strand. Thus in eukaryotes, the single-stranded primer for DNA

Table 15.1 Major Replisome Proteins in Bacteria, Eukaryotes, and Archaea

| Function | Bacteria | Eukaryotes | Archaea |
|----------------------------|--|--|---|
| Initiator; binds origin | DnaA | ORC | Orc1/Cdt1 |
| Helicase loader | DnaC | Cdc6 and Cdt1 | Orc1/Cdt1 |
| Helicase | DnaB | MCM complex | MCM |
| Single-strand binding | SSB proteins | RPA | Species-specific proteins |
| Primer synthesis | DnaG primase | Pol α -primase ¹ | Primase (heterodimer) |
| Replicative DNA polymerase | DNA polymerase III (C-family polymerase) | DNA polymerase δ and DNA polymerase ϵ (B-family polymerases) | B-family polymerase (both crenarchaeotes and euryarchaeotes) and D-family polymerase (euryarchaeotes) |
| Clamp loader | γ complex | RF-C | RF-C |
| Clamp | β clamp | PCNA | PCNA |
| Ligase | DNA ligase ² | DNA ligase I ² | LigA ² |
| Primer removal | Ribonuclease H; DNA polymerase I | RNaseH/Dna2/Fen1 | RNaseH/Fen1 |

¹ Eukaryotic primases are heterodimers associated with DNA polymerase α .

² Bacterial DNA ligases use NAD^+ or ATP to power ligation of DNA fragments (see figure 13.15). Eukaryotes hydrolyze ATP to power ligation, as do most archaea. One NAD^+ -dependent DNA ligase has been identified in an archaeon.

| Table 15.2 DNA Polymerase Families | | |
|------------------------------------|--|---|
| Family | Example(s) | Functions/Comments |
| A | Bacterial DNA polymerase I | Replacement of RNA primers present in Okazaki fragments |
| B | Archaeal DNA polymerase B (Pol B) Eukaryotic DNA polymerases α , δ , and ϵ | Replicative DNA polymerases |
| C | Bacterial DNA polymerase III | Replicative DNA polymerase |
| D | Archaeal DNA polymerase D (Pol D) | Replicative DNA polymerase in some archaea; unique to archaea |
| X | Eukaryotic DNA polymerase β | DNA repair |
| Y | Bacterial DNA polymerase IV (Din B) | DNA repair |
| Reverse transcriptase (RT) | Retroviral reverse transcriptases Telomerase RT | RNA-dependent DNA polymerase |

replication is an RNA-DNA hybrid molecule. Once the primer is formed, the other two DNA polymerases take over. Considerable evidence suggests that DNA polymerase ϵ (Pol ϵ) is responsible for leading-strand synthesis, whereas DNA polymerase δ (Pol δ) carries out lagging-strand synthesis. Thus unlike most bacteria where DNA polymerase III synthesizes both leading and lagging strands, two distinct DNA polymerases carry out these functions in eukaryotes.

Telomeres and Telomerases: Protecting the Ends of Linear DNA Molecules

The fact that the DNA in eukaryotic chromosomes is linear poses several problems. Without protection, the ends are susceptible to degradation by enzymes called DNases. They are also able to fuse with the ends of other DNA molecules, thus generating aberrant chromosomes, which may not segregate properly during cell division. Finally, linear chromosomes present a problem during replication because of DNA polymerase's need for a primer that provides a free 3'-OH. When the primer for the Okazaki fragment at the end of the daughter strand is removed, the daughter molecule is shorter than the parent molecule. Over numerous rounds of DNA replication and cell division, this leads to a progressively shortened chromosome. Ultimately the chromosome loses critical genetic information, which could be lethal to the cell. This problem is called the "end replication problem," and a cell must solve it if it is to survive.

Eukaryotic cells have solved the difficulties related to having linear chromosomes by forming complex structures called

Figure 15.2 Telomere Structure. Telomeres consist of the end of the DNA molecule complexed with proteins. The location, number, and nature of the proteins differ from organism to organism. In this drawing, identical proteins are shown having the same shape. Different shapes indicate that the protein is not the same. Note that some proteins bind the single-stranded G-tail, whereas others bind upstream where the DNA is double stranded. (a) Telomere of the ciliate protists *Stylonychia* and *Oxytricha* spp. (b) Telomeres of budding yeasts such as *Saccharomyces cerevisiae*. (c) Telomere of fission yeasts such as *Schizosaccharomyces pombe*.

telomeres (figure 15.2) at the ends of their chromosomes and by using an enzyme called telomerase (figure 15.3). Telomeres are protein-DNA complexes that protect the linear DNA within them from degradation and end fusion. The protein component of a telomere varies from species to species, as does the length of DNA present. Telomeric DNA contains many copies of a particular sequence of nucleotides, placed one after the other (tandem repeats). Importantly, the DNA is single-stranded at the very end and is called the G-tail because it is rich in guanosine bases; telomerase uses the G-tail to maintain chromosome length.

Telomerase has two important components: an internal RNA template and an enzyme called telomerase reverse transcriptase (RT). The internal RNA template is complementary to a portion of the G-tail and base-pairs with it (figure 15.3). The internal RNA template provides the template for DNA synthesis, which is catalyzed by telomerase RT (i.e., the 3'-OH of the G-tail serves as the primer for DNA synthesis). After being lengthened sufficiently, there is room for synthesis of an RNA primer, and the single strand of telomere DNA can serve as the template for synthesis of the complementary strand. Thus the length of the chromosome is maintained.

Telomerase RT deserves additional comment. As described in the preceding paragraph, telomerase RT synthesizes DNA using an RNA template. Enzymes with this capability are defined

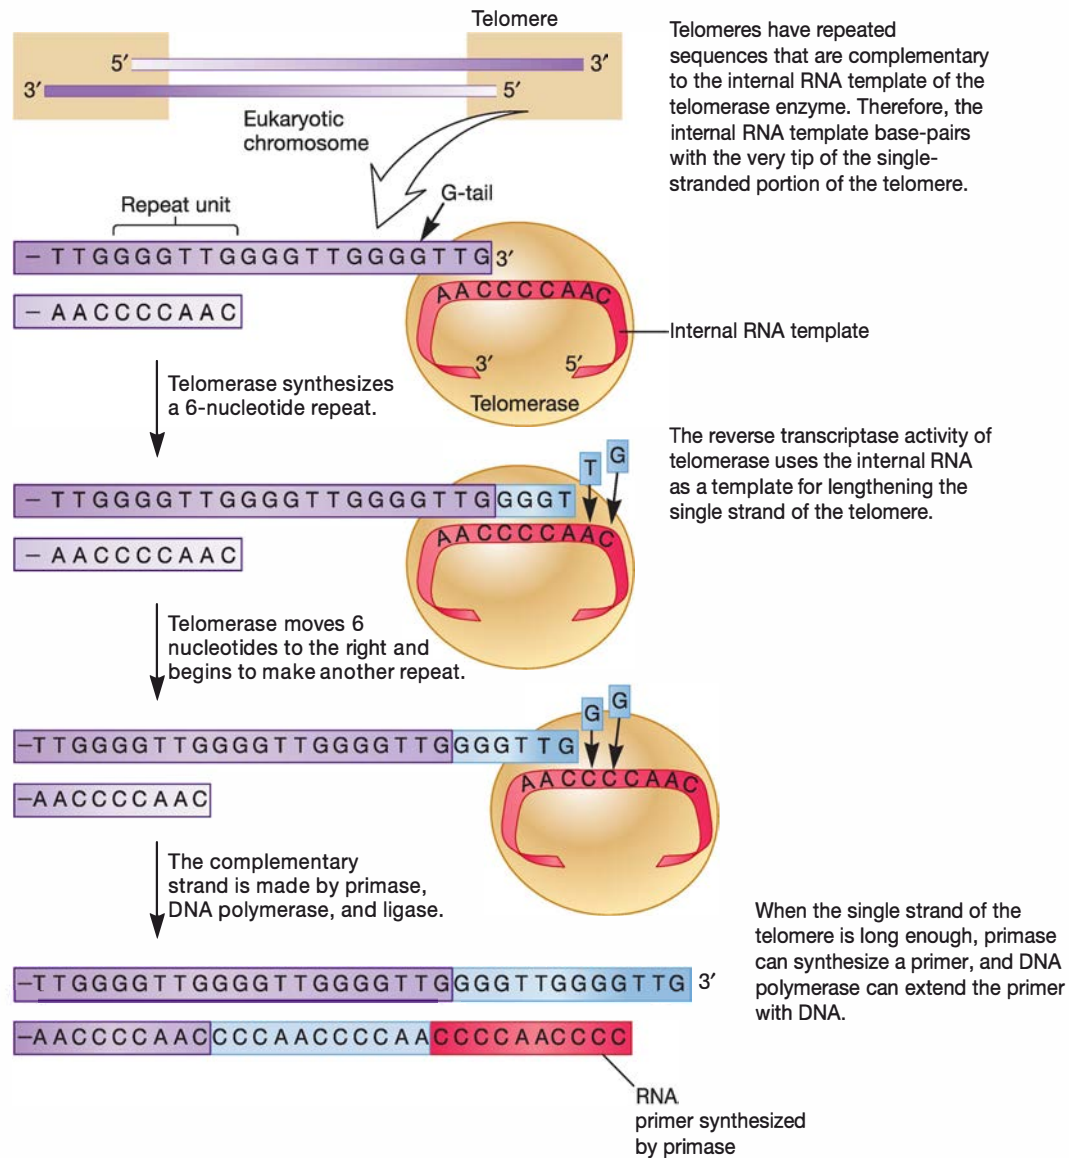

Figure 15.3 Replication of the Telomeric DNA of Eukaryotic Chromosomes by Telomerase. Telomerase contains an RNA molecule that can base-pair with a small portion of the 3' overhang (the G-tail). The RNA serves as a template for DNA synthesis catalyzed by the reverse transcriptase activity of the enzyme. The 3'-OH of the telomere DNA serves as the primer and is lengthened. The process shown is repeated many times until the 3' overhang is long enough to serve as the template for the complementary telomere DNA strand.

as RNA-dependent DNA polymerases. RNA-dependent DNA polymerases are not unique to telomerases; certain viruses use RNA-dependent DNA polymerases to complete their life cycles (e.g., human immunodeficiency viruses and hepatitis B viruses). These interesting viruses are described in chapter 27.

DNA Replication in Archaea

The mixture of bacterial and archaeal features is obvious when archaeal genomes are examined. Archaeal chromosomes are similar in size to those of bacteria. In addition, all known archaeal chromosomes are circular, like many bacterial chromosomes.

However, some archaea have histones associated with their chromosomes just like eukaryotes.

DNA replication in archaea also illustrates their “hybrid” natures. The circular chromosomes of archaea are replicated by replisomal proteins that are similar to those of eukaryotes (table 15.1). Most archaeal cells have a single origin of replication, like bacterial chromosomes; however, a few have more than one. The reason for this is unknown, as archaeal chromosomes are not especially large. However, having more than one origin may be related to the speed at which the replisome travels around the DNA. Those with faster speeds have single origins, whereas those with slower speeds have more than one origin. Thus having

multiple origins may serve the same purpose as in eukaryotes: decreasing the time needed to replicate the chromosome.

Analysis of archaeal primases and replicative DNA polymerases has led to some intriguing discoveries. Archaeal primases are uniquely heterodimeric; that is, they are composed of two different protein subunits. One is the catalytic subunit and the other is a regulatory subunit. Early studies of the catalytic subunit functioning alone *in vitro* yielded a surprise—DNA was produced, rather than RNA. Later studies revealed that when both the regulatory subunit and the catalytic subunit were used, both RNA and DNA could be made *in vitro*. It has been suggested that these two capabilities might be used *in vivo* by archaea to synthesize hybrid RNA-DNA molecules, as occurs in eukaryotes. Additional research is needed to resolve this issue.

The first archaeal DNA polymerases isolated and characterized were from members of the phylum *Crenarchaeota*. These enzymes belong to the same family of DNA polymerases as the replicative eukaryotic DNA polymerases (B family polymerases; table 15.2) and are called Pol B. Later studies examined the DNA polymerases from members of the other major archaeal phylum, *Euryarchaeota*. These studies revealed that euryarchaeotes use two DNA polymerases to replicate their chromosomes: Pol B and a unique archaeal DNA polymerase called Pol D. Pol D enzymes are so distinct, they are the sole members of the D family of DNA polymerases (table 15.2). Current models propose that Pol D has two functions: lagging-strand synthesis and initiation of leading-strand synthesis. Pol B is thought to eventually replace Pol D and complete synthesis of the leading strand.

Retrieve, Infer, Apply

1. What is the advantage of having multiple origins of replication for a eukaryote? What is the most plausible reason some archaeal species have multiple origins?
2. Refer to chapter 13 (see figure 13.13) and draw the last replication fork present near the end of a chromosome. Use your drawing to illustrate the end replication problem.
3. Review the steps in mitosis and meiosis. Why would having unprotected ends of linear DNA disrupt these two important cellular processes?
4. Outline the process used by telomerase to maintain chromosome length.
5. The discovery of telomerase activity in an archaeon would be a surprise. Why?

15.3 Transcription

After reading this section, you should be able to:

- Compare and contrast gene structure of eukaryotic, archaeal, and bacterial cells
- Create a table to distinguish eukaryotic, archaeal, and bacterial promoters, RNA polymerases, and transcription factors
- Discuss the modifications made to eukaryotic mRNA molecules during and after synthesis

Transcription is essentially the same in all cellular organisms: one strand of a gene, the template strand, directs RNA synthesis, and RNA is made from the 5' to the 3' end by enzymes called RNA polymerases. Bacterial RNA polymerase holoenzymes consist of six subunits (see figure 13.23), one of which is the sigma factor. Sigma factor positions the core enzyme at the promoter but does not catalyze RNA synthesis (see figure 13.24). Promoters are located upstream of the coding regions of the gene. Bacteria have a single RNA polymerase (but multiple, different sigma factors) that transcribes all genes, and transcription occurs in the cytoplasm.

One important feature of bacterial transcription is related to the organization of their genes. Often genes of related function are organized into operons. Importantly, the genes in the operon are transcribed from a single promoter. The resulting product is a polycistronic RNA (see figure 13.22). Transcripts encoding tRNA and rRNA molecules are processed to yield the individual molecules (see figure 13.21). Polycistronic transcripts encoding proteins have translation start and stop signals for each protein-coding region. In all cases, operons have regions that are transcribed but not translated (i.e., leaders, intergenic spaces, and trailers). For most protein-coding genes, the coding information within a gene is continuous.

Transcription in Eukaryotes

The differences in transcription observed in members of the three domains arise in part from differences in cell structure, gene organization, and RNA polymerase structure. In eukaryotes, transcription occurs in the nucleus, and the RNA products must move to the cytoplasm, where they function in translation. Gene structure and organization in eukaryotes also is strikingly different from that seen in bacteria. The vast majority of eukaryotes have singlet protein-coding genes. That is, each gene has its own promoter and the transcript synthesized from the gene is **monocistronic**. Furthermore, many eukaryotic protein-coding genes are composed of sequences called exons and introns. An **exon** contains sequences that code for part of the polypeptide, whereas an **intron** is a stretch of noncoding sequences. Thus the coding portion of a eukaryotic gene is not continuous. Both exons and introns are transcribed, yielding an exon- and intron-containing transcript called a **primary** or **pre-mRNA**. The introns are spliced out of the primary transcript before the protein is made (p. 360).

Eukaryotic RNA Polymerases

Eukaryotes have three major RNA polymerases. RNA polymerase I catalyzes rRNA synthesis, RNA polymerase II is responsible for mRNA synthesis, and RNA polymerase III synthesizes all the tRNAs and one rRNA (5S rRNA). All five of the bacterial RNA polymerase core enzyme subunits are conserved in eukaryotic RNA polymerases (table 15.3). However, eukaryotic RNA polymerases have several additional subunits.

Table 15.3 Subunits of RNA Polymerases (RNAP) and Their Homologues

| Bacteria Core RNAP Subunits ¹ | Archaeal RNAP Subunits ² | Eukaryotic RNAP II Subunits | Eukaryotic RNAP III Subunits | Eukaryotic RNAP I Subunits |
|--|-------------------------------------|-----------------------------|------------------------------|----------------------------|
| β | Rpo1 (RpoA) ³ | RPB1 | C160 | A190 |
| β | Rpo2 (RpoB) | RPB2 | C128 | A135 |

1 Sigma factor (σ) found in the bacterial holoenzyme is treated here as a transcription factor. Archaea and eukaryotes have numerous transcription factors (table 15.4). Most archaeal transcription factors have homologues in eukaryotic organisms.

2 Only those archaeal subunits observed in all archaea studied thus far are listed.

3 Alternate names for subunits are in parentheses.

4 Some archaea have a subunit homologous to RPB8.

Transcription Initiation in Eukaryotes

Most research on transcription in eukaryotes and archaea has been on the transcription of protein-coding genes. That is our focus. In eukaryotes, RNA polymerase II (often referred to as RNAPII) is responsible for transcribing protein-coding genes. This enzyme is a large aggregate, at least 500,000 daltons in size, with about 10 subunits (table 15.3).

Transcription initiation requires that RNAPII be recruited to a promoter. Eukaryotic promoters differ from those in bacteria (figure 15.4). One of the first features discovered in eukaryotic promoters was the conserved nucleotide sequence TATA; thus the region is named the TATA box. Later other elements were identified. These elements define the core promoter, which is so named because one or more of the core promoter elements are found in all promoters recognized by RNAPII. It was initially thought that all RNAPII promoters contain a TATA box. However, it has recently been determined that many RNAPII promoters lack a TATA box.

With or without a TATA box, RNAPII must be properly oriented on the promoter for the correct mRNA to be made. Unlike bacterial RNA polymerase, which uses a single sigma factor for this purpose, RNAPII requires several proteins called transcription factors to recognize its promoters and transcribe

Figure 15.4 Eukaryotic and Archaeal Promoters. (a) Eukaryotic promoters contain one or more of the elements shown. However, it is very rare for all of the elements to be present. BRE is the TFIIB recognition element. Inr is the *initiator* element; transcription initiates within this site. DPE is the *downstream promoter* element. The approximate positions of each promoter element are indicated. (b) An archaeal promoter. Promoter element designations are the same as those in eukaryotic promoters.

a gene (table 15.4). One of the most important for transcription initiation is the TATA-binding protein (TBP), which is often a component of a complex of proteins called TFIID (short for transcription factor *D* for RNA polymerase *II*). TBP positions

Table 15.4 Eukaryotic and Archaeal Transcription Factors

| Eukaryotic Transcription Factor ¹ | Homologous Archaeal Transcription Factor |

| TFIIH | |

¹ Only those eukaryotic transcription factors shown in figure 15.5 are listed.

² Eukaryotic TBP is often part of a complex of proteins called TFIID.

³ TFI indicates that the protein is a transcription factor for RNA polymerase II. TF indicates that the protein is a transcription factor for archaeal RNA polymerase.

RNA polymerase at both TATA box-containing promoters and those that lack the TATA box. The transcription factors listed in table 15.4 are termed basal transcription factors because they are required for initiation of transcription at all RNAPII promoters.

One sequence of events to direct RNAPII to the promoter and initiate transcription is illustrated in figure 15.5. Studies of transcription initiation in numerous eukaryotes have shown that this is not the only sequence of events nor are these the only proteins involved. One complex of proteins deserves mention: **mediator**. Mediator is sometimes involved in recruiting certain basal transcription factors to the promoter during transcription initiation. It is noteworthy because it, as well as TFIID, also plays important roles in regulating gene expression, as we discuss in section 15.5.

From Pre-mRNA to mRNA: A Unique Eukaryotic Process

Unlike nearly all bacterial mRNAs, the initial transcript synthesized from a eukaryotic protein-coding gene must be modified before giving rise to a translatable mRNA. Modification begins during the elongation phase of transcription and is completed after transcription ends. It starts with the addition of an unusual nucleotide to the 5' end of the transcript when the transcript is only about 25 ribonucleotides long (figure 15.6). The **5' cap**, as it is called, is 7-methylguanosine. After the 5' cap is added and a sufficiently long transcript is generated, removal of introns begins. After synthesis is completed, any remaining introns are removed, and the pre-mRNA is modified further by the addition of a **3' poly-A tail**, about 200 nucleotides long (figure 15.6). Both the 5' cap and poly-A tail help protect the mRNA from enzymatic attack. Furthermore, they enable the cell to recognize that the

Figure 15.5 Initiation of Transcription in Eukaryotes. Shown is initiation using a promoter containing a TATA box. TATA-binding protein (TBP), which is often a component of a complex of proteins called TFIID (transcription factor IID), binds the TATA box. Note that numerous other transcription factors are required for initiation of transcription, unlike bacteria, where only sigma factor is needed.

mRNA is intact and ready to be transported from the nucleus to the cytoplasm. The 5' cap has the additional important function of serving as a recognition signal for binding of ribosomes to the mRNA so that it can be translated.

Figure 15.6 Modifications Made to the Ends of Eukaryotic mRNA.

MICRO INQUIRY What functions are served by the 5' cap and the 3' poly-A tail?

Introns are removed from the pre-mRNA by a large complex of proteins and RNA molecules that is unique to eukaryotic cells. This large complex, called a **spliceosome**, is composed of several small nuclear ribonucleoproteins (snRNPs, pronounced “snurps”) and several non-snRNP splicing factors. The snRNPs consist of small nuclear RNA (snRNA) molecules (about 60 to 300 nucleotides long) associated with proteins. Some snRNPs recognize and bind exon-intron junctions (**figure 15.7**). Exon-intron junctions have a GU sequence at the intron’s 5’ boundary and an AG sequence at its 3’ end. Thus the intron’s borders are clearly marked for accurate removal.

Sometimes a pre-mRNA is spliced so that different patterns of exons remain or the junction of two exons varies. This **alternative splicing** allows a single gene to code for more than one protein. The splice pattern determines which protein is synthesized. Splice patterns can be cell-type specific or determined by the needs of the cell. The importance of alternative splicing in multicellular eukaryotes was clearly demonstrated when it was discovered that the human genome has only about 20,000 genes, rather than the anticipated 100,000. It is thought that alternative splicing is one mechanism by which human cells produce a vast array of proteins using fewer genes. This mechanism for expanding the coding capacity of a genome is not available to bacteria and archaea because introns in their protein-coding genes are very rare. *Processing of Genetic Information: Prokaryotes Versus Eukaryotes*

Transcription in Archaea

If transcription in archaea were described in a newspaper article, the headline might be something like this: “Eukaryotic-like RNA polymerases functions in bacteria-like environment.” This is because archaeal transcription occurs in the cytoplasm, as it does for bacteria. Many (although perhaps not quite as many) archaeal genes are organized into operons, as are bacterial genes. Thus many archaeal mRNAs are polycistronic. Introns are rare in protein-coding archaeal genes (as they are in bacteria), and they are removed by a process different than that used by eukaryotes (again as they are in bacteria). Finally, archaeal cells use a single RNA polymerase to catalyze transcription.

The archaeal RNA polymerase is large and most similar to RNA polymerase II of eukaryotes (table 15.3 and **figure 15.8**). Likewise, transcription initiation in archaea is very similar to that seen in eukaryotes, as evidenced by the similarity in promoters (**figure 15.4**) and the use of similar transcription factors throughout the transcription cycle (table 15.4). The archaeal process can be thought of as a simplified version of that in eukaryotes. As shown in **figure 15.9**, two archaeal transcription factors are important for recruiting the archaeal RNA polymerase to a promoter: TATA-binding protein (TBP) and transcription factor B (TFB). A third transcription factor TFE then associates with RNA polymerase and promotes unwinding of the DNA to form the open complex (see **figure 13.26**). RNA polymerase then moves down the gene, transcribing it.

Figure 15.7 Removal of an Intron by a Spliceosome.

Figure 15.8 Bacterial, Archaeal, and Eukaryotic RNA Polymerases.

15.4 Translation and Protein Maturation and Localization

After reading this section, you should be able to:

- Differentiate the structure of eukaryotic, archaeal, and bacterial ribosomes
- Identify the initiator tRNA used by eukaryotic and archaeal cells
- Discuss the role of molecular chaperones in eukaryotic and archaeal cells
- Create a concept map or table that distinguishes the translocation and secretion systems observed in the three domains of life

For organisms to survive, they must be able to synthesize the proteins they need (translation), fold them into a functional conformation, and localize the proteins to the correct site within (or outside) the cell. In bacteria, translation initiation requires three protein initiation factors (IFs), the initiator tRNA (fMet-tRNA^{Met}), and the two ribosomal subunits (50S and 30S subunits) (see figure 13.38). The 16S rRNA and a sequence in the mRNA called the Shine-Dalgarno sequence interact to position the ribosome such that the initiator tRNA is at the start codon (AUG), which is located in the P site of the ribosome. The A site of the ribosome is empty and awaits the aminoacyl-tRNA that corresponds to the second codon in the coding portion of the mRNA. Elongation then ensues with the assistance of three elongation factors (EFs; see figure 13.39). Translation is tightly coupled with transcription, and polysomes are often observed (figure 13.33). Translation terminates when the ribosome encounters a stop codon; three release factors (RFs) then contribute to the separation of the two ribosomal subunits and the release of the polypeptide (see figure 13.41). Chaperones help the protein fold (see figure 13.42). Representatives of all types of **chaperones** have been identified in bacteria. In addition to their folding responsibilities, some chaperones deliver proteins to systems that will insert them into the plasma membrane, translocate them into the periplasmic space, or secrete them to the external environment.

In this section, we focus on translation, and protein folding and localization as they occur in eukaryotes and archaea. As with DNA replication and transcription, the overall processes are similar in all organisms. Therefore we focus our attention primarily on those aspects of the eukaryotic and archaeal processes that differ from those observed in bacteria.

Translation in Eukaryotes

There are many obvious differences between bacterial and eukaryotic translation. One is that eukaryotic ribosomes are larger than those in bacteria and require more initiation factors to be positioned properly on the mRNA. The 5' cap and the 3' poly-A tail of eukaryotic mRNAs are integral to translation initiation. The process begins with mRNA activation. Activation is brought about by the binding of several eukaryotic initiation factors (eIFs) to the 5' end of the mRNA and attachment of poly-A binding proteins (PABPs) to the 3' end. The eIFs and PABPs interact, causing the mRNA to fold back on itself with the eIFs and PABPs forming a bridge between the two ends (figure 15.10). Meanwhile, the initiator tRNA (Met-tRNA^{Met}) interacts with the 40S ribosomal subunit (the small subunit, SSU) to form a structure termed the 43S complex. Formation of the 43S complex is facilitated by several additional eIFs. The 43S complex then binds the activated mRNA, generating the 43S•mRNA complex.

As seen in figure 15.10, at this point in translation initiation, the SSU is not positioned at the start codon of the mRNA as it is in bacteria. Rather, it is at the 5' end of the mRNA. The 43S complex slides down the mRNA scanning for the start codon. Once the start codon is encountered, scanning ceases and the 60S ribosomal subunit (large subunit) joins with the 43S•mRNA complex, forming the complete 80S ribosome. Translation can now commence.

Elongation and termination proceed in a fashion similar to that seen in bacteria. Three elongation factors function in both bacteria and eukaryotes, and the bacterial and eukaryotic factors are very similar structurally and functionally. Polysomes are used during translation of eukaryotic mRNAs. However, because of the circularization of the mRNA during translation initiation, the polysomes have a characteristic structure (figure 15.11). Another difference is seen in the termination step. In eukaryotes, a single release factor (eRF) functions as opposed to three RFs in bacteria.

Protein Folding in Eukaryotes

Eukaryotes, like bacteria, use chaperones to help many proteins fold properly and restore proper folding if the protein is denatured by environmental conditions. As we introduce in chapter 13, chaperones were first identified by their role in protecting the proteins of heat-stressed cells and are often called heat-shock proteins (HSPs). There are numerous HSPs, and these are often sorted into types of HSPs based on their size. For instance, the bacterial chaperones GroEL and GroES have a molecular weight of about 60,000 and are included with other HSPs of similar size. All are referred to as HSP60s. Representatives of all types of chaperones are found in eukaryotes.

Protein Localization and Secretion in Eukaryotes

Proteins produced by eukaryotic cells have numerous possible destinations because these cells are highly compartmentalized, having many membrane-bound organelles such as the endoplasmic reticulum (ER), mitochondria, chloroplasts, and lysosomes. Although mitochondria and chloroplasts have genomes that encode some of their proteins, most are encoded in the nucleus and

Figure 15.10 Translation Initiation in Eukaryotes. To simplify the drawing, many additional eukaryotic initiation factors (eIFs) are not shown. The upper left portion of the figure shows mRNA activation; the upper right shows the formation of the 40S complex. The 40S complex binds to the 5' end of the activated mRNA and then moves down the mRNA to find the first AUG. This positions the initiator tRNA carrying methionine in what will become the peptidyl (P) site of the ribosome after the addition of the 60S subunit. The acceptor (A) site is vacant and ready for the arrival of the tRNA carrying the second amino acid encoded by the mRNA. Met is methionine. PABP is poly-A binding protein. E site is exit site.

translated in the cytosol (i.e., the liquid portion of the cytoplasm). Thus some proteins synthesized in the cytosol stay there, but many are moved to specialized cellular compartments or are secreted. As described in chapter 5, proteins that are secreted or that move between the endoplasmic reticulum, Golgi apparatus, endosomes, and other membranous components of the endocytic and secretory pathways are delivered to these organelles or the plasma

Figure 15.11 Eukaryotic Polysome. Schematic representation of a polysome. The distinctive circular form results from the interaction of the two ends of the mRNA brought about by the poly-A-binding proteins, eIF-4E, eIF-4G, and other initiation factors.

membrane by small vesicles that pinch off from the membrane of one organelle (e.g., the ER) and then fuse with a target membrane. This mechanism for localizing and secreting proteins is often called **vesicular transport**, and it does not involve the translocation of proteins across membranes. However, in order for proteins to move from the cytosol to the ER, mitochondria, and chloroplasts, the proteins must be translocated across membranes. This transmembrane transport involves translocator systems that are similar to certain translocation and protein secretion systems used by bacteria, as well as other proteins found in bacterial membranes. **Organelles of the secretory and endocytic pathways** (section 5.4); **Protein maturation and secretion** (section 13.8)

The best-studied protein translocation system in eukaryotes is the **Sec pathway** (figure 15.12). Central to the functioning of this pathway in eukaryotes is the Sec61 $\alpha\beta\gamma$ translocon through which unfolded proteins move. Several proteins that make up the Sec system in eukaryotes are homologous to Sec proteins in bacteria (table 15.5). In eukaryotes, the Sec pathway functions to move proteins from the cytosol into the membrane or lumen of the ER. It also functions in chloroplasts to move proteins from the stroma into the thylakoid membrane or the thylakoid lumen. Like the Sec system of bacteria, posttranslationally translocated proteins are

Table 15.5 Sec Protein Homologues

| Bacteria | Eukaryotes | Archaea |
|----------|----------------------------|-------------------|
| SecY | Sec61 α | SecY ¹ |
| SecE | Sec61 γ | SecE ² |
| SecG | — | — |
| — | Sec61 β ² | Sec61 β |

¹ Although given the same name as the bacterial protein, this archaeal protein's structure is more like the eukaryotic homologue.

² All Sec systems have three proteins that form the pore through which proteins move. However, the Sec61 β protein differs from SecG both in structure and in function.

Figure 15.12 Comparison of the Sec Systems Found in Bacteria, Eukaryotes, and Archaea. In bacteria, translocation can occur posttranslationally or cotranslationally. In most cases, cotranslational translocation inserts the protein into the plasma membrane. In eukaryotes, posttranslational and cotranslational translocation are also observed. In archaea, it is thought that only cotranslational translocation occurs. SecDF proteins are common in euryarchaeotes but not crenarchaeotes.

Figure 15.13 Translocation of Proteins from Cytosol to Locations in the Mitochondrion.

A simplified diagram of the translocation systems used to localize proteins in mitochondria. The type of protein dictates its final location. TOM moves proteins across the outer membrane (OM) of the mitochondrion. Some of these proteins will be moved across or into the inner membrane (IM) by the TIM system. Other proteins are inserted into the OM by SAM (sorting and assembly machinery). A complex of proteins similar to SAM exists in Gram-negative bacteria (BAM). Oxa1 inserts proteins made in the mitochondrial matrix into the IM. Oxa1 is related to a bacterial translocase called YidC, which inserts proteins into the plasma membrane.

targeted to the Sec translocon by a **signal peptide** at their amino-terminus (see figure 13.44).

Localization of proteins in the membranes, intermembrane spaces, and matrix of mitochondria occurs by very different mechanisms. For a mitochondrial matrix protein to arrive at its destination, it must be translocated through the outer and inner membranes of the mitochondrion (see figure 5.15). Proteins are moved across the outer membrane by a system of proteins called the TOM complex (translocase of the outer mitochondrial membrane). The TIM complex (translocase of the inner mitochondrial membrane) moves proteins across the inner membrane (figure 15.13). The evolutionary history of the proteins in these complexes is still being debated. However, the channel formed by one of the TOM complex proteins is a β -barrel, as are many outer membrane proteins of bacteria (e.g., porins; see figure 3.27). At the core of the TIM complex is a protein that exhibits some homology to a bacterial transporter protein that functions in amino acid uptake. It is expected that as more genomes are analyzed, more protein homologies will be discovered. **◀◀ Mitochondria (section 5.6)**

Translation, Protein Maturation, and Protein Localization in Archaea

Most studies of archaeal translation have focused on translation initiation. These studies have yielded some surprising results. First, transcription and translation are tightly coupled, as in

bacteria. Thus translation of mRNAs can begin before synthesis of the mRNA is finished. Some archaeal mRNAs have a Shine-Dalgarno sequence in the leader. Translation initiation of these mRNAs proceeds by a mechanism similar to that seen for bacteria. However, the initiator tRNA is Met-tRNA^{Met}, as in eukaryotes. Furthermore, more initiation factors (called archaeal IFs or aIFs) are involved than in bacteria. Some are similar to eIFs, while other aIFs are unique, not having any counterparts in either bacteria or eukaryotes. Little is known about the functions of aIFs. Other archaeal mRNAs lack Shine-Dalgarno sequences, yet they too are translated. How this occurs is still unknown. For those archaeal mRNAs that are polycistronic, translation is initiated and proceeds from initiation sites for each coding-sequence carried by the mRNA. Thus each coding-region in the polycistronic mRNA yields a separate protein, as occurs in bacteria. Archaeal elongation factors are similar to those in both bacteria and eukaryotes. Thus elongation factors, as opposed to initiation factors, are highly conserved in all cellular organisms. Finally, archaea use a single release factor during translation termination, as do eukaryotes.

Folding of archaeal proteins is accomplished with the aid of chaperones (i.e., heat-shock proteins; HSPs). With the exception of the very largest HSPs (HSP100s and HSP90s), representatives of all types of chaperones are found in archaea. As you might imagine, archaeal chaperones have been of particular interest to microbiologists because many archaea live in extreme environments that require mechanisms such as chaperones to protect their proteins. One well-studied archaeal chaperone is the GroEL-like chaperone of *Pyrodicticum occultum*, an archaeon that grows at temperatures as high as 110°C. This Hsp60-type chaperone, like other HSP60s, hydrolyzes ATP as it helps proteins fold (see figure 13.42). The *P. occultum* GroEL hydrolyzes ATP most rapidly at 100°C and makes up almost three-quarters of the cell's soluble protein when *P. occultum* grows at 108°C.

Archaeal protein translocation systems are less well studied than those of bacteria and eukaryotes. However, they exhibit the mosaicism that is common to many aspects of archaeal physiology and structure. Thus far, two protein translocation systems have been identified: the Sec pathway and the TAT pathway (see figure 13.45). The archaeal Sec pathway is best studied and presents a clear example of the mixing of bacterial and eukaryotic characteristics (figure 15.12 and table 15.5). In archaea, the Sec translocon is called the SecYE β translocon because it consists of SecY and SecE, which have homologues in both bacteria and eukaryotes but are most similar to those of eukaryotes (table 15.5), and Sec61 β , which is found in eukaryotic cells. Thus far, only cotranslational translocation has been observed in archaea. **◀◀ Protein maturation and secretion (section 13.8)**

1. Is it surprising that polysomes are observed in all cellular organisms? Explain your answer.
2. List the aspects of translation in archaea that are similar to translation in bacteria. Create a similar list that compares archaeal translation to that seen in eukaryotes. What generalizations can be made from these comparisons?
4. What features of the mitochondrial protein import systems (TOM and TIM complexes) provide evidence that mitochondria evolved from endosymbiotic bacteria? Explain your choices.

15.5 Regulation of Cellular Processes

After reading this section, you should be able to:

- List the steps at which eukaryotic and archaeal cells can regulate cellular processes
- Explain why the separation in time and space of transcription and translation in eukaryotic cells is important to the possible regulatory mechanisms used
- Write a paragraph comparing the mechanisms by which eukaryotic and bacterial regulatory proteins control transcription
- Discuss the importance of small RNA molecules in regulating gene expression in eukaryotes

As is the case in bacteria, the regulation of cellular processes in eukaryotes and archaea can occur at transcriptional, translational, and posttranslational levels (**figure 15.14**; and *see figure 14.1*). Much of the research on regulation in eukaryotes and archaea has focused on transcription initiation. That is our focus here.

Regulation of Transcription Initiation in Eukaryotes

As described in section 15.3, transcription initiation in eukaryotes involves numerous transcription factors called basal transcription factors. In addition, other transcription factors such as mediator (p. 360) can play important roles, depending on the organism and the gene being transcribed. Regulation of transcription initiation in eukaryotes is often brought about by DNA-binding proteins that can act either positively (i.e., transcription activators that increase transcription levels) or negatively (i.e., transcription repressors that decrease transcription levels).

The binding sites of numerous eukaryotic activator and repressor proteins have been identified. Two different transcription activator binding sites are sometimes distinguished: **upstream activating sequences (UASs)** and enhancers. UASs are near the promoter of the gene they regulate. **Enhancers** can be either upstream or downstream of the promoter, and importantly, they can exert their effects from a great distance (**figure 15.15**). Despite the differences between UASs and enhancers, they function in a similar way. Both are binding sites for transcription activators

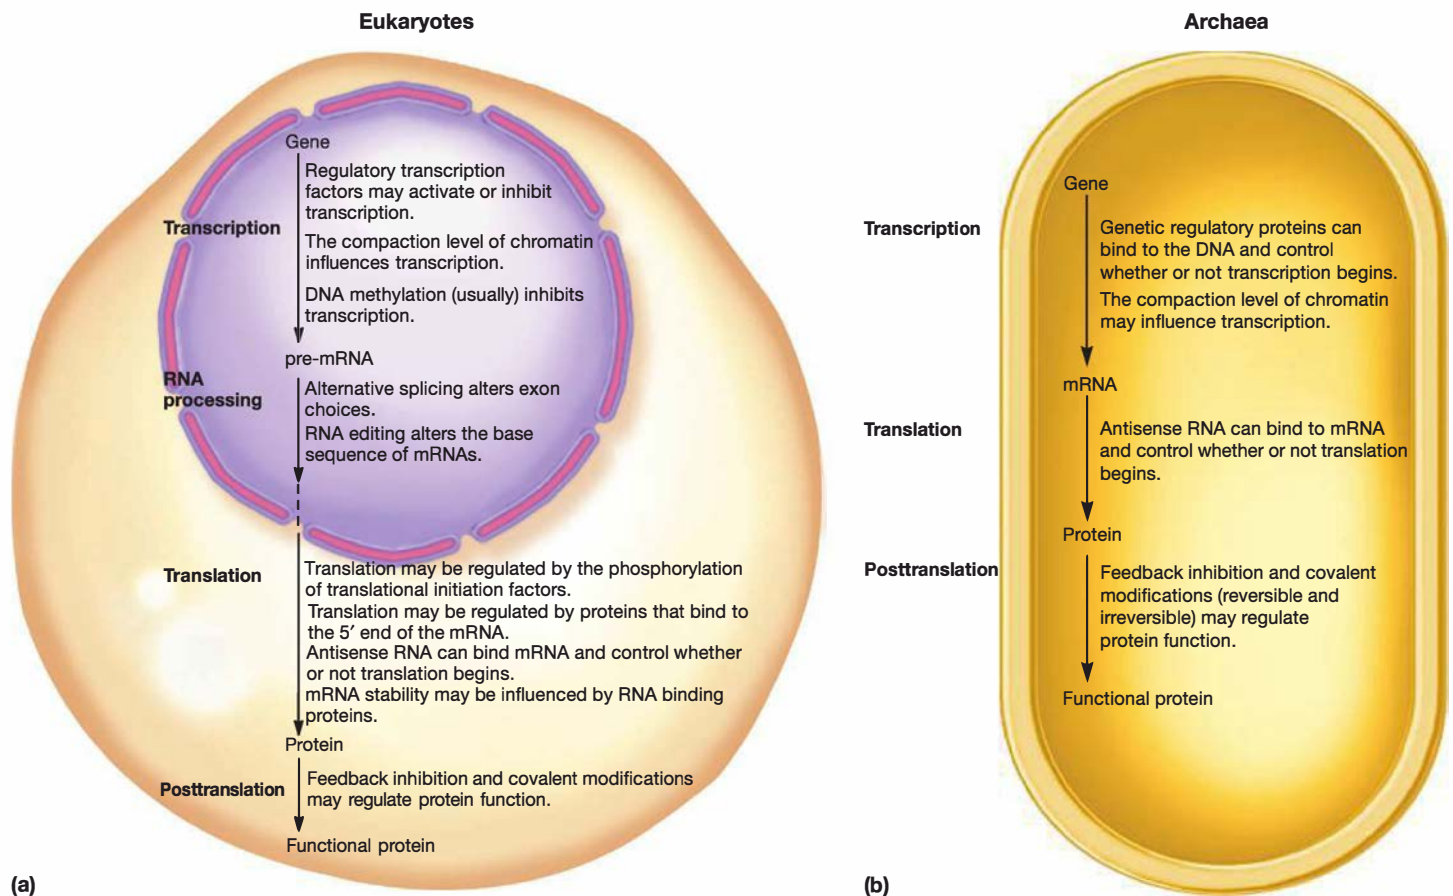

Figure 15.14 Gene Expression and Common Regulatory Mechanisms in Eukaryotes and Archaea.

The transcriptional activator interacts with mediator. This enables RNA polymerase to form a preinitiation complex that can proceed to the elongation phase of transcription.

The transcriptional repressor interacts with mediator so that transcription is repressed.

Figure 15.15 Enhancers and Silencers Exert Their Effects from a Distance. Enhancers and silencers are regulatory sites on DNA bound by activator proteins, which increase the rate of transcription, and repressor proteins, which inhibit transcription, respectively. Both sites can be quite far from the genes they regulate. Most models propose that when the regulatory protein binds its recognition site, it subsequently interacts with mediator or a basal transcription factor (e.g., TFIID), causing a DNA loop to form.

which then interact with other proteins to promote transcription, including mediator and TFIID. Transcription repressors bind DNA sites called **silencers**. Silencers, like enhancers, can regulate transcription even when located far from the gene they regulate. Eukaryotic repressor proteins interact with other proteins to bring about repression. The existence of regulatory sites that are far removed from the gene being regulated presents a problem: how does the cell prevent an enhancer or silencer from affecting transcription of the wrong gene? Eukaryotic cells have solved this problem by having sites called **insulators**. **Insulators** are so named because they “insulate” genes by preventing the “spread” of the effects of activators and repressor proteins beyond a certain area of the chromosome.

Regulation of the *GAL* genes in the yeast *Saccharomyces cerevisiae* has served as an important model for regulation of transcription initiation in eukaryotes (figure 15.16). These genes encode proteins needed for the uptake and catabolism of the sugar galactose. *GAL* genes are controlled by an activator protein (Gal4) that binds a UAS near each *GAL* gene. The Gal4 protein's ability to activate transcription of *GAL* genes is controlled by another protein (Gal80), which inhibits Gal4 when no galactose is present. When galactose is available, Gal80 is prevented from inhibiting Gal4, and Gal4 activates transcription by recruiting several proteins to the UAS, including the basal transcription factors. Finally, RNA polymerase II binds, setting the stage for transcription to start. The regulation of yeast *GAL* genes has been an important model because it exemplifies many of the features of eukaryotic regulation. These include chromatin remodeling,

acetylation of histones, formation of activation complexes, and the indirect influence of activators and repressors on genes.

Chromatin remodeling and histone acetylation deserve additional comment. Both are important in regulation of gene expression because they facilitate changes in chromatin structure such that promoters can become either more or less accessible to the transcription machinery. Both chromatin remodeling and histone acetylation are catalyzed by enzymes that alter nucleosomes (figure 15.16). Recall from chapter 5 that the nucleosome core is composed of DNA wound around two copies each of the major histone proteins H2A, H2B, H3, and H4 (see figure 5.11). In addition to the major histone proteins, which are produced in great abundance, eukaryotic cells also produce small quantities of variant forms of histones H2A, H2B, and H3. These variant forms can replace a major histone, thereby altering chromatin structure. In addition, the major histone proteins can be covalently modified—often by addition or removal of acetyl, methyl, or phosphoryl groups. Some scientists have suggested that variant histones and covalent modification of histones are used by cells as signals; some indicate that a gene should be expressed, whereas others repress transcription. For instance, acetylation of histones promotes transcription; methylation of histones often represses transcription.

Other Regulatory Mechanisms in Eukaryotes

In addition to controlling transcription initiation with regulatory proteins, eukaryotes use a variety of other methods to regulate gene expression (figure 15.1a). Eukaryotes produce antisense RNAs that function at the level of translation, as described for bacteria in

Gal4 protein is an activator that is part of the regulatory system controlling transcription of *GAL* genes. It recognizes and binds to an upstream activating sequence specific for *GAL* genes (UAS_{GAL}).

In the absence of galactose, the protein Gal80 binds Gal4 and prevents it from activating transcription.

When galactose is available, the protein Gal3 moves into the nucleus and binds Gal80. The Gal80/Gal3 complex moves to the cytoplasm. This allows Gal4 to begin to activate transcription of *GAL* genes.

Gal4 recruits a number of protein complexes, including mediator, SAGA, and SWI/SNF. The SAGA complex transfers an acetyl group to a histone in a nucleosome. This facilitates the removal of the nucleosome by the SWI/SNF complex.

Removal of the nucleosome enables SAGA and mediator to recruit the basal transcription factors (BTFs) and RNA polymerase II to the core promoter.

Figure 15.16 Regulation of *GAL* genes in *Saccharomyces cerevisiae*. TBP is TATA-binding protein, one of the basal transcription factors (BTFs) recruited to the promoter when galactose is available.

section 14.4. Riboswitches have been identified in some eukaryotes. However, they work by controlling whether or not RNA splicing occurs, rather than affecting transcription elongation or translation. Eukaryotes also produce numerous small RNA (sRNA) molecules that regulate gene expression. Some sRNA molecules are important components of the spliceosome, where they contribute to the selection of splice sites used during mRNA processing (alternative splicing; p. 361). In doing so, different proteins can be made at certain times in the life cycle of the organism by combining different exons. **◀ Riboswitches (section 14.3); Regulation of translation by riboswitches (section 14.4)**

One of the most interesting regulatory mechanisms observed in eukaryotes is brought about by very small antisense RNAs called **micro RNAs (miRNAs)** or small interfering RNAs. Micro RNAs are formed when larger RNA molecules are cut by an RNase (usually an RNase called Dicer). Once formed, the miRNAs interact with a protein called argonaute (AGO) to form a complex called the RNA-induced silencing complex (RISC). The miRNA within the RISC then base-pairs with a target mRNA. In

plants and animals, this leads to inhibition of gene expression at the level of translation by several mechanisms. These include preventing translation initiation, inhibiting translation elongation, and degradation of mRNA.

Small interfering RNAs (siRNAs) are formed in a similar manner as miRNAs, and they can also function at the translational level. However, siRNAs additionally regulate transcription. They do so by interacting with several proteins, including argonaute, to form a complex termed RNA-induced transcriptional silencing (RITS) complex. The siRNA directs the RITS complex to a target area on the chromosome by a mechanism that is not yet understood. Once bound to the chromosome, the RITS complex initiates chromatin remodeling that results in a highly compacted form of chromatin called heterochromatin. Heterochromatin is so compacted that any promoters in it cannot be recognized by the basal transcription factors and RNA polymerase. Therefore transcription is prevented.

🌀 *Control of Gene Expression in Eukaryotes*

Regulation of Transcription Initiation in Archaea

The regulation of gene expression in archaea has garnered a great deal of interest. This is because the archaeal transcription and translation machinery is most similar to that of eukaryotes, yet it functions in anucleate cells with circular chromosomes. The question being asked is whether archaeal regulation of gene expression is more like bacterial regulation or more like eukaryotic regulation. Thus far, the answer is mixed.

Some archaeal regulatory proteins are bacteria-like in their action. For example, some repressor proteins attach to operators in a fashion similar to bacterial repressors (see figure 14.3). However, other repressor proteins function in a unique manner: instead of binding an operator, they associate with the TATA box in the promoter, thereby preventing the TATA-binding protein (TBP) from attaching.

One interesting observation is that many archaea contain different forms of transcription factor B (TFB) and TBP (figure 15.9). Evidence suggests that certain combinations of TFB and TBP are used to initiate transcription of distinct subsets of genes and operons in the genome. This is reminiscent of the use of different sigma factors by bacteria to control transcription of suites of genes in response to certain environmental conditions.

Finally, the association of histones with the chromosomes of some archaea opens the possibility that they play a role in regulating transcription. Some evidence suggests that the presence of histones at or near a promoter can inhibit transcription. Furthermore,

one transcription activator protein has been shown to counteract this inhibition. One explanation for this observation is that the activator protein competes with histones for promoter binding. Once the activator attaches to the promoter, it allows TFB, TBP, and RNA polymerase to bind and initiate transcription.

Retrieve, Infer, Apply

1. List two similarities and two differences between bacterial and eukaryotic regulatory proteins.
2. What regulatory sequences in bacterial genomes are analogous to the enhancers and silencers observed in eukaryotic genomes?
3. How are antisense RNAs, micro RNAs, and small interfering RNAs alike? How do they differ?

Key Concepts

15.1 Why Consider Eukaryotic and Archaeal Genetics Together?

- Despite having prokaryotic cell architecture, archaea exhibit unique characteristics that distinguish them from bacteria.
- Examination of the machinery involved in processing and expressing archaeal genomes has revealed that it is more like that of eukaryotes than that of bacteria.

15.2 DNA Replication

- Eukaryotic DNA has many replicons and replication origins (**figure 15.1**). DNA replication is initiated when certain proteins are recruited to origins of replication by a set of proteins called the origin of recognition complex (ORC).
- In eukaryotes, three different DNA polymerases are part of the replisome. DNA polymerase α -primase synthesizes an RNA-DNA hybrid molecule that serves as the primer for DNA synthesis. DNA polymerase ϵ carries out leading strand synthesis, and DNA polymerase δ is responsible for lagging strand synthesis.
- Telomerase is responsible for replicating the ends of eukaryotic chromosomes (**figure 15.3**).
- All known archaeal cells have circular DNA. Their chromosomes are thought to be replicated in a manner similar to circular bacterial chromosomes. However, some archaeal species have more than one origin of replication.
- In archaea, the replisomes of all species examined thus far contain a primase and a DNA polymerase (Pol B) similar to those in eukaryotic replisomes. Some archaea have a second DNA polymerase (Pol D) that is unique to archaea (**table 15.2**).

15.3 Transcription

- Most eukaryotic protein-coding genes are not organized into operons. Therefore the mRNAs that arise from them are monocistronic.
- Three RNA polymerases transcribe genes in eukaryotes. RNA polymerase II transcribes protein-coding genes. RNA polymerase I transcribes rRNA genes, and RNA

Summing Up

We began this chapter by discussing the historical treatment of archaea as simply an unusual group of bacteria. It is currently recognized that archaea define a distinct taxon at the domain level and that they are more related to eukaryotes than to bacteria, despite having a prokaryotic-type cell architecture. Throughout this chapter, we have provided examples of the interesting mix of bacterial and eukaryotic features in archaea. As more is learned about archaea (and eukaryotic microbes), we expect even more surprises than those already discovered.

polymerase III transcribes the 5S rRNA and all tRNA genes. All three eukaryotic RNA polymerases have more subunits than bacterial RNA polymerases (**table 15.3**).

- The promoters of eukaryotes are distinctive, as is the mechanism of transcription initiation (**figures 15.4 and 15.5**). Several basal transcription factors are involved in positioning an RNA polymerase at a promoter.
- RNA polymerase II synthesizes pre-mRNA, which is modified by addition of a 3' poly-A sequence and a 5' cap (**figure 15.6**) and by removal of introns by spliceosomes (**figure 15.7**).
- Many archaeal genes are organized into operons (though perhaps not as many as in bacteria). Archaea have a single RNA polymerase that is similar to eukaryotic RNA polymerase II. The archaeal RNA polymerase requires two transcription factors to be positioned properly at a promoter (**figure 15.9**). Archaeal promoters have elements that are similar to those in eukaryotes, including a TATA box (**figures 15.4 and 15.9**).

15.4 Translation and Protein Maturation and Localization

- Translation initiation in eukaryotes requires more initiation factors than it does in bacteria (**figure 15.10**). Initiation involves an interaction of the 5' and 3' ends of the mRNA, followed by binding of the 43S complex (SSU of the ribosome and initiator tRNA) to the 5' end of the message. The 43S complex then scans the mRNA until it encounters a start codon. Translation elongation is similar in eukaryotes and bacteria. Translation termination requires a single release factor, rather than the three used in bacteria.
- Protein folding in eukaryotes is aided by chaperone proteins. Homologues of all types of chaperones are found in eukaryotes.
- In eukaryotes, proteins are translocated into the endoplasmic reticulum (ER) membrane by a Sec system (**figure 15.12**). The proteins are then trafficked between the ER, plasma membrane, Golgi, and other components of the endocytic and secretory pathways by vesicular transport.

Localization of proteins in mitochondria and chloroplasts involves translocation systems that are related to bacterial membrane proteins (**figure 15.13**).

- In archaea, transcription and translation are coupled, as in bacteria. Some archaeal mRNAs have a Shine-Dalgarno sequence that is thought to function in positioning the ribosome as it does in bacteria. However, other archaea lack a Shine-Dalgarno sequence. How the ribosome is positioned on these mRNAs is not known. Other aspects of archaeal translation are similar to those seen in eukaryotes, including the protein factors and initiator tRNA used.
- Archaea use chaperones to help fold proteins. With the exception of HSP90s and HSP100s, all types of chaperones have been observed.
- Archaea use the Sec and Tat pathways to translocate proteins into or across the plasma membrane. The archaeal Sec system proteins are similar to the eukaryotic Sec system proteins (**figure 15.12**).

15.5 Regulation of Cellular Processes

- Eukaryotes have regulatory sites for the binding of transcription regulatory proteins. Activators bind either

enhancers or upstream activating sites, and repressors bind sites called silencers (**figure 15.15**). The regulatory proteins exert their actions indirectly by affecting the activity of transcription factors, histone-modifying enzymes, and chromatin-remodeling enzymes (**figure 15.16**).

- Micro RNAs are used by eukaryotic cells to regulate translation. Micro RNAs are part of a complex that targets a particular mRNA and inhibits its translation.
- Small interfering RNAs are also used to control translation, in a manner similar to that used by micro RNAs. However, some small interfering RNAs regulate transcription. This is accomplished by causing the formation of heterochromatin, a highly compacted form of chromatin, in the region targeted by the small interfering RNA.
- The mechanism of action of archaeal proteins that regulate transcription initiation is best understood for repressor proteins. Some repressor proteins bind an operator sequence and are thought to work in a manner similar to that seen in bacteria. Other repressor proteins inhibit transcription by localizing to the TATA box, thereby preventing the archaeal transcription factors from attaching to the DNA and initiating transcription.

Compare, Hypothesize, Invent

1. Budding yeasts such as *S. cerevisiae* exhibit telomerase activity throughout their life cycles, whereas human somatic cells do not exhibit telomerase activity. Suggest why this is so.
2. All of the subunits in bacterial RNA polymerases have homologues in both archaeal and eukaryotic RNA polymerases. What does this suggest about the evolution of these enzymes?
3. Would you expect that one day microbiologists might discover small interfering RNAs in archaea? If so, how might they function? Explain your answer.
4. In the chapter opening story, it was stated that the next step in using algae to produce plastics is to maximize expression of the bacterial polyhydroxyalkanoate-synthesizing gene in algal cells. Suggest one genetic change that might be made to increase its expression.
5. The yeast *S. cerevisiae* continues to be an important model organism for understanding regulation of gene expression. In

2011 scientists from the University of Wisconsin-Madison reported their studies to determine the mechanism of action of a yeast repressor protein called PUF. In previous studies, it had been shown that PUF binds elements in the 3' untranslated region (UTR) of mRNA molecules. This observation raised the possibility that PUF might interact with poly-A binding proteins (PABPs) to exert its effect. The scientists examined translation in three different experimental conditions: translation of mRNAs that lacked poly-A tails, translation in mutants that lacked PABP, and translation in mutant forms of PABP. What information would be provided by examining translation in each of the experimental conditions used? Suggest a mechanism by which PUF interaction with PABP might repress translation.

Mechanisms of Genetic Variation

A Master Thief

The archaeon *Haloarcula marismortui* and other haloarchaea have an interesting evolutionary history. They are thought to have evolved from methanogens. Thus they began their existence as strict anaerobes that carried out chemolithotrophy. Today they are found in habitats with plenty of light and lots of organic material. Importantly, they now are metabolically flexible, functioning either as aerobic chemoorganotrophs when oxygen is readily available or as phototrophs when the environment becomes microoxic. How did they make this drastic change?

Evidence suggests that *H. marismortui* and its haloarchaeal cousins successfully morphed into their new way of life by becoming master thieves; they stole genes from other organisms in their environment. In particular, haloarchaea stole many genes from bacteria. *H. marismortui* has done this so well, it has cobbled together several bacterial genes to create a unique anaplerotic pathway called the methylaspartate cycle (see figure 20.5). This pathway is especially important when *H. marismortui* is starving. Under starvation conditions, it catabolizes carbon and energy stores such as polyhydroxyalkanoates (PHAs) by a process that yields acetyl-CoA. Acetyl-CoA can then be used not only to make ATP but also to generate many precursor metabolites; thus the need for anaplerotic reactions (see section 12.5).

As clever as *H. marismortui* has been, it is not alone in its ability to capture and use genes from other organisms. All bacteria and archaea do so. As more and more bacterial and archaeal genomes have been sequenced and annotated, it has become increasingly clear that taking the genes from other microbes has occurred many times. One outcome of this is to increase the genetic diversity of a population of microbes, thus raising the probability that some members of the population will survive in spite of dramatic environmental changes.

Genetic diversity also is necessary for evolution to occur. Organisms with certain genotypes, and therefore phenotypes, may survive to eventually evolve into new species. Note that the change in phenotype of

*Microbial thieves such as *Haloarcula marismortui* don't wear masks or dress in black, but they are very adept at keeping genes they obtain from other microbes in their environment.*

concern here is not due to changes in gene expression brought about by the types of regulatory processes discussed in chapters 14 and 15. Rather, we are referring to heritable changes in phenotype brought about by changes in the nucleotide sequence of a microbe's genome.

How the genomes of microbes are altered to increase genetic diversity in a population is the topic of this chapter. As you will see, microbes have numerous mechanisms for introducing genetic diversity; our main focus is on how this is accomplished in the absence of sexual reproduction. Some of the mechanisms we discuss can create changes in the genome that are actually detrimental. Thus we also consider processes that help balance the stability of the genome with the capacity to introduce genetic variation.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Draw a simple diagram that illustrates the three chemical moieties that define a nucleotide (section 13.2)
- ✓ State the base-pairing rules
- ✓ Explain the importance of the reading frame of a protein-coding gene (section 13.6)
- ✓ Describe the major events of meiosis
- ✓ Describe the major types of plasmids (section 3.6)
- ✓ Create a concept map or table that distinguishes the secretion systems observed in Gram-negative bacteria (section 13.8)

16.1 Mutations

After reading this section, you should be able to:

- Distinguish spontaneous from induced mutations, and list the most common ways each arises
- Construct a table, concept map, or picture to summarize how base analogues, DNA-modifying agents, and intercalating agents cause mutations
- Discuss the possible effects of mutations

Perhaps the most obvious way genetic diversity can be created is by **mutations** (Latin *mutare*, to change). Several types of mutations exist. Some arise from the alteration of single pairs of nucleotides and from the addition or deletion of one nucleotide pair in the coding regions of a gene. Such small changes in DNA are called **point mutations** because they affect only one base pair in a given location. Larger mutations are less common. These include large insertions, deletions, inversions, duplications, and translocations of nucleotide sequences.

Mutations occur in one of two ways. (1) **Spontaneous mutations** arise occasionally in all cells and in the absence of any added agent. (2) **Induced mutations** are the result of exposure to a **mutagen**, which can be either a physical or a chemical agent. Mutations are characterized according to either the kind of genotypic change that has occurred or their phenotypic consequences.

Figure 16.1 Tautomerization and Transition Mutations. Errors in replication due to base tautomerization. (a) Normally AT and GC pairs are formed when keto groups participate in hydrogen bonds. In contrast, enol tautomers produce AC and GT base pairs. The alteration in the base is shown in blue. (b) Mutation as a consequence of tautomerization during DNA replication. The temporary enolization of guanine leads to the formation of an AT base pair in the mutant, and a GC-to-AT transition mutation occurs. The process requires two replication cycles. Mutation only occurs if the abnormal first-generation GT base pair is missed by repair mechanisms. Wild type is the form of the gene before mutation occurred.

quences. In this section, the molecular basis of mutations and mutagenesis is first considered. Then the phenotypic effects of mutations are discussed.

Spontaneous Mutations

Spontaneous mutations result from errors in DNA replication, spontaneously occurring lesions in DNA, or the action of mobile genetic elements such as transposons (section 16.5). A few of the more prevalent mechanisms are described here.

Replication errors can occur when the nitrogenous base of a nucleotide shifts to a different form (isomer) called a tautomeric form. Nitrogenous bases typically exist in the keto form (see figure 13.5) but are in equilibrium with the rarer imino and enol forms (figure 16.1a). The shift from one form to another changes the hydrogen-bonding characteristics of the bases, allowing purine for purine or pyrimidine for pyrimidine substitutions that can eventually lead to a stable alteration of the nucleotide sequence (figure 16.1b). Such substitutions are known as **transition mutations** and are relatively common. On the other hand, **transversion mutations**—mutations where a purine is substituted for a pyrimidine or a pyrimidine for a purine—are rarer due to the steric problems of pairing purines with purines and pyrimidines with pyrimidines.

Replication errors can also result in the insertion and deletion of nucleotides. These mutations generally occur where there is a short stretch of repeated nucleotides. In such a location, the pairing of template and new strand can be displaced by the distance of the repeated sequence, leading to insertions or deletions of bases in the new strand (figure 16.2).

Spontaneous mutations can originate from lesions in DNA as well as from replication errors. For example, it is possible for purine nucleotides to be depurinated; that is, to lose their base. This results in the formation of an apurinic site, which does not

base pair normally and may cause a mutation after the next round of replication (figure 16.3). Likewise, pyrimidines can be lost, forming an apyrimidinic site. Other lesions are caused by reactive forms of oxygen such as oxygen free radicals and peroxides produced during aerobic metabolism. For example, guanine can be converted to 8-oxo-7,8-dihydrodeoxyguanine, which often pairs with adenine, rather than cytosine, during replication.

Induced Mutations

Any agent that damages DNA, alters its chemistry, or in some way interferes with its functioning will probably induce mutations. Mutagens can be conveniently classified according to their mode of

Figure 16.2 Insertions and Deletions. A mechanism for the generation of insertions and deletions during replication. The direction of replication is indicated by the blue arrow. In each case, there is strand slippage resulting in the formation of a small loop that is stabilized by hydrogen bonding in the repetitive sequence, the AT stretch in this example. (a) If the new strand slips, an addition of one T results. (b) Slippage of the parental strand yields a deletion (in this case, a loss of two Ts).

action. Three common types of chemical mutagens are base analogues, DNA-modifying agents, and intercalating agents. A number of physical agents (e.g., radiation) are mutagens that damage DNA.

Base analogues are structurally similar to normal nitrogenous bases and can be incorporated into the growing polynucleotide chain during replication (table 16.1). Once in place, these compounds typically exhibit base-pairing properties different from the bases they replace and can eventually cause a stable mutation. A widely used base analogue is 5-bromouracil, an analog of thymine. It undergoes a tautomeric shift from the normal keto form to an enol much more frequently than does a normal base. The enol tautomer forms hydrogen bonds like cytosine, pairing with guanine rather than adenine. The mechanism of action of other base analogues is similar to that of 5-bromouracil.

There are many **DNA-modifying agents**—mutagens that change a base's structure and therefore alter its base-pairing specificity. Some of these mutagens are selective; they preferentially react with certain bases and produce a particular kind of DNA damage. For example, methyl-nitrosoguanidine is an alkylating agent that adds methyl groups to guanine, causing it to mispair with thymine (figure 16.4). A subsequent round of replication can then result in a GC-AT transition. Hydroxylamine is another example of a DNA-modifying agent. It hydroxylates the nitrogen attached to the number 4 carbon (C-4) of cytosine (see figure 13.5), causing it to base pair like thymine.

Intercalating agents distort DNA to induce single nucleotide pair insertions and deletions. These mutagens are planar and insert themselves (intercalate) between the stacked bases of the helix. This results in a mutation, possibly through the formation of a loop in DNA. Intercalating agents include acridines such as proflavin and acridine orange.

Many mutagens, and indeed many carcinogens, damage bases so severely that hydrogen bonding between base pairs is

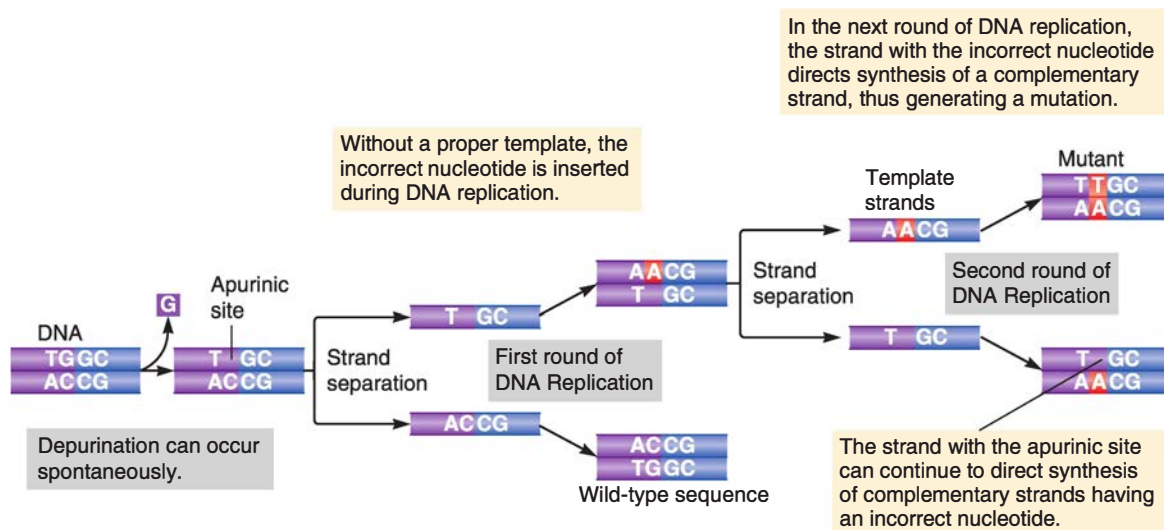

Figure 16.3 Mutation Due to Formation of an Apurinic Site. Apurinic sites can arise spontaneously (depurination). They do not provide a template for DNA replication, and as a result, an incorrect nucleotide can be inserted. A similar process can introduce mutations at sites where apyrimidinic sites arise.

Table 16.1 Examples of Mutagens

| Mutagen | Effect(s) on DNA Structure |
|------------------------|--|
| Chemical | |
| 5-Bromouracil | Base analogue |
| 2-Aminopurine | Base analogue |
| Ethyl methanesulfonate | Alkylating agent |
| Hydroxylamine | Hydroxylates cytosine |
| Nitrogen mustard | Alkylating agent |
| Nitrous oxide | Deaminates bases |
| Proflavin | Intercalating agent |
| Acridine orange | Intercalating agent |
| Physical | |
| UV light | Promotes pyrimidine dimer formation |
| X rays | Cause base deletions, single-strand nicks, cross-linking, and chromosomal breaks |

**Figure 16.4** Methyl-Nitrosoguanidine Mutagenesis. Methyl-nitrosoguanidine methylates guanine.

impaired or prevented and the damaged DNA can no longer act as a template for replication. For instance, ultraviolet (UV) radiation generates cyclobutane dimers, usually thymine dimers, between adjacent pyrimidines (**figure 16.5**). Other examples are ionizing radiation and carcinogens such as the fungal toxin aflatoxin B1 and other benzo(a)pyrene derivatives.

Effects of Mutations

The effects of a mutation can be described at the protein level and in terms of observed phenotypes. In all cases, the impact is readily noticed only if it produces a change in phenotype. In general, the more prevalent form of a gene and its associated phenotype is called the **wild type**. A mutation from wild type to a mutant form is a **forward mutation** (**table 16.2**). The effect of a forward mutation can be reversed by a second mutation that restores the wild-type phenotype. The second mutation can occur at the same site as the original mutation or at another site. When the second mutation is at the same site as the original mutation (e.g., the same base pair in a codon), it is called a **reversion mutation**. Some reversion mutations re-establish the original wild-type sequence. Others create a new codon that codes for the same amino acid. Reversions

**Figure 16.5** Thymine Dimers Are Formed by Ultraviolet Radiation.

| Table 16.2 Types of Point Mutations | | |
|---|--------------------|--|
| Type of Mutation | Change in DNA | Example |
| Forward Mutations | | |
| None | None | 5'-A-T-G-A-C-C-T-C-C-C-G-A-A-A-G-G-G-3' Met - Thr - Ser - Pro - Lys - Gly |

| Nonsense | Base substitution | 5'-A-T-G-A-C-C-T-C-C-C-C-G-T-A-A-G-G-G-3' Met - Thr - Ser - Pro - STOP! |
| Frameshift | Insertion/deletion | 5'-A-T-G-A-C-C-T-C-C-G-C-C-G-A-A-A-G-G-G-3' Met - Thr - Ser - Ala - Glu - Arg |
| Reverse Mutations | | |
| | Base substitution | 5'-A-T-G-A-C-C-T-C-C $\xrightarrow{\text{forward}}$ A-T-G-C-C-C-T-C-C $\xrightarrow{\text{reverse}}$ A-T-G-A-C-C-T-C-C Met - Thr - Ser Met - Pro - Ser Met - Thr - Ser |
| | Base substitution | 5'-A-T-G-A-C-C-T-C-C $\xrightarrow{\text{forward}}$ A-T-G-A-C-C-T-G-C $\xrightarrow{\text{reverse}}$ A-T-G-A-C-C-A-G-C Met - Thr - Ser Met - Thr - Cys Met - Thr - Ser |
| | Base substitution | 5'-A-T-G-A-C-C-T-C-C $\xrightarrow{\text{forward}}$ A-T-G-C-C-C-T-C-C $\xrightarrow{\text{reverse}}$ A-T-G-C-T-C-T-C-C Met - Thr - Ser Met - Pro - Ser Met - Leu - Ser (polar amino acid) (nonpolar amino acid) (polar amino acid) pseudo-wild type |
| Suppressor Mutations | | |
| Frameshift of opposite sign (intragenic suppressor) | Insertion/deletion | 5'-A-T-G-A-C-C-T-C-C-C-C-G-A-A-A-G-G-G-3' Met - Thr - Ser - Pro - Lys - Gly ↓ Forward mutation 5'-A-T-G-A-C-C-T-C-C-G-C-C-G-A-A-A-G-G-G-3' Met - Thr - Ser - Ala - Glu - Arg ↓ Suppressor mutation (deletion) 5'-A-T-G-A-C-C-C-C-G-C-C-G-A-A-A-G-G-G-3' Met - Thr - Pro - Pro - Lys - Gly |
| Extragenic suppressor Nonsense suppressor | | Gene (e.g., for tyrosine tRNA) undergoes a mutation in its anticodon region that enables it to recognize and align with a nonsense mutation (e.g., UAG). Thus an amino acid (tyrosine) is inserted at the mutant stop codon and translation continues. |
| Physiological suppressor | | A defect in one chemical pathway is circumvented by another mutation; for example, one that opens up another chemical pathway to the same product or one that permits more efficient uptake of a compound produced in small quantities because of the original mutation. |

can also restore the wild-type phenotype by creating a codon that specifies an amino acid that is similar to the amino acid found at that location in the wild-type protein (e.g., both amino acids are nonpolar). If the wild-type phenotype is restored by a second mutation at a different site than the original mutation, it

is called a **suppressor mutation**. Suppressor mutations may be within the same gene (intragenic suppressor mutation) or in a different gene (extragenic suppressor mutation). Because point mutations are the most common types of mutations, their effects are the focus here.

Mutations in Protein-Coding Genes

Point mutations in protein-coding genes can affect protein structure in a variety of ways. Point mutations are named according to if and how they change the encoded protein. The most common types of point mutations are silent mutations, missense mutations, nonsense mutations, and frameshift mutations. Examples of each are shown in table 16.2.

Silent mutations change the nucleotide sequence of a codon but do not change the amino acid encoded by that codon. This is possible because the genetic code exhibits degeneracy. Therefore when there is more than one codon for a given amino acid, a single base substitution may result in the formation of a new codon for the same amino acid. For example, if the codon CGU were changed to CGC, it would still code for arginine, even though a mutation had occurred. When there is no change in the protein, there is no change in the phenotype of the organism.

◀◀ *The genetic code (section 13.6)*

Missense mutations involve a single base substitution that changes a codon for one amino acid into a codon for another. For example, the codon GAG, which specifies glutamic acid, could be changed to GUG, which codes for valine. The effects of missense mutations vary. They alter the primary structure of a protein, but the effect of this change may range from complete loss of activity to no change at all. This is because the effect of missense mutations on protein function depends on the type and location of the amino acid substitution. For instance, replacement of a nonpolar amino acid in the protein's interior with a polar amino acid can drastically alter the protein's three-dimensional structure and therefore its function. Similarly the replacement of a critical amino acid at the active site of an enzyme often destroys its activity. However, the replacement of one polar amino acid with another at the protein surface may have little or no effect. Such mutations are called **neutral mutations**. Missense mutations play a very important role in providing new variability to drive evolution because they often are not lethal and therefore remain in the gene pool. ▶▶ *Proteins (appendix I)*

🌀 *Mutation by Base Substitution*

Nonsense mutations convert a sense codon (i.e., one that codes for an amino acid) to a nonsense codon (i.e., a stop codon: one that does not code for an amino acid). This causes the early termination of translation and therefore results in a shortened polypeptide. Depending on the location of the mutation in the gene, the phenotype may be more or less severely affected. Most proteins retain some function if they are shortened by only one or two amino acids; complete loss of normal function usually results if the mutation occurs closer to the beginning or middle of the gene.

Frameshift mutations arise from the insertion or deletion of base pairs within the coding region of the gene. Since the code consists of a precise sequence of triplet codons, the addition or deletion of fewer than three base pairs causes the reading frame to be shifted for all subsequent codons downstream. Frameshift mutations usually are very deleterious and yield mutant phenotypes resulting from the synthesis of nonfunctional proteins. In addition, frameshift mutations often produce a stop codon so

that the peptide product is shorter as well as different in sequence. Of course, if the frameshift occurs near the end of the gene or if there is a second frameshift shortly downstream from the first that restores the reading frame, the phenotypic effect might not be as drastic. A second, nearby frameshift that restores the proper reading frame is an example of an intragenic suppressor mutation (table 16.2). 🌀 *Addition and Deletion Mutations*

Changes in protein structure can alter the phenotype of an organism in many ways. Morphological mutations change the microorganism's colonial or cellular morphology. Lethal mutations, when expressed, result in the death of the microorganism. Because a microbe must be able to grow to be isolated and studied, lethal mutations are recovered only if they are conditional mutations. **Conditional mutations** are those that are expressed only under certain environmental conditions. For example, a conditional lethal mutation in *Escherichia coli* might not be expressed under permissive conditions such as low temperature but would be expressed under restrictive conditions such as high temperature. Thus the mutant would grow normally at cooler temperatures but would die at high temperatures.

Biochemical mutations are those causing a change in the biochemistry of the cell. Since these mutations often inactivate a biosynthetic pathway, they frequently eliminate the capacity of the mutant to make an essential molecule such as an amino acid or nucleotide. A strain bearing such a mutation has a conditional phenotype: it is unable to grow on medium lacking that molecule but grows when the molecule is provided. Such mutants are called **auxotrophs**, and they are said to be auxotrophic for the molecule they cannot synthesize. If the wild-type strain from which the mutant arose is a chemoorganotroph able to grow on a minimal medium containing only salts (to supply needed elements such as nitrogen and phosphorus) and a carbon source, it is called a **prototroph**. Another type of biochemical mutant is the resistance mutant. These mutants have acquired resistance to some pathogen, chemical, or antibiotic. Auxotrophic and resistance mutants are quite important in microbial genetics due to the ease of their detection and their relative abundance.

Mutations in Regulatory Sequences

Some of the most interesting and informative mutations studied by microbial geneticists are those that occur in the regulatory sequences responsible for controlling gene expression. Constitutive lactose operon mutants in *E. coli* are excellent examples. Many of these mutations map in the operator site and produce altered operator sequences that are not recognized by the repressor protein. Therefore the operon is continuously transcribed, and β -galactosidase is always synthesized. Mutations in promoters also have been identified. If the mutation renders the promoter sequence nonfunctional, the mutant will be unable to synthesize the product, even though the coding region of the structural gene is completely normal. Without a fully functional promoter, RNA polymerase rarely transcribes a gene as well as wild type. ◀◀ *Regulation of transcription initiation (section 14.2)*

Mutations in tRNA and rRNA Genes

Mutations in tRNA and rRNA alter the phenotype of an organism through disruption of protein synthesis. In fact, these mutants often are initially identified because of their slow growth. On the other hand, a suppressor mutation involving tRNA restores normal (or near normal) growth rates. In these mutations, a base substitution in the anticodon region of a tRNA allows the insertion of the correct amino acid at a mutant codon (table 16.2).

Retrieve, Infer, Apply

1. List three ways in which spontaneous mutations might arise.
2. Compare and contrast the means by which the mutagens 5-bromouracil, methyl-nitrosoguanidine, proflavin, and UV radiation induce mutations.
3. Give examples of intragenic and extragenic suppressor mutations.
4. Sometimes a point mutation does not change the phenotype. List all the reasons why this is so.
5. Why might a missense mutation at a protein's surface not affect the phenotype of an organism, whereas the substitution of an internal amino acid does?

16.2 Detection and Isolation of Mutants

After reading this section, you should be able to:

- Differentiate mutant detection from mutant selection
- Design an experiment to isolate mutant bacteria that are threonine auxotrophs
- Propose an experiment to isolate revertants of a threonine auxotroph and predict the types of mutations that might lead to the revertant phenotype
- Explain how the Ames test is used to screen for potential carcinogens and evaluate its effectiveness

Mutations often arise spontaneously and provide genetic diversity, which enhances survival during changing environmental conditions; thus mutations are of value to microbes. Mutations are also of practical importance to microbial geneticists. Mutant strains have been used to reveal mechanisms of complex processes such as DNA replication, endospore formation, and regulation of transcription. They are also useful as selective markers in recombinant DNA procedures. ►► *Recombinant DNA technology (chapter 17)*

To study microbial mutants, they must be readily detected, even when they are rare, and then efficiently isolated from wild-type organisms and other mutants that are not of interest. Microbial geneticists typically increase the likelihood of obtaining mutants by using mutagens to increase the rate of mutation. The rate can increase from the usual one mutant per 10^7 to 10^{11} cells to about one per 10^3 to 10^6 cells. Even at this rate, carefully devised means for detecting or selecting a desired mutation must be used. This section describes some techniques used in mutant detection, selection, and isolation.

Mutant Detection

When collecting mutants of a particular organism, the wild-type characteristics must be known so that an altered phenotype can be recognized. A suitable detection system for the mutant phenotype also is needed. The use of detection systems is called screening. Screening for mutant phenotypes in haploid organisms is straightforward because the effects of most mutations can be seen immediately. Some screening procedures require only examination of colony morphology. For instance, if albino mutants of a normally pigmented bacterium are being studied, detection simply requires visual observation of colony color. Other screening methods are more complex. For example, the **replica plating** technique is used to screen for auxotrophic mutants. It distinguishes between mutants and the wild-type strain based on their ability to grow in the absence of a particular biosynthetic end product (**figure 16.6**). A lysine auxotroph, for instance, grows on lysine-supplemented media but not on a medium lacking an adequate supply of lysine because it cannot synthesize this amino acid.

Once a screening method is devised, mutants are collected. However, mutant collection can present practical problems. Consider a search for the albino mutants mentioned previously. If the mutation rate were around one in a million, on average a million or more organisms would have to be tested to find one albino mutant. This probably would require several thousand plates. The task of isolating auxotrophic mutants in this way would be even more taxing with the added labor of replica plating. Thus, if possible, it is more efficient to use a selection system employing some environmental factor to separate mutants from wild-type microorganisms. Examples of selection systems are described next.

Mutant Selection

An effective selection technique uses incubation conditions under which the mutant grows because of properties conferred by the mutation, whereas the wild type does not. Selection methods often involve reversion or suppressor mutations or the development of resistance to an environmental stress. For example, if the intent is to isolate revertants from a lysine auxotroph (Lys^-), the approach is quite easy. A large population of lysine auxotrophs is plated on minimal medium lacking lysine, incubated, and examined for colony formation. Only cells that have mutated to restore the ability to manufacture lysine will grow on minimal medium. Several million cells can be plated on a single Petri dish, but only the rare revertant cells will grow. Thus many cells can be tested for mutations by scanning a few Petri dishes for growth.

Methods for selecting mutants resistant to a particular environmental stress follow a similar approach. Often wild-type cells are susceptible to virus attack, antibiotic treatment, or specific temperatures, so it is possible to grow the microbe in the presence of the stress and look for surviving organisms. Consider the example of a phage-sensitive wild-type bacterium. When it is cultured in medium lacking the virus and then plated on selective medium containing viruses, any colonies that form are resistant to virus attack and very likely are mutants in this regard.

Figure 16.6 Replica Plating. The use of replica plating to isolate a lysine auxotroph. After growth of a mutagenized culture on a complete medium, a piece of sterile velvet is pressed on the plate surface to pick up bacteria from each colony. Then the velvet is pressed to the surface of other plates, and organisms are transferred to the same position as on the master plate. After the location of Lys^- colonies growing on the replica with complete medium is determined, the auxotrophs can be isolated and cultured.

MICRO INQUIRY How would you screen for a tryptophan auxotroph? How would you select for a mutant that is resistant to the antibiotic ampicillin but sensitive to tetracycline (assume the parental strain is resistant to both antibiotics)?

Substrate utilization mutations also can be selected. Many bacteria use only a few primary carbon sources. With such bacteria, it is possible to select mutants by plating a culture on medium containing an alternate carbon source. Any colonies that appear can use the substrate and are probably mutants.

Mutant screening and selection methods are used for purposes other than understanding more about the nature of genes or the biochemistry of a particular microorganism. One very important role of mutant selection and screening techniques is in the study of carcinogens. Next we briefly describe one of the first and perhaps best known of the carcinogen testing systems.

Mutagens and Carcinogens

An increased understanding of the mechanisms of mutation and their role in cancer has stimulated efforts to identify environmental carcinogens—agents that cause cancer. The observation that many carcinogens also are mutagens was the basis for development of the Ames test by Bruce Ames in the 1970s. This test determines if a substance increases the rate of mutation; that is, if it is a mutagen. If the substance is a mutagen, then it is also likely to be carcinogenic if an animal is exposed to it at sufficient levels. Note that the test does not directly test for carcinogenicity. This is because it uses a bacterium as the test organism. Carcinogenicity can only be directly demonstrated with animals. Such testing is extremely expensive and takes much longer to complete than does the Ames test. Thus the Ames test serves as an inexpensive screening procedure to identify chemicals that may be carcinogenic and thus deserve further testing.

The Ames test is a mutational reversion assay employing several “tester” strains of *Salmonella enterica* serovar Typhimurium. Each tester strain has a different mutation in the histidine biosynthesis operon and therefore is a histidine auxotroph. The bacteria also have mutational alterations of their cell walls that make them more permeable to test substances. To further increase assay sensitivity, the strains are defective in their ability to repair DNA.

In the Ames test, tester strains of *S. Typhimurium* are plated with the substance being tested and the number of visible colonies that form are determined (figure 16.7). To ensure that DNA replication can take place in the presence of the potential mutagen, the bacteria and test substance are mixed in dilute molten top agar to which a trace of histidine has been added. This molten mix is then poured on top of minimal agar plates and incubated for 2 to 3 days at 37°C. All of the histidine auxotrophs grow for the first few hours in the presence of the test compound until the histidine is depleted. This is necessary because replication is required for the development of a mutation (figure 16.1). However, this initial growth does not produce a visible colony. Once the histidine supply is exhausted, only revertants that have mutationally regained the ability to synthesize histidine continue to grow and produce visible colonies. These colonies need only be counted and compared to controls to estimate the relative mutagenicity of the compound: the more colonies, the greater the mutagenicity.

Figure 16.7 The Ames Test for Mutagenicity.

Some chemicals tested may not be mutagenic unless they are transformed into another, more active form. In animals, such transformations occur in the liver. Indeed, many known carcinogens (e.g., aflatoxins; see figure 41.6) are not actually carcinogenic until they are modified in the liver by enzymes that function to destroy toxins and other materials that may be circulating in the blood. However, in some cases, these enzymes transform chemicals into more dangerous forms. For this reason, a mammalian liver extract is often added to the molten top agar prior to plating the bacterial cells used in the Ames test. The extract converts potential mutagens into derivatives that readily react with DNA, mimicking the enzymatic transformations that occur in mammals. Carrying out the Ames test with and without the addition of the extract shows which compounds have intrinsic mutagenicity and which need activation after uptake. Despite the use of liver extracts, only about half of all potential carcinogens are detected by the Ames test.

1. Describe how replica plating is used to detect and isolate auxotrophic mutants.
2. Why are mutant selection techniques generally preferable to screening methods?
3. Briefly discuss how reversion mutations, resistance to an environmental factor, and the ability to use a particular nutrient can be employed in mutant selection.
4. Describe how you would isolate a mutant that required histidine for growth and was resistant to penicillin. The wild type is a prototroph.
5. What is the Ames test and how is it carried out? What assumption concerning mutagenicity and carcinogenicity is it based upon?

16.3 DNA Repair

After reading this section, you should be able to:

- Compare and contrast excision repair, direct repair, mismatch repair, and recombinational repair
- Propose a scenario that would elicit the SOS response and describe the response to those conditions

If there is a microbial equivalent of an extreme sport, *Deinococcus radiodurans*'s ability to repair its genome after it has been blasted apart by a high dose of radiation might be a contender. Surprisingly, this ability is primarily related to the resistance of *D. radiodurans* proteins and the structure of its genome, rather than to its DNA repair mechanisms. Its radiation-resistant proteins are able to begin repairing the genome quickly. Repair is aided by the genome consisting of two chromosomes, each having numerous areas of homology. This allows the DNA fragments to anneal to each other, facilitating the piecing together of the shattered genome. Other than this, *D. radiodurans* uses pretty much the same DNA repair mechanisms as other organisms. Obviously mutations can have disastrous effects. Therefore it is imperative that a microorganism be able to repair changes. Microbes have numerous repair mechanisms. Repair in *E. coli* is best understood and is briefly described in this section.

▶▶ *Deinococcus-Thermus* (section 21.2)

Proofreading: The First Line of Defense

As we discuss in chapter 13, replicative DNA polymerases sometimes insert the incorrect nucleotide during DNA replication. However, these DNA polymerases have the ability to evaluate the hydrogen bonds formed between the newly added nucleotide and the template nucleotide, and correct any errors immediately; that is, before the next nucleotide is added. This ability is called **proofreading**. When a DNA polymerase detects that a mistake has been made, it backs up, removing the incorrect nucleotide with its 3' to 5' exonuclease activity (see figure 13.16). It then restarts DNA replication, this time inserting the correct nucleotide. Proofreading is very efficient, but it does not always correct errors in replication. Furthermore, it is not useful for correcting induced mutations. *E. coli* uses other repair mechanisms to help ensure the stability of its genome. ◀◀ *DNA replication in bacteria* (section 13.3)

Mismatch Repair

When proofreading by replicative DNA polymerases fails, mismatched bases are usually detected and repaired by the **mismatch repair** system (figure 16.8). In *E. coli* the enzyme MutS scans the newly replicated DNA for mismatched pairs. Another enzyme, MutH, removes a stretch of newly synthesized DNA around the mismatch. A DNA polymerase then replaces the excised nucleotides, and the resulting nick is sealed by DNA ligase.

The MutS protein slides along the DNA until it finds a mismatch. MutL binds MutS and the MutS/MutL complex binds to MutH, which is already bound to a hemimethylated sequence.

Figure 16.8 Methyl-Directed Mismatch Repair in

***E. coli*.** The role of MutH is to identify the methylated strand of DNA, which is the nonmutated parental strand. The methylated adenine is designated by an m.

MICRO INQUIRY How is mismatch repair similar to DNA polymerase proofreading? How is it different?

Successful mismatch repair depends on the ability of enzymes to distinguish between old and newly replicated DNA strands. This distinction is possible because newly replicated DNA strands lack methyl groups on their bases, whereas older

DNA has methyl groups on the bases of both strands. DNA methylation is catalyzed by DNA methyltransferases and results in three different products: N6-methyladenine, 5-methylcytosine, and N4-methylcytosine. After strand synthesis, the *E. coli* DNA adenine methyltransferase (DAM) methylates adenine bases in GATC sequences to form N6-methyladenine. For a short time after the replication fork has passed, the new strand lacks methyl groups while the template strand is methylated. In other words, the DNA is temporarily hemimethylated. The repair system cuts out the mismatch from the unmethylated strand.

Excision Repair

Excision repair corrects damage that causes distortions in the double helix. Two types of excision repair systems have been described: nucleotide excision repair and base excision repair. They both use the same approach to repair: Remove the damaged portion of a DNA strand and use the intact complementary strand as the template for synthesis of new DNA. They are distinguished by the enzymes used to correct DNA damage.

In **nucleotide excision repair**, an *E. coli* enzyme called UvrABC endonuclease removes damaged nucleotides and a few nucleotides on either side of the lesion. The resulting single-stranded gap is filled by DNA polymerase I, and DNA ligase joins the fragments (**figure 16.9**). This system can remove thymine dimers (**figure 16.5**) and repair almost any other injury that produces a detectable distortion in DNA.

Base excision repair employs enzymes called DNA glycosylases. These enzymes remove damaged or unnatural bases yielding apurinic or apyrimidinic (AP) sites. Enzymes called AP endonucleases recognize the damaged DNA and nick the backbone at the AP site (**figure 16.10**). DNA polymerase I removes the damaged region, using its 5' to 3' exonuclease activity. It then fills in the gap, and DNA ligase joins the DNA fragments.

Direct Repair

Thymine dimers and alkylated bases often are corrected by **direct repair**. For instance, **photoreactivation** repairs thymine dimers (**figure 16.5**) by splitting them apart with the help of visible light. This photochemical reaction is catalyzed by the enzyme photolyase. Methyl and some other alkyl groups that have been added to guanine can be removed with the help of an enzyme known as alkyltransferase or methylguanine methyltransferase. Thus damage to guanine from mutagens such as methyl-nitrosoguanidine (**figure 16.4**) can be repaired directly.  **Direct Repair**

Recombinational Repair

Recombinational repair corrects damaged DNA in which both bases of a pair are missing or damaged, or where there is a gap opposite a lesion. In this type of repair, a protein called **RecA** cuts a piece of template DNA from a sister molecule and puts it into the gap or uses it to replace a damaged strand

Figure 16.9 Nucleotide Excision Repair in *E. coli*.

MICRO INQUIRY How is damaged DNA recognized by the UvrAB complex?

Figure 16.10 Base Excision Repair.

SOS Response

Despite having multiple repair systems, sometimes the damage to an organism's DNA is so great that the normal repair mechanisms just described cannot repair all the damage. As a result, DNA synthesis stops completely. In such situations, a global control network called the **SOS response** is activated. In this response, over 40 genes are activated when a transcriptional repressor called LexA is destroyed. LexA negatively controls these genes, and once it is destroyed, they are transcribed and the SOS response ensues.

The SOS response, like recombinational repair, depends on the activity of RecA. RecA binds to single- or double-stranded DNA breaks and gaps generated by cessation of DNA synthesis. RecA binding initiates recombinational repair. Simultaneously RecA takes on coprotease function. It interacts with LexA, causing LexA to destroy itself (autoprotoleolysis). Destruction of LexA increases transcription of genes for excision repair and recombinational repair, in particular.

The first genes transcribed in the SOS response are those that encode the Uvr proteins needed for nucleotide excision repair (figure 16.9). Then expression of genes involved in recombinational repair is further increased. To give the cell time to repair its DNA, the protein SfiA is produced; SfiA blocks cell division. Finally, if the DNA has not been fully repaired after

(figure 16.11). Although bacterial cells are haploid, another copy of the damaged segment often is available because either it has recently been replicated or the cell is growing rapidly and has more than one copy of its chromosome. Once the template is in place, the remaining damage can be corrected by another repair system.

Figure 16.11 Recombinational Repair.

about 40 minutes, a process called **translesion DNA synthesis** is triggered. In this process, DNA polymerase IV (also known as DinB; Din is short for *damage inducible*) and DNA polymerase V (UmuCD; Umu is short for *UV mutagenesis*) synthesize DNA across gaps and other lesions (e.g., thymine dimers) that had stopped DNA polymerase III. However, because an intact template does not exist, these DNA polymerases often insert incorrect bases. Furthermore, they lack proofreading activity. Therefore even though DNA synthesis continues, it is highly error prone and results in the generation of numerous mutations.

The SOS response is so named because it is made in a life-or-death situation. The response increases the likelihood that some cells will survive by allowing DNA synthesis to continue. For the cell, the risk of dying because of failure to replicate DNA is greater than the risk posed by the mutations generated by this error-prone process.

Retrieve, Infer, Apply

1. Compare and contrast the two types of excision repair.
2. What role does DNA methylation play in mismatch repair?
3. When *E. coli* cells are growing rapidly, they may contain up to four copies of their chromosomes. Why is this important if *E. coli* needs to carry out recombinational repair?
4. Explain how the following DNA alterations and replication errors would be corrected (there may be more than one way): base addition errors by DNA polymerase III during replication, thymine dimers, AP sites, methylated guanines, and gaps produced during replication.

16.4 Creating Additional Genetic Variability

After reading this section, you should be able to:

- Describe in general terms how recombinant eukaryotic organisms arise
- Distinguish vertical gene transfer from horizontal gene transfer
- Summarize the four possible outcomes of horizontal gene transfer
- Compare and contrast homologous recombination and site-specific recombination

In section 16.1, we discuss the consequences of mutations in terms of their effect on a protein and the phenotype of the organisms bearing the mutation. However, the effect also depends on the environment in which the organism lives. In other words, those mutations that don't immediately kill the organism are subject to selective pressure. Selective pressure determines if a mutation will persist in a population to become an alternate form of the gene. An alternate form of a gene is termed an **allele**. The existence of alleles for each gene in a genome means each organism in a population can have a distinctive (and probably a unique) set of alleles making up its genome; that is, its genotype. Each genotype in a population can be selected for or selected against. Organisms with genotypes, and therefore phenotypes, that are best suited to the

environment survive and are most likely to pass on their genes. Shifts in environmental pressures can lead to changes in the population and ultimately result in the evolution of new species. The mechanisms by which new combinations of genes are generated are the topic of this section. All involve **recombination**, the process in which one or more nucleic acid molecules are rearranged or combined to produce a new genotype. Geneticists refer to organisms produced following a recombination event as recombinant organisms or simply **recombinants**.

Sexual Reproduction and Genetic Variability

The transfer of genes from parents to progeny is called **vertical gene transfer**. This type of gene transfer is observed in all organisms. In eukaryotes capable of sexual reproduction, vertical gene transfer is accompanied by genetic recombination, which occurs in two ways. The first is from crossing-over between sister chromosomes during meiosis. This creates new mixtures of alleles on homologous chromosomes. The second type of recombination results from fusion of gametes. Since each gamete contains alleles from the parent, when the gametes fuse, the parental alleles are combined in the zygote. As a result of these two types of recombination events, progeny organisms are not identical to their parents or to each other.

Horizontal Gene Transfer: Creating Variability the Asexual Way

Bacteria and archaea do not reproduce sexually. This suggests that genetic variation in populations of these microbes should be relatively limited, only occurring with the advent of a new mutation and its transfer to the next generation by vertical gene transfer. However, this is not the case. Bacteria and archaea have evolved three different mechanisms for creating recombinants.

These mechanisms are referred to collectively as **horizontal (lateral) gene transfer (HGT)**. HGT is distinctive from vertical gene transfer because genes from one independent, mature organism are transferred to another mature organism, often creating a stable recombinant having characteristics of both the donor and the recipient. **Horizontal Gene Transfer**

The importance of HGT cannot be overstated. HGT has been important in the evolution of many species, and it continues to be commonplace in many environments. Indeed, studies reveal that HGT is the main mechanism by which bacteria and archaea evolve. In addition to the example provided in the chapter opening story, many examples are known of DNA transfer between distantly related genera, particularly among bacterial cells sharing an ecological niche (e.g., the human gut). Another important example is the transfer of groups of genes encoding virulence factors from pathogenic bacteria to other bacteria. These groups of genes are called pathogenicity islands, and their discovery has provided valuable insights into the evolution of pathogenic bacteria. Finally, in most cases, the acquisition of new traits by HGT enables microbes to rapidly expand their ecological niche. This is clearly seen when HGT results in the spread of antibiotic-resistance genes among pathogenic bacteria. **Evolutionary processes and the concept of a microbial species (section 19.5); Pathogenicity islands (section 35.2)**

During HGT, a piece of donor DNA, sometimes called the **exonote**, enters a recipient cell. The transfer can occur in three ways: direct transfer between two cells temporarily in physical contact (conjugation), transfer of a naked DNA fragment (transformation), and transport of DNA by viruses (transduction). If the donor DNA contains genes already present in the recipient, the recipient will become temporarily diploid for those genes. This partially diploid cell is sometimes called a **merozygote** (*meros*, Greek meaning “part”; **figure 16.12**). The donor DNA

Figure 16.12 The Fate of Donor DNA During Horizontal Gene Transfer.

has four possible fates in the recipient. First, when the donor DNA has a sequence homologous to one in the recipient's chromosome (sometimes called an endogenote), integration may occur. That is, the donor's DNA may pair with the recipient's DNA and be incorporated to yield a recombinant genome. The recombinant then reproduces, yielding a population of stable recombinants. Second, if the donor DNA is able to replicate itself (e.g., it is a plasmid), it may persist separate from the recipient's chromosome. When the recipient reproduces, the donor DNA replicates and a population of stable recombinants is formed. Third, the donor DNA remains in the cytoplasm but is unable to replicate. When the recipient reproduces, the progeny cells lack the donor DNA and it is eventually lost from the population. Finally, a process called host restriction may occur. In this process, host cell nucleases degrade the donor DNA, thereby preventing the formation of a recombinant cell. ►► *Restriction enzymes (section 17.1)*

Molecular Recombination: Joining DNA Molecules Together

Crossing-over during meiosis and integration of donor DNA into the recipient's chromosome during HGT occur by similar mechanisms. **Homologous recombination** is the most common mechanism. It occurs wherever there are long regions of the same or similar nucleotide sequence in two DNA molecules (e.g., sister chromosomes in diploid eukaryotes or similar sequences on both a chromosome and plasmid). Homologous recombination results from DNA strand breakage and reunion leading to crossing-over. It is carried out by the products of the *rec* genes, including the RecA protein, which is also important for DNA repair (section 16.3). The other major type of recombination is **site-specific recombination**. Site-specific recombination differs from homologous recombination in three significant ways. First, it does not require long regions of sequence homology. Second, recombination occurs at specific target sites in DNA molecules, and third, it is catalyzed by enzymes collectively called **recombinases**. Site-specific recombination is used by some viruses to integrate their genomes into host chromosomes. It is also the type of recombination used by transposable elements to move from one place to another in DNA molecules, as we discuss in section 16.5.

3. What four fates can DNA have after entering a bacterium?
4. How does homologous recombination differ from site-specific recombination?

16.5 Transposable Elements

After reading this section, you should be able to:

- Differentiate insertion sequences from transposons
- Distinguish simple transposition from replicative transposition
- Defend this statement: "Transposable elements are important factors in the evolution of bacteria and archaea"

As more and more genomes have been sequenced and annotated, it has become increasingly apparent that the genomes of all organisms are rife with genetic elements that are able to move into and out of the genomes where they reside. These elements are often referred to as "jumping genes," mobile genetic elements, and transposable elements. **Transposition** refers to the movement of a mobile genetic element.

Mobile genetic elements were first discovered in the 1940s by Barbara McClintock (1902–1992) during her studies on maize genetics (a discovery for which she was awarded the Nobel Prize in 1983). As more and more types of mobile genetic elements were discovered, new nomenclature was developed to distinguish one type from another. As is often the case when a scientific field expands and its language evolves, the nomenclature became unwieldy and confusing. In 2008 a group of prominent scientists studying bacterial and archaeal mobile genetic elements proposed a new definition for **transposable elements**: "specific DNA segments that can repeatedly insert into one or more sites or into one or more genomes." This new definition encompasses elements that differ in structure, mechanisms of integration and excision, target sites, and ability to be transferred from one cell to another by HGT (**table 16.3**). 🌀 *Transposition: Shifting Segments of the Genome*

Table 16.3 Some Types of Transposable Elements

| Transposable Element | Description |
|----------------------------------|---|
| Insertion sequences (IS) | Small genetic elements consisting of a transposase gene bracketed by inverted repeats |
| Composite transposons | Contain genes unrelated to transposition bounded at each end by IS elements, which supply the transposase activity needed for transposition |
| Unit transposons | Contain one or more genes encoding enzymes needed for transposition, as well as other genes unrelated to transposition (e.g., antibiotic-resistance genes). They are not associated with an IS element. |
| Integrative conjugative elements | In addition to transposition functions, contain genes for conjugative transfer to a new host cell and other genes (e.g., antibiotic-resistance genes) |

Figure 16.13 Transposable Elements. All transposable elements contain common features. These include inverted repeats (IRs) at the ends of the element and a recombinase (e.g., transposase) gene. (a) Insertion sequences (IS) consist only of IRs on either side of the transposase gene. (b) Composite transposons and (c) unit transposons contain additional genes (e.g., antibiotic-resistance genes) in addition to the recombinases that enable them to transpose. In composite transposons, the additional genes are flanked by insertion sequences, which supply the transposase. Unit transposons are not associated with insertion sequences. DRs, direct repeats in host DNA, flank a transposable element.

MICRO INQUIRY What features are common to all types of transposable elements?

The enzymes that function in transposition are collectively termed recombinases. However, the recombinase used by a specific mobile genetic element may be called an integrase, resolvase, or transposase. There is tremendous interest in these enzymes because it has been discovered that their mechanisms of action are similar to those used to rearrange the gene segments that encode important immune system proteins such as antibodies and T-cell receptors (see figure 34.15). They are also similar to those that move so-called gene cassettes into and out of sites that control their expression.

The simplest mobile genetic elements in bacteria are **insertion sequences**, or IS elements for short (figure 16.13a). An IS element is a short sequence of DNA (around 750 to 1,600 base pairs [bp] in length). It contains only the gene for the enzyme transposase, and it is bounded at both ends by inverted repeats—identical or very

similar sequences of nucleotides in reversed orientation. Inverted repeats are usually about 15 to 25 base pairs long and vary among IS elements so that each type of IS has its own characteristic inverted repeats. **Transposase** is required for transposition and accurately recognizes the ends of the IS. Each IS element is named by giving it the prefix IS followed by a number. IS elements have been observed in a variety of bacteria and some archaea.

Transposons are more complex in structure than IS elements. Some transposons (composite transposons; table 16.3) consist of a central region containing genes unrelated to transposition (e.g., antibiotic-resistance genes) flanked on both sides by IS elements that are identical or very similar in sequence (figure 16.13b). The flanking IS elements encode the transposase used by the transposon to move. Other transposons lack IS elements and encode their own transposition enzymes (figure 16.13c). Most transposon names begin with the prefix Tn.

Some transposons bear transfer genes and can move between bacteria through the process of conjugation, as we discuss in section 16.6.

They are called **conjugative transposons** or **integrative conjugative elements (ICEs)**. A well-studied example of an ICE is Tn916 from *Enterococcus faecalis*. Although Tn916 cannot replicate autonomously, it can transfer itself from *E. faecalis* to a variety of recipients and integrate into their chromosomes. ICEs are primarily observed in Gram-positive bacteria.

Two major transposition methods have been identified: simple transposition and replicative transposition (figure 16.14). **Simple transposition** is also called **cut-and-paste transposition**. In this method, transposase catalyzes excision of the transposable element, followed by cleavage of a new target site and ligation of the

Figure 16.14 Comparison of Simple and Replicative Transposition.

TE, transposable element.

Figure 16.15 Simple Transposition. TE, transposable element; IR, inverted repeat.

element into this site (**figure 16.15**). Target sites are specific sequences about five to nine base pairs long. When a mobile genetic element inserts at a target site, the target sequence is duplicated so that short, direct-sequence repeats flank the element's terminal inverted repeats. In **replicative transposition**, the original transposon remains at the parental site on the chromosome and a copy is inserted at the target DNA site (**figure 16.14b**). **Simple Transposition**

Transposable elements are of interest for many reasons. Their movement into a chromosome can alter gene function either by causing mutations in the genes into which they move or by providing promoters that are regulated differently than the normal promoter. They are also important evolutionary forces. They contribute to the evolution of an organism's chromosome, plasmids, and other mobile genetic elements. Of particular note is the role of mobile genetic elements in the spread of antibiotic resistance, as we discuss in section 16.9.

Retrieve, Infer, Apply

1. How does a transposon differ from an insertion sequence?
2. What is simple (cut-and-paste) transposition? What is replicative transposition? How do the two mechanisms of transposition differ? What happens to the target site during transposition?
3. What effect would you expect the existence of transposable elements to have on the rate of microbial evolution? Give your reasoning.

16.6 Bacterial Conjugation

After reading this section, you should be able to:

- Identify the type of plasmids that are important creators of genetic variation
- Describe the features of the F factor that allow it to (1) transfer itself to a new host cell and (2) integrate into a host cell's chromosome
- Outline the events that occur when an F^+ cell encounters an F^- cell
- Distinguish F^+ , Hfr, and F' cells from each other
- Explain how Hfr cells arise
- Outline the events that occur when an Hfr cell encounters an F^- cell

Conjugation, the transfer of DNA by direct cell-to-cell contact, depends on the presence of a **conjugative plasmid**. Recall from chapter 3 that **plasmids** are small, double-stranded DNA molecules that can exist independently of host chromosomes. They have their own replication origins, replicate autonomously, and are stably inherited. Some plasmids are **episomes**, plasmids that can exist either with or without being integrated into host chromosomes.

Perhaps the best-studied conjugative plasmid is **F factor**. It plays a major role in conjugation in *E. coli*, and it was the first conjugative plasmid to be described (**figure 16.16**). The F factor is about 100,000 bases long and bears genes responsible for cell attachment and plasmid transfer between specific *E. coli* cells. Most

Figure 16.16 The F plasmid. Transfer (*tra*) genes are shown in red, and some of their functions are indicated. The plasmid also contains three insertion sequences and a transposon. The site for initiation of rolling-circle replication and gene transfer during conjugation is *oriT*.

Figure 16.17 Bacterial Conjugation. An electron micrograph of two *E. coli* cells in an early stage of conjugation. The F^+ cell to the right is covered with fimbriae, and a sex pilus connects the two cells.

of the information required for plasmid transfer is located in the *tra* operon, which contains at least 28 genes. Many of these direct the formation of sex pili that attach the F^+ cell (the donor cell containing an F plasmid) to an F^- cell (**figure 16.17**). Other gene products aid DNA transfer. In addition, the F factor has several IS elements that assist plasmid integration into the host cell's chromosome. Thus the F factor is an episome that can exist outside the bacterial chromosome or be integrated into it (**figure 16.18**).

The initial evidence for bacterial conjugation came from an elegant experiment performed in 1946 by Joshua Lederberg (1925–2008) and Edward Tatum (1909–1975). They mixed two auxotrophic strains, incubated the culture for several hours in

nutrient medium, and then plated it on minimal medium. To reduce the chance that their results were due to a reversion or suppressor mutation, they used double and triple auxotrophs on the assumption that two or three simultaneous reversion or suppressor mutations would be extremely rare. When recombinant prototrophic colonies appeared on the minimal medium after incubation, they concluded that the two auxotrophs were able to associate and undergo recombination.

Lederberg and Tatum did not directly prove that physical contact of the cells was necessary for gene transfer. This evidence was provided several years later by Bernard Davis (1919–1994), who constructed a U-tube consisting of two pieces of curved glass tubing fused at the base to form a U shape with a glass filter between the halves. The filter allowed passage of media but not bacteria. The U-tube was filled with a growth medium and each side inoculated with a different auxotrophic strain of *E. coli*. During incubation, the medium was pumped back and forth through the filter to ensure medium exchange between the halves. When the bacteria were later plated on minimal medium, Davis discovered that if the two auxotrophic strains were separated from each other by the filter, gene transfer did not take place. Therefore direct contact was required for the recombination that Lederberg and Tatum had observed.

Bacterial Conjugation

$F^+ \times F^-$ Mating

In 1952 William Hayes (1913–1994) demonstrated that the gene transfer observed by Lederberg and Tatum was unidirectional. That is, there were definite donor (F^+ , or fertile) and recipient (F^- , or nonfertile) strains, and gene transfer was nonreciprocal. He also

Figure 16.18 F Plasmid Integration. The reversible integration of an F plasmid or factor into a host bacterial chromosome. The process begins with association between plasmid and bacterial insertion sequences. The O arrowhead (white) indicates the site at which oriented transfer of chromosome to the recipient cell begins. A, B, 1, and 2 represent genetic markers.

MICRO INQUIRY What does the term *episome* mean?

found that in $F^+ \times F^-$ mating, the progeny were only rarely changed with regard to auxotrophy (i.e., chromosomal genes usually were not transferred). However, F^- strains frequently became F^+ .

These results are now understood and readily explained in the following way. An F^+ strain contains an extrachromosomal F factor carrying the genes for sex pilus formation and plasmid transfer. The **sex pilus** is used to establish contact between the F^+ and F^- cells (figure 16.19). Once contact is made, the pilus retracts, bringing the cells into close physical contact. The F^+ cell prepares for DNA transfer by assembling a type IV secretion apparatus, using many of the same genes used for sex pilus biogenesis; the sex pilus is embedded in the secretion structure (figure 16.20). The F factor then replicates by rolling-circle replication. **Conjugation: Transfer of the F Plasmid**

During **rolling-circle replication**, one strand of the circular DNA is nicked, and the free 3'-hydroxyl end is extended by replication enzymes (figure 16.21). The 3' end is lengthened while the growing point rolls around the circular template and the 5' end of

the strand is displaced to form an ever-lengthening tail, much like the peel of an apple is displaced by a knife as an apple is pared. The single-stranded tail may be converted to the double-stranded form by complementary strand synthesis. We are concerned here with rolling-circle replication of a plasmid. However, rolling-circle replication is also observed during the replication of some viral genomes (e.g., phage lambda). **Rolling-Circle Replication**

During conjugation, rolling-circle replication is initiated by a complex of proteins called the relaxosome, which are encoded by the F factor (figure 16.16). The relaxosome nicks one strand of the F factor at a site called *oriT* (for origin of transfer). Relaxase, an enzyme associated with the relaxosome, remains attached to the 5' end of the nicked strand. As F factor is replicated, the displaced strand and the attached relaxase enzyme move through the type IV secretion system to the recipient cell. During plasmid transfer, the entering strand is copied to produce double-stranded DNA. When this is completed, the F^- recipient cell becomes F^+ .

Figure 16.19 F Factor–Mediated Conjugation. The F factor encodes proteins for building the sex pilus and the type IV secretion system that transfers DNA from the donor to the F⁻ recipient. One protein, the coupling factor, is thought to guide the DNA to the secretion system. During F⁺ × F⁻ conjugation, only the F factor is transferred because the plasmid is extrachromosomal. The recipient cell becomes F⁺.

Figure 16.20 The Type IV Secretion System Encoded by F Factor.

The F factor–encoded type IV secretion system is composed of numerous Tra proteins, including TraA proteins, which form the sex pilus, and TraD, which is the coupling factor. Some Tra proteins are located in the plasma membrane (PM); others extend into the periplasm (P) and pass through the peptidoglycan layer (PG) into the outer membrane (OM) and its lipopolysaccharide (LPS) layer.

Hfr Conjugation

By definition, an F^+ cell has the F factor free from the chromosome, so in an $F^+ \times F^-$ mating, chromosomal DNA is not transferred. However, within this population, a few cells have the F plasmid integrated into their chromosomes. This explains why not long after the discovery of $F^+ \times F^-$ mating, a second type of F factor–mediated conjugation was discovered. In this type of conjugation, the donor transfers chromosomal genes with great efficiency but does not change the recipient bacteria into F^+ cells. Because of the high frequency of recombinants produced by this mating, it is referred to as **Hfr conjugation** and the donor is called an **Hfr strain**.

Hfr strains contain the F factor integrated into their chromosome, rather than free in the cytoplasm (**figure 16.22a**). When integrated, the F plasmid's *tra* operon is still functional; the plasmid can direct the synthesis of pili, carry out rolling-circle replication, and transfer genetic material to an F^- recipient cell. However, rather than transferring just itself, the F factor also directs the transfer of the host chromosome. DNA transfer begins when the integrated F factor is nicked at *oriT*. As it is replicated, the F factor begins to move into the recipient (**figure 16.22b**). Initially only part of the F factor is transferred, followed by the donor's chromosome. If the cells remain connected, the entire chromosome with the rest of the integrated F factor will be transferred; this takes about 100 minutes to accomplish. However, the connection between the cells usually breaks before this process is finished. Thus a complete F factor is rarely transferred, and the recipient remains F^- .

Figure 16.21 Rolling-Circle Replication. A single-stranded tail, often composed of more than one genome copy, is generated and can be converted to the double-stranded form by synthesis of a complementary strand. The “free end” of the rolling-circle strand is probably bound to the primosome. OH 3' is the 3'-hydroxyl and P 5' is the 5'-phosphate created when the DNA strand is nicked.

When an Hfr strain participates in conjugation, bacterial genes are transferred to the recipient in either a clockwise or a counterclockwise direction around a circular chromosome, depending on the orientation of the integrated F factor. After the replicated donor chromosome enters the recipient cell, it may be degraded or incorporated into the F^- genome by recombination.

Transfer of Chromosomal DNA

Figure 16.22 Creation of Hfr Strains and Hfr \times F^- Conjugation. (a) Integration of the F factor into the donor cell's chromosome creates an Hfr cell. (b) During Hfr \times F^- conjugation, some plasmid genes and some chromosomal genes are transferred to the recipient. Note that only a portion of the F factor moves into the recipient. Because the entire plasmid is not transferred, the recipient remains F^- . In addition, the incoming DNA must recombine into the recipient's chromosome if it is to be stably maintained.

F' Conjugation

Because the F plasmid is an episome, it can leave the bacterial chromosome and resume status as an autonomous F factor. Sometimes during excision an error occurs and a portion of the chromosome is excised, becoming part of the F plasmid.

Figure 16.23 F' Conjugation. (a) Due to an error in excision, the A gene of an Hfr cell is picked up by the F factor. (b) During conjugation, the A gene is transferred to a recipient, which becomes diploid for that gene (i.e., Aa).

Because this erroneously excised plasmid is larger and genotypically distinct from the original F factor, it is called an **F' plasmid** (figure 16.23a). A cell containing an F' plasmid retains all of its genes, although some of them are on the plasmid. It mates only with an F⁻ recipient, and F' × F⁻ conjugation is similar to an F⁺ × F⁻ mating. Once again, the plasmid is transferred as it is copied by rolling-circle replication. Bacterial genes on the chromosome are not transferred (figure 16.23b), but bacterial genes on the F' plasmid are transferred. These genes need not be incorporated into the recipient chromosome to be expressed. The recipient becomes F' and is partially diploid because the same bacterial genes present on the F' plasmid are also found on the recipient's chromosome. In this way, specific bacterial genes may spread rapidly throughout a bacterial population.

Other Examples of Bacterial Conjugation

Although most research on plasmids and conjugation has been done using *E. coli* and other Gram-negative bacteria, conjugative plasmids are present in Gram-positive bacteria belonging to genera such as *Bacillus*, *Streptococcus*, *Enterococcus*, *Staphylococcus*, and *Streptomyces*. Much less is known about these systems. It appears that fewer transfer genes are involved, possibly because a sex pilus may not be required for plasmid transfer. For example, *Enterococcus faecalis* recipient cells release short peptide chemical signals that activate transfer genes in donor cells containing the proper plasmid. Donor and recipient cells directly adhere to one another through plasmid-encoded proteins released by the activated donor cell. Plasmid transfer then occurs.  *Transfer of a Plasmid*

16.7 Bacterial Transformation

After reading this section, you should be able to:

- Describe the factors that contribute to a bacterium being naturally transformation competent
- Predict the outcomes of transformation using a DNA fragment versus using a plasmid
- Design an experiment to transform bacteria that are not naturally competent with a plasmid that carries genes encoding ampicillin resistance and the protein that generates green fluorescence

The second way DNA can move between bacteria is through transformation, discovered by Fred Griffith in 1928. **Transformation** is the uptake by a cell of DNA, either a plasmid or a fragment of linear DNA, from the surroundings and maintenance of the DNA in the recipient in a heritable form. In natural transformation, the DNA comes from a donor bacterium. The process is random, and any portion of the donor's genome may be transferred.

When bacteria lyse, they release considerable amounts of DNA into the surrounding environment. These fragments may be relatively large and contain several genes. If a fragment contacts a **competent cell**—a cell that is able to take up DNA and be transformed—the DNA can be bound to the cell and taken inside (figure 16.24a). The transformation frequency of very competent cells is around 10^{-3} for most genera when an excess of DNA is used. That is, about one cell in every thousand will take up and integrate the gene.

Competency is a complex phenomenon and depends on several conditions. Bacteria need to be in a certain stage of growth; for example, *Streptococcus pneumoniae* becomes competent during the exponential phase when the population reaches about 10^7 to 10^8 cells per milliliter. When a population becomes competent, bacteria such as *S. pneumoniae* secrete a small protein called competence factor that stimulates the production of eight to 10 new proteins required for transformation. Natural transformation has been discovered in some archaea and in members of several bacterial phyla (e.g., *Deinococcus-Thermus*, *Cyanobacteria*, *Chlorobi*, *Proteobacteria*, and *Firmicutes*). Natural transformation occurs in soil and aquatic ecosystems and in vivo during infection; it also is an important route of HGT in biofilm and other microbial communities.

The mechanism of transformation has been intensively studied in *S. pneumoniae* (figure 16.25). A competent cell binds a double-stranded DNA fragment if the fragment is moderately large; the process is random, and donor fragments compete with each other. The DNA then is cleaved by endonucleases to double-stranded fragments about 5,000 to 15,000 base pairs in size. DNA uptake requires energy expenditure. One strand is hydrolyzed by an envelope-associated exonuclease during uptake; the other strand associates with small proteins and moves through the plasma membrane. The single-stranded fragment can then align with a homologous region of the genome and be integrated into the chromosome.

Transformation in *Haemophilus influenzae*, a Gram-negative bacterium, differs from that in *S. pneumoniae* in several respects. *H. influenzae* does not produce a protein factor to stimulate the development of competence, and it takes up DNA from only closely related species (*S. pneumoniae* and most other naturally competent bacteria are less particular about the source of the DNA). Double-stranded DNA, complexed with proteins, is taken in by membrane vesicles. The specificity of *H. influenzae* transformation is due to an 11 base pair sequence that is repeated over 1,400 times in the *H. influenzae* genome. DNA must have this sequence to be bound by a competent cell.

The protein complexes that take up free DNA must be able to move it through the bacterial cell wall. As expected,

(a) Transformation with DNA fragments

(b) Transformation with a plasmid

Figure 16.24 Bacterial Transformation. Transformation with (a) DNA fragments and (b) plasmids. Transformation with a plasmid often is induced artificially in the laboratory. The transforming DNA is in purple, and integration is at a homologous region of the genome.

the machinery is quite large and complicated. **Figure 16.26a** illustrates the complex used by the Gram-negative bacterium *Neisseria gonorrhoeae*. The protein PilQ aids in the movement across the outer membrane, and the pilin complex (PilE) moves the DNA through the periplasm and peptidoglycan. ComE is a DNA-binding protein; N is the nuclease that degrades one strand before the DNA enters the cytoplasm

Figure 16.25 Bacterial Transformation as Seen in *S. pneumoniae*.

MICRO INQUIRY According to this model, what would happen if DNA that lacked homology to the *S. pneumoniae* chromosome were taken into the cell?

through the transmembrane channel formed by ComA. The machinery in the Gram-positive bacterium *Bacillus subtilis* is depicted in figure 16.26b. It is localized to the poles of the cell, and many of the components are similar to those of *N. gonorrhoeae*: the pilin complex (ComGC), DNA-binding protein (ComEA), nuclease (N), and channel protein (ComEC). ComFA is a DNA translocase that moves the DNA into the

cytoplasm. A Gram-negative equivalent of ComFA has not been identified yet in *N. gonorrhoeae*.

Bacterial Transformation

Microbial geneticists exploit transformation to move DNA (usually recombinant DNA) into cells. Because many species, including *E. coli*, are not naturally transformation competent, these bacteria must be made artificially competent by certain treatments. Two common techniques are electrical shock and exposure to calcium chloride. Both approaches render the cell membrane temporarily more permeable to DNA, and both are used to transform *E. coli* cells that have been made artificially competent. To increase the transformation frequency with *E. coli*, strains that lack one or more nucleases are used. These strains are especially important when transforming the cells with linear DNA, which is vulnerable to attack by nucleases. It is easier to transform bacteria with plasmid DNA since plasmids can replicate within the host and are not as easily degraded as are linear fragments (figure 16.24b).

16.8 Transduction

After reading this section, you should be able to:

- Differentiate generalized transduction from specialized transduction
- Correlate a phage's life cycle to its capacity to mediate generalized or specialized transduction
- Draw a figure, create a concept map, or construct a table that distinguishes conjugation, transformation, and transduction

The third mode of bacterial gene transfer is **transduction**, which is mediated by viruses. It is a frequent mode of horizontal gene transfer in nature. Indeed evidence suggests that the number of genes moved by marine viruses from one host cell to another is huge (perhaps 10^{24} per year). Furthermore, viruses in marine environments and hot springs move genes between organisms in all three domains of life. ►► *Aquatic viruses (section 30.2)*

Recall from chapter 6 that virus particles are structurally simple, often composed of just a nucleic acid genome protected by a protein coat called the capsid. Viruses are unable to multiply autonomously. Instead, they infect and take control of a host cell, forcing the host to make many copies of the virus. Viruses that infect bacteria are called bacteriophages, or phages for short. **Virulent bacteriophages** multiply in their bacterial host immediately after entry. After the progeny phage particles reach a certain

number, they cause the host to lyse, so they can be released and infect new host cells (**figure 16.27**). Thus this process is called the **lytic cycle**. **Temperate bacteriophages**, on the other hand, do not immediately kill their host. Many temperate phages enter the host bacterium and insert their genomes into the bacterial chromosome. The inserted viral genome is called a **prophage**. The host bacterium is unharmed by this, and the phage genome is passively replicated as the host cell's genome is replicated. The relationship between these viruses and their host is called **lysogeny**, and bacteria that have been lysogenized are called **lysogens**. Temperate phages can remain inactive in their hosts for many generations. However, they can be induced to switch to a lytic cycle under certain conditions, including UV irradiation. When this occurs, the prophage is excised from the bacterial genome and the lytic cycle proceeds. ◀◀ *Types of viral infections (section 6.4)*

Transduction is the transfer of bacterial or archaeal genes by virus particles. It is important to understand that host genes are packaged in the virus particle because of errors made during the virus's life cycle. The virion containing these genes then transfers them to a recipient cell. Two kinds of bacterial transduction have been described: generalized and specialized.

Generalized Transduction

Generalized transduction occurs during the lytic cycle of virulent and some temperate phages. Any part of the bacterial genome

Figure 16.27 **Lytic and Lysogenic Cycles of Temperate Phages.** Virulent phages undergo only the lytic cycle. Temperate phages have two phases to their life cycles. The lysogenic cycle allows the genome of the virus to be replicated passively as the host cell's genome is replicated. Certain environmental factors such as UV light can cause a switch from the lysogenic cycle to the lytic cycle. In the lytic cycle, new virions are made and released when the host cell lyses.

MICRO INQUIRY What is the term used to describe a lysogenic phage genome when it is integrated into the host genome?

can be transferred (figure 16.28). During the assembly stage, when the viral chromosomes are packaged into capsids, random fragments of the partially degraded bacterial chromosome may mistakenly be packaged. Because the capsid can contain only a limited quantity of DNA, the viral DNA is left behind. The quantity of bacterial DNA carried depends primarily on the size of the capsid. The P22 phage of *S. Typhimurium* can carry about 1% of the bacterial genome; the P1 phage of *E. coli* and a variety of Gram-negative bacteria can package about 2.0 to 2.5% of the genome. The resulting virion often injects the DNA into another bacterial cell but cannot initiate a lytic cycle. This phage particle is known as a generalized transducing particle and is simply a

carrier of genetic information from the original bacterium to another cell. As in transformation, once the DNA fragment has been injected, it must be incorporated into the recipient cell's chromosome to preserve the transferred genes. The DNA remains double stranded during transfer, and both strands are integrated into the recipient's chromosome. About 70 to 90% of the transferred DNA is not integrated but often is able to remain intact temporarily and be expressed. Abortive transductants are bacteria that contain this nonintegrated, transduced DNA and are partial diploids.

Specialized Transduction

In **specialized transduction**, only specific portions of the bacterial genome are carried by transducing particles. Specialized transduction is made possible by an error in the lysogenic life cycle of phages that insert their genomes into a specific site in the host chromosome. When a prophage is induced to leave the host chromosome, excision is sometimes carried out improperly. The resulting phage genome contains portions of the bacterial chromosome (about 5 to 10% of the bacterial DNA) next to the integration site, much like the situation with F' plasmids (figure 16.29). However, the transducing particle is defective because it lacks some viral genes and cannot reproduce without assistance. In spite of this, it will inject the remaining viral genome and any bacterial genes it carries into another bacterium. The bacterial genes may become stably incorporated under the proper circumstances.

The best-studied example of specialized transduction is carried out by the *E. coli* phage lambda. The lambda genome inserts into the host chromosome at specific locations known as attachment or *att* sites (figure 16.30). The phage *att* sites and bacterial *att* sites are similar and can complex with each other. The *att* site for lambda is next to the *gal* and *bio* genes on the *E. coli* chromosome; consequently when lambda excises incorrectly to generate a specialized transducing particle, these bacterial genes are most often present. The product of cell lysis (lysate) resulting from the induction of lysogenized *E. coli* contains normal phage and a few defective transducing particles. These particles are called lambda *dgal* if they carry the galactose utilization genes or lambda *dbio* if they carry the *bio* from the other side of the *att* site (figure 16.30). ▶▶ *Bacteriophage lambda* (section 27.2) 🌟 *Specialized Transduction*

16.9 Evolution in Action: The Development of Antibiotic Resistance in Bacteria

After reading this section, you should be able to:

- Report the common reasons for increasing drug resistance
- Describe common mechanisms by which antimicrobial drug resistance occurs
- Suggest strategies to overcome drug resistance

The long-awaited “superbug” arrived in the summer of 2002. *Staphylococcus aureus*, a common but sometimes deadly bacterium, had acquired a new antibiotic-resistance gene. The new strain was isolated from foot ulcers on a diabetic patient in Detroit, Michigan. **Methicillin-resistant *S. aureus* (MRSA)** had been well-known as the bane of hospitals. This newer strain had developed resistance to vancomycin, one of the few antibiotics thought to still control *S. aureus*. This new vancomycin-resistant *S. aureus* (VRSA) strain also resisted most other antibiotics, including ciprofloxacin, methicillin, and penicillin. Isolated from the same patient was another dread of hospitals—**vancomycin-resistant enterococci (VRE)**. Genetic analyses revealed that the patient’s own vancomycin-sensitive *S. aureus* had acquired the vancomycin-resistance gene, *vanA*, from VRE through conjugation. So was born a new threat to the health of the human race.

The spread of drug-resistant pathogens is one of the most serious threats to public health in the twenty-first century. There are two types of resistance: inherent and acquired. An example of inherent resistance is that of the cell wall-less mycoplasma’s resistance to penicillin, which interferes with peptidoglycan synthesis. Similarly, many Gram-negative bacteria are unaffected by penicillin G because it cannot penetrate the bacterial outer membrane. Acquired resistance occurs when there is a change in the genome of a bacterium that converts it from one that is sensitive to an antibiotic to one that is now resistant. This

Figure 16.29 Specialized Transduction by a Temperate Bacteriophage. Recombination can produce two types of transductants.

MICRO INQUIRY Compare the number of transducing particles that arise during generalized (figure 16.28) and specialized transduction. Why is there such a big difference?

section describes the ways in which bacteria acquire drug resistance and how resistance spreads within a bacterial population. ◀◀ *Synthesis of peptidoglycan* (section 12.4); *Typical Gram-negative cell walls* (section 3.4); ▶▶ *Class Mollicutes (Phylum Tenericutes; section 21.3)*

Mechanisms of Drug Resistance

Bacteria have evolved several resistance mechanisms (figure 16.31). One is to modify the target of the antibiotic by mutating a gene that functions in the synthesis of the target. This is possible because each chemotherapeutic agent acts on a specific target enzyme or cellular structure. For instance, resistance to vancomycin arises when bacteria change the terminal D-alanine in the pentapeptide of peptidoglycan into either D-lactate or D-serine (see figure 12.10). The affinity of ribosomes for erythromycin and chloramphenicol also can be decreased by a change in the 23S rRNA to which they bind. Antimetabolite action may be resisted through alteration of susceptible enzymes. For example, in sulfonamide-resistant bacteria, the enzyme that uses *p*-aminobenzoic acid during folic acid synthesis often has a much lower affinity for sulfonamides.

◀◀ *Antibacterial drugs* (section 9.4)

A second resistance strategy is **drug inactivation**. The best-known example is the hydrolysis of the β -lactam ring of penicillins by penicillinase and other β -lactamase enzymes. Drugs also are inactivated by the addition of chemical groups. For example, chloramphenicol contains two hydroxyl groups that can be modified by the addition of acetyl-CoA. Aminoglycosides (see figure 9.8a) can be modified and inactivated in several ways. For instance, acetyltransferases catalyze the acetylation of amino groups. Some aminoglycoside-modifying enzymes catalyze the addition of phosphates (by phosphotransferases) or adenylyl groups (by adenylyl transferases) to hydroxyl groups present on the aminoglycoside. Because they involve gaining a new function, this resistance strategy is most often accomplished by the acquisition of a gene (or genes) by HGT.

Some bacteria pump the drug out of the cell after it has entered, using translocases, often called **efflux pumps**, that expel drugs. Efflux pumps are

relatively nonspecific and pump many different drugs; therefore, they often confer multidrug-resistance. Many efflux pumps are drug/proton antiporters; that is, protons enter the cell as the drug leaves. Such systems are present in *E. coli*, *Pseudomonas aeruginosa*, and *S. aureus*, to name a few.

Finally, resistant bacteria may either use an **alternate pathway** to bypass the sequence inhibited by the agent or increase the production of the target metabolite. For example, some bacteria are resistant to sulfonamides simply because they use preformed folic acid from their surroundings, rather than synthesize it themselves. Other strains increase their rate of folic acid production and thus counteract sulfonamide inhibition. Again, these changes are most often mediated by HGT.

Figure 16.30 The Mechanism of Transduction for Phage Lambda and *E. coli*. Integrated lambda phage lies between the *gal* and *bio* genes. When it excises normally (top left), the new phage is complete and contains no bacterial genes. Excision rarely occurs asymmetrically (top right), and either the *gal* or *bio* genes are picked up and some phage genes are lost (only aberrant excision involving the *gal* genes is shown). The result is a defective lambda phage that carries bacterial genes and can transfer them to a new recipient.

MICRO INQUIRY Why can't the *gal* and *bio* genes be transduced by the same transducing particle?

Figure 16.31 Antibiotic-Resistance Mechanisms. Bacteria can resist the action of antibiotics by (1) preventing access to (or altering) the target of the antibiotic, (2) degrading the antibiotic, (3) altering the antibiotic, or (4) rapidly extruding the antibiotic.

The Origin and Transmission of Drug Resistance

Within three years after the widespread use of penicillin began, penicillin-resistant bacteria were found in clinical specimens. To understand the origin of drug resistance, it is important to recall that in nature, antibiotic-producing microbes must also protect themselves from the antibiotics they secrete. In other words, gaining the function of antibiotic production requires that the microbe also gain resistance—otherwise they would “commit suicide” by producing the antibiotic. In antibiotic-producing microorganisms, the genes that encode resistance proteins are often referred to as immunity genes. Immunity genes are usually coordinately regulated with genes that code for antibiotic biosynthetic enzymes. It is believed that many genes that encode antibiotic resistance in bacteria were “captured” by means of horizontal gene transfer (HGT), which moved resistance genes from antibiotic producers to nonproducers, giving rise to a large pool of resistance-encoding genes outside the producing microorganisms. It is therefore not surprising that in nonproducing bacteria, genes for drug resistance may be present on bacterial chromosomes, plasmids, transposons, and other mobile genetic elements. Because they are often found on mobile genetic elements, they can freely exchange between bacteria. In addition to the resistance genes transferred to nonproducers,

some nonproducers can become resistant due to spontaneous chromosomal mutations. Usually such mutations result in a change in the drug target; therefore the antibiotic cannot bind and inhibit growth. This is exemplified by the vancomycin, chloramphenicol, and sulfonamide resistance discussed earlier (p. 399).

Frequently a bacterial pathogen is drug resistant because it has a plasmid bearing one or more resistance genes; such plasmids are called **R plasmids** (resistance plasmids; **figure 16.32**). Plasmid-borne resistance genes often code for enzymes that destroy or modify drugs (e.g., the hydrolysis of penicillin or the acetylation of chloramphenicol and aminoglycoside drugs). Plasmid-associated genes have been implicated in resistance to aminoglycosides, chloramphenicol, penicillins, cephalosporins, erythromycin, tetracyclines, sulfonamides, and others. Once a bacterial cell possesses an R plasmid, the plasmid (or its genes) may be transferred to other cells quite rapidly through HGT. Because a single plasmid may carry genes for resistance to several drugs, a pathogen population can become resistant to several antibiotics simultaneously, even though the infected patient is being treated with only one drug.

Antibiotic-resistance genes can be located on genetic elements other than plasmids. Many transposons contain genes for antibiotic resistance and can move rapidly between plasmids and through a bacterial population. They are found in both Gram-negative and Gram-positive bacteria. Some examples and their resistance markers are Tn5 (kanamycin, bleomycin, streptomycin), Tn21 (streptomycin, spectinomycin, sulfonamide), Tn551 (erythromycin), and Tn4001 (gentamicin, tobramycin, kanamycin). Tn5 is of particular note because it is a replicative transposon. Thus it not only moves but also leaves a copy of itself in its original location. Recall that some transposons are conjugative transposons (or ICEs; table 16.3). Because they are capable of moving between bacteria by conjugation, they are also effective in spreading resistance.

Antibiotic-resistance genes are sometimes part of a DNA segment called an integron. An **integron** consists of a gene encoding an integrase and one or more genes (e.g., antibiotic-resistance genes) that form a “gene cassette.” The integrase enzyme catalyzes excision of the gene cassette from the integron. The cassette can be “captured” by another integron using its integrase enzyme. Thus gene cassettes can be moved from one integron to another. If a gene cassette is captured by an integron in a conjugative plasmid, the gene cassette can be transferred to other cells by conjugation (section 16.6).

Our focus here has been on the origin and transmission of resistance genes from antibiotic producers to nonproducers. What is important to recognize is that expression of these genes by nonproducers can be costly, expending considerable energy and metabolites. Often, resistance genes are lost if the bacteria are not exposed to the antibiotic. Thus, exposure to the antibiotic is a selective force that helps maintain the resistance gene in a population of bacteria. As we discuss in chapter 9, measures are being developed to decrease the use (especially misuse) of antibiotics to help alleviate the antibiotic-resistance problem.

Figure 16.32 An R Plasmid. Plasmid R1 is an R plasmid that contains the replicative transposon Tn3. Tn3 contains the gene for β -lactamase (*bla*), an enzyme that confers resistance to the antibiotic ampicillin (amp). The arrows below the Tn3 genes indicate the direction of transcription. Note that Tn3 is inserted into another transposable element, Tn4. Tn4 carries genes that provide resistance to streptomycin (Sm) and sulfonamide (Su). The R1 plasmid also carries resistance genes for kanamycin (Km) and chloramphenicol (Cm). The RTF region of R1 codes for proteins needed for plasmid replication and transfer.

MICRO INQUIRY As a replicative transposon, what would happen if Tn3 “hopped” from this R1 plasmid into a different plasmid?

Key Concepts

16.1 Mutations

- A mutation is a stable, heritable change in the nucleotide sequence of the genetic material.
- Spontaneous mutations can arise from replication errors (transition, transversion, and insertion and deletion of nucleotides), and from DNA lesions (apurinic sites, apyrimidinic sites, oxidation of DNA) (figures 16.1–16.3).
- Induced mutations are caused by mutagens. Mutations may result from the incorporation of base analogs, specific mispairing due to alterations of a base caused by DNA-modifying agents, the presence of intercalating agents, and severe damage to the DNA caused by exposure to radiation (table 16.1; figures 16.4 and 16.5).
- Mutations are usually recognized when they cause a change from the more prevalent wild-type phenotype. A mutant phenotype can be restored to wild type by reversion mutations or suppressor mutations (table 16.2).
- There are four important types of point mutations: silent mutations, missense mutations, nonsense mutations, and frameshift mutations (table 16.2).

- Mutations can affect phenotype in numerous ways. Some major types of mutations are categorized based on their effects on phenotype are morphological, lethal, conditional, biochemical, and resistance mutations.

16.2 Detection and Isolation of Mutants

- A sensitive and specific screening method is needed for detecting and isolating mutants. An example is replica plating for the detection of auxotrophs (figure 16.6).
- One of the most effective techniques for isolating mutants is to select for mutants by adjusting environmental conditions so that the mutant will grow while the wild type does not.
- Because many carcinogens are also mutagenic, one can test for mutagenicity with the Ames test and use the results as an indirect indication of carcinogenicity (figure 16.7).

16.3 DNA Repair

- Cells have multiple mechanisms for correcting mispaired and damaged DNA when proofreading is not effective.
- Mismatch repair is similar to excision repair, except that it replaces mismatched base pairs (figure 16.8).
- Excision repair systems remove damaged portions from a single strand of DNA (e.g., thymine dimers) and use the other strand as a template for filling in the gap (figures 16.9 and 16.10).
- Direct repair systems correct damaged DNA without removing damaged regions. For instance, during photoreactivation, thymine dimers are repaired by splitting the two thymines apart. This is catalyzed in the presence of light by the enzyme photolyase.
- Recombinational repair removes damaged DNA by recombination of the damaged DNA with a normal DNA strand elsewhere in the cell (figure 16.11).
- When DNA damage is severe, DNA replication is halted, and this triggers the SOS response. During the SOS response, genes of DNA repair systems are transcribed at a higher rate. In addition, special DNA polymerases are produced, which are able to replicate damaged DNA. However, they do so without a proper template and therefore create mutations.

16.4 Creating Additional Genetic Variability

- In sexual organisms, the mixing of parental DNA molecules in the progeny, as well as crossing-over that occurs during gamete formation generates genetic diversity.
- Horizontal gene transfer (HGT) is an important mechanism for creating genetic diversity in bacteria and archaea. It is a one-way process in which donor DNA is transferred from the donor to a recipient. In many transfers, the donor DNA must be integrated into the recipient's chromosome to be stably maintained (figure 16.12).

- The formation of recombinant microbes by HGT involves recombination of DNA molecules. Often this is accomplished by homologous recombination, in which DNA molecules pair due to large areas of sequence similarity. Some viral genomes and all known transposable elements integrate into other DNA molecules by site-specific recombination. This type of recombination does not require extensive sequence homology.

16.5 Transposable Elements

- Mobile genetic elements (transposable elements) are DNA segments that move about the genome in a process known as transposition.
- There are numerous types of transposable elements, including insertion sequences and several types of transposons (table 16.3 and figure 16.13).
- Simple (cut-and-paste) transposition and replicative transposition are two distinct mechanisms of transposition (figures 16.14 and 16.15).

16.6 Bacterial Conjugation

- Conjugation is the transfer of genes between bacteria that depends upon direct cell-to-cell contact and is mediated by a plasmid. The F factor is one type of conjugative plasmid (figure 16.16). F factor conjugation in *E. coli* is accomplished by a sex pilus and a type IV secretion system.
- In $F^+ \times F^-$, mating, the F factor remains independent of the chromosome and a copy is transferred to the F^- recipient; donor genes are not usually transferred (figure 16.19).
- Hfr strains transfer bacterial genes to recipients because the F factor is integrated into the host chromosome. A complete copy of the F factor is not often transferred (figure 16.22).
- When the F factor leaves an Hfr chromosome, it occasionally picks up some bacterial genes to become an F' plasmid, which readily transfers these genes to other bacteria (figure 16.23).

16.7 Bacterial Transformation

- Transformation is the uptake of naked DNA by a competent cell and its incorporation into the genome (figures 16.24 and 16.25).
- Only certain bacterial species are naturally transformation competent. Other species can be made competent by artificial means.

16.8 Transduction

- Bacterial viruses (bacteriophages) can multiply and destroy the host cell (lytic cycle) or become a latent prophage that remains within the host (lysogenic cycle) (figure 16.27).
- Transduction is the transfer of genes by viruses.
- In generalized transduction, any host DNA fragment can be packaged in a virus capsid and transferred to a recipient (figure 16.28).
- Certain temperate phages carry out specialized transduction by incorporating bacterial genes during

prophage induction and then donating those genes to another bacterium (figures 16.29 and 16.30).

16.9 Evolution in Action: The Development of Antibiotic Resistance in Bacteria

- Bacteria can become resistant to a drug by modifying the target of the drug; altering or degrading the drug; or by

pumping the drug out as soon as it enters, using an efflux pump (figure 16.31).

- Genes encoding resistance can be found on chromosomes, R plasmids (figure 16.32), and transposable elements. Thus resistance genes are readily moved from one cell to another by horizontal gene transfer.

Compare, Hypothesize, Invent

1. Mutations are often considered harmful. Give an example of a mutation that would be beneficial to a microorganism. What gene would bear the mutation? How would the mutation alter the gene's role in the cell, and what conditions would select for this mutant allele?
2. Mistakes made during transcription affect the cell but are not considered "mutations." Why not?
3. Given what you know about the differences between bacterial and eukaryotic cells, give two reasons why the Ames test detects only about half of potential carcinogens, even when liver extracts are used.
4. Suppose that transduction took place when a U-tube experiment was conducted. How would you confirm that a virus was passed through the filter and transduced the recipient?
5. Suppose that you carried out a U-tube experiment with two auxotrophs and discovered that recombination was not blocked by the filter but was stopped by treatment with deoxyribonuclease. What gene transfer process is responsible? Why would it be best to use double or triple auxotrophs in this experiment?
6. What would be the evolutionary advantage of having a period of natural "competence" in a bacterial life cycle? What would be possible disadvantages?
7. Unlike *E. coli*, *S. pneumoniae* lacks the capacity to mount an SOS response (p. 382). Prudhomme and colleagues tested to see if transformation might be an alternative response to DNA damage. To do this, they treated *S. pneumoniae* with the drug mitomycin C, which blocks the replication fork, thereby generating a region of single-stranded DNA to which the protein RecA binds. They discovered that

transformation in *S. pneumoniae* was indeed induced by mitomycin C exposure. They then tested an assortment of antibiotics that are known to trigger the SOS response in *E. coli* for their ability to induce transformation in *S. pneumoniae*. They found that some but not all of the antibiotics resulted in *S. pneumoniae* transformation.

Suggest why *S. pneumoniae* responds to certain stresses by genetic transformation. Do you think the discovery that certain antibiotics trigger transformation in this pathogen should be considered when prescribing antibiotics currently used and designing new drugs? If so, explain why and how.

Read the original paper: Prudhomme, M., et al. 2006. Antibiotic stress induces genetic transformability in the human pathogen *Streptococcus pneumoniae*. *Science* 313:89.

8. *Helicobacter pylori* is a gastric pathogen that causes ulcers and cancer of the stomach. It is naturally competent and its genome encodes at least four type IV secretion systems. Thus it is not surprising that isolates of *H. pylori* are able to transfer chromosomal DNA using a conjugation-like mechanism. *Campylobacter jejuni* is closely related to *H. pylori* and is a major cause of food-borne illness. Microbiologists were curious to see if *H. pylori* could transfer DNA to *C. jejuni* via conjugation.

How would you design such an experiment? How would you detect successful conjugation without resorting to molecular genetic techniques such as DNA sequencing? What kinds of controls would you need to include so that you could be confident of your experimental results?

Read the original paper: Oyarzabal, O. A., et al. 2007. Conjugative transfer of chromosomally encoded antibiotic resistance from *Helicobacter pylori* to *Campylobacter jejuni*. *J. Clin. Microbiol.* 45:402.

Recombinant DNA Technology

Archeological Digs Reveal Source of Ancient Pathogen

A 9,000-year-old grave holding a mother and her infant, and 4,000-year-old Egyptian mummies have helped unravel the mystery of the origin of tuberculosis (TB). Probably the world's most widespread disease, TB currently affects 2 billion people, about a third of the world's population. Most are infected with the Gram-positive bacterium *Mycobacterium tuberculosis*, but *M. canettii* and *M. africanum* are known to cause disease in humans.

Animals, including cows, also can contract TB. Before pasteurization, *M. bovis* was responsible for about 6% of human TB deaths. Because people can contract TB from cattle, it was long believed that the first human TB case was caused by *M. bovis*. A *M. bovis* strain was thought to have slowly evolved to the current *M. tuberculosis*. However, this notion was questioned in 2003, when it was reported that a third of 85 mummies examined from Thebes West, Upper Egypt, were infected with an ancient strain of *M. tuberculosis*. (Note that the incidence of TB has not improved in over 4,000 years!) Then in 2008, a team of scientists from Britain and Israel tested the remains of a mother and her baby buried together prior to the advent of dairy farming. The burial site, Atlit-Yam, Israel, was later flooded and covered with a thick layer of mud and clay, and eventually seawater. This kept the bodies in an anoxic state, slowing the rate of decay. In both Egypt and Israel, preservation made it possible for scientists to recover snippets of DNA from the bones and use the polymerase chain reaction (PCR; section 17.2) to verify the presence of nucleotide sequences unique to *M. tuberculosis*, not *M. bovis*.

So where did this pathogen come from? The best hypothesis is that TB arose in Africa from an ancestor of *M. africanum*, perhaps as many as 3 million years ago. Subsequently an *M. africanum*-like strain left Africa

The polymerase chain reaction (PCR) has revolutionized forensic biology. Whether scientists are solving a crime or exploring ancient Egyptian civilizations, PCR allows them to answer questions they previously would not have asked.

with the migration of ancient populations; it is this microbe that most likely evolved into the successful pathogen that still dominates human infectious disease.

The success of this amazing piece of archeological detective work was made possible by PCR. In this chapter, we introduce some of the techniques used in recombinant DNA technology—a field revolutionized by PCR. PCR enables the production of massive quantities of DNA encoding only the relevant trait and often represents one of the first steps in genetic cloning—the generation of a large number of genetically identical DNA molecules (**figure 17.1**). It should be kept in mind that for centuries, people have been genetically engineering domestic animals and crops through directed breeding; today's technology allow scientists to change only the genetic information that is relevant to the desired outcome. Here we review the essential methods used in biotechnology, which requires an understanding of basic genetic principles.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Identify the key structural elements of DNA, RNA, and protein (section 13.2)
- ✓ Diagram the flow of cellular information from gene to protein as well as protein localization (e.g., subcellular localization or export) (section 13.8)
- ✓ Explain the general structural differences in a eukaryotic gene and a bacterial gene, including regulatory, coding, and noncoding sequences (sections 13.4 and 15.3)
- ✓ Describe the capacity of proteins to recognize and bind to DNA (sections 13.2 and 14.2)
- ✓ List three differences between a plasmid and a chromosome (sections 3.6 and 16.6)

17.1 Key Developments in Recombinant DNA Technology

After reading this section, you should be able to:

- Explain how restriction enzymes recognize and digest DNA to create either blunt or sticky ends
- Explain the general principles by which molecules are electrophoretically separated
- Draw a sample agarose gel in which molecular weight markers and digested DNA can be visualized
- Discuss the use of single-stranded oligonucleotide probes to identify specific fragments of DNA (or RNA)
- Diagram the reaction catalyzed by reverse transcriptase and describe its application to biotechnology

The pace of research and discovery in the last half century has been remarkable (**table 17.1**), thanks to the development of recombinant DNA technologies. Many early discoveries are essential to biotechnology as it is practiced today; these are now discussed.

Restriction Enzymes

Recombinant DNA is DNA with a new nucleotide sequence. Such DNA is formed by joining fragments from two or more different sources. One of the first breakthroughs leading to recombinant DNA technology was the discovery by Werner Arber and Hamilton Smith in the late 1960s of bacterial enzymes that cut double-stranded DNA. These enzymes, known as **restriction enzymes** or restriction endonucleases, recognize and cleave specific sequences about four to eight base pairs long (**figure 17.2**). Restriction enzymes identify specific DNA sequences called recognition sites. Each restriction enzyme has its own recognition site. Hundreds of different restriction enzymes have been purified and are commercially available. Type I and type III endonucleases identify their unique recognition sites and then cleave DNA at a defined distance from it. The more common type II endonucleases cut DNA directly at their recognition sites. These enzymes can be used to prepare DNA fragments containing specific genes or portions of genes. For example, the restriction enzyme EcoRI, isolated by Herbert Boyer in 1969 from *Escherichia coli*, cleaves DNA between G and A in the base sequence 5'-GAATTC-3' (**figure 17.3**). Because DNA is antiparallel, this sequence is reversed on the complementary strand of DNA. When EcoRI cleaves between the G and A residues, unpaired 5'-AATTC-3' remains at the end of each strand. The complementary bases on two EcoRI-cut fragments can hydrogen bond, thus EcoRI and other endonucleases like it generate cohesive or **sticky ends**. In contrast, cleavage by restriction enzymes such as AluI and HaeIII leaves blunt ends. A few restriction enzymes and their recognition sites are listed in **table 17.2**. Note that each enzyme is named after the bacterium from which it is purified. 🌀 *Restriction Enzymes*

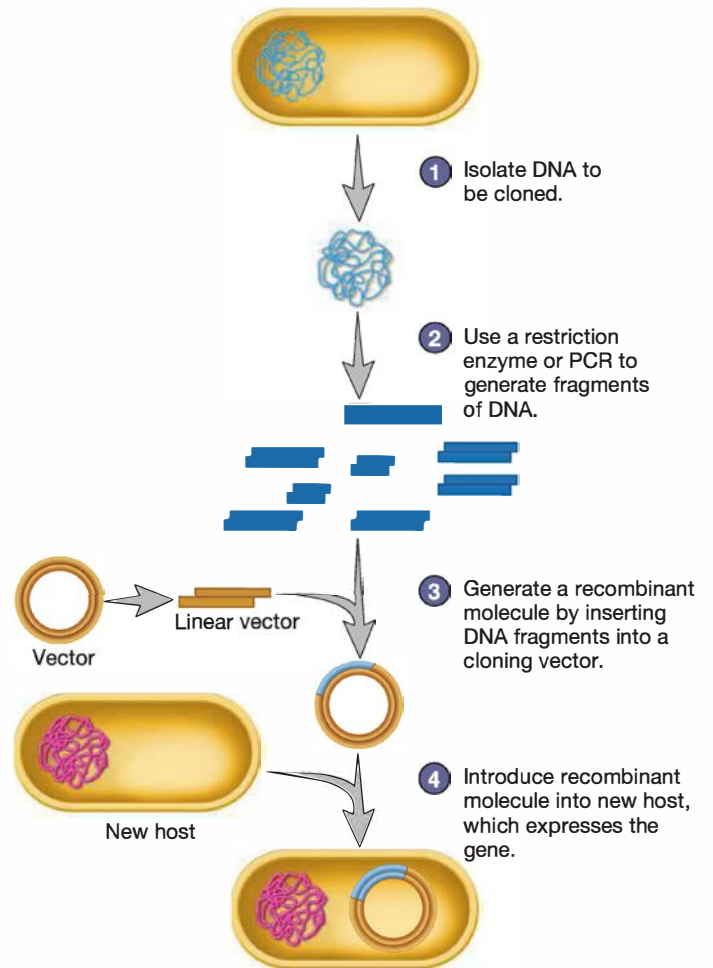

Figure 17.1 Steps in Cloning a Gene. Each step shown in this overview is discussed in more detail in this chapter.

MICRO INQUIRY Which of the DNA molecules shown are recombinant?

Genetic Cloning and cDNA Synthesis

An important advance in cloning DNA came in 1972, when David Jackson, Robert Symons, and Paul Berg reported that they had successfully generated recombinant DNA molecules. They allowed the sticky ends of fragments to anneal—that is, to base pair with one another—and then covalently joined the fragments with the enzyme DNA ligase (see **figure 13.15**). Within a year, plasmid vectors that carry foreign DNA fragments during gene cloning had been developed and combined with foreign DNA (**figure 17.4**). Recombinant plasmids replicate within a microbial host and maintain the cloned fragment of DNA.

🌀 Early Genetic Engineering Experiment

Once genes could be recombined into cloning vectors, biologists sought to clone specific genes from various organisms. However, it was evident that cloning eukaryotic DNA into bacterial hosts would be problematic. This is because eukaryotic pre-mRNA must be processed (e.g., introns spliced out), and bacteria lack the molecular machinery to perform

Table 17.1 Some Milestones in Biotechnology and Recombinant DNA Technology

| | |
|------|--|
| 1958 | DNA polymerase purified |
| 1970 | A complete gene synthesized in vitro Discovery of the first sequence-specific restriction endonuclease and the enzyme reverse transcriptase |
| 1972 | First recombinant DNA molecules generated |
| 1973 | Use of plasmid vectors for gene cloning introduced |
| 1975 | Southern blotting technique for detecting specific DNA sequences developed |
| 1976 | First prenatal diagnosis using a gene-specific probe |
| 1977 | Methods for rapid DNA sequencing invented Discovery of introns and exons in eukaryotic genes |
| 1978 | Human genomic library constructed |
| 1979 | Insulin synthesized using recombinant DNA |
| 1982 | Commercial production by <i>Escherichia coli</i> of genetically engineered human insulin |
| 1983 | Engineered Ti plasmids used to transform plants |
| 1985 | Development of the polymerase chain reaction technique |
| 1987 | Insertion of a functional gene into a fertilized mouse egg cures a normally fatal genetic disease |
| 1988 | First successful production of a genetically engineered staple crop (soybeans) |
| 1989 | First field test of a genetically engineered virus (a baculovirus that kills cabbage looper caterpillars) |
| 1990 | Production of the first fertile corn transformed with a foreign gene (a gene for resistance to the herbicide bialaphos) |
| 1991 | Development of transgenic pigs and goats capable of manufacturing proteins such as human hemoglobin First test of gene therapy on human cancer patients |
| 1994 | The Flavr Savr tomato introduced, the first genetically engineered whole food approved for sale Fully human monoclonal antibodies produced in genetically engineered mice |
| 1995 | <i>Haemophilus influenzae</i> genome sequenced |
| 1998 | First cloned mammal (the sheep Dolly) |
| 2003 | Completion of the draft of the human genome |
| 2005 | Reconstruction of 1918 influenza virus |
| 2007 | First complete human genome from a single individual sequenced |
| 2010 | First bacterium with synthetic genome constructed |

Figure 17.2 Restriction Endonuclease Binding to DNA. The structure of BamHI binding to DNA viewed down the DNA axis. The enzyme's two subunits lie on each side of the DNA double helix. The α -helices are in green, the β conformations in purple, and the DNA is in orange.

this task. In 1970 Howard Temin and David Baltimore independently discovered the enzyme that solved this dilemma. They isolated the enzyme **reverse transcriptase (RT)** from retroviruses. These viruses have an RNA genome that is copied into DNA prior to replication. The mechanism by which reverse transcriptase accomplishes this is outlined in [figure 17.5](#). Processed mRNA can be used as a template for **complementary DNA (cDNA)** synthesis in vitro. The resulting cDNA can then be cloned, without the need for RNA processing.  **Retroviruses** ([section 27.8](#))  **cDNA**

Figure 17.3 Restriction Endonuclease Action. The cleavage catalyzed by the restriction endonuclease EcoRI. The enzyme makes staggered cuts on the two DNA strands to form sticky ends.

MICRO INQUIRY Examine the uncut piece of DNA shown in the upper half of this figure. Where would an exonuclease cleave?

Table 17.2 Some Type II Restriction Endonucleases and Their Recognition Sequences

| Enzyme | Microbial Source | Recognition Sequence ¹ | Ends Produced |
|---------|-------------------------------------|---|--|
| AluI | <i>Arthrobacter luteus</i> | 5' AGCT 3' 3' TCGA 5' (Arrows point to the G in AGCT and the A in TCGA) | 5' AG CT 3' 3' TC GA 5' |

¹ The arrows indicate the sites of cleavage on each strand.

MICRO INQUIRY: Which of the above enzymes yield blunt ends? Which yield sticky ends with a 5' overhang? What about a 3' overhang?

Gel Electrophoresis

The concept of **gel electrophoresis** was first introduced in the 1930s with the development of sucrose gel electrophoresis for the separation of proteins. The following 40 years brought the development of a variety of different gel systems, but it was not until the 1970s that the precursors to present-day techniques appeared.

Agarose and polyacrylamide gel electrophoresis is now routinely used to separate DNA fragments. When DNA molecules are placed at the negative end of an electrical field, they migrate toward the pole with a positive charge (**figure 17.6**). Each fragment's

Figure 17.4 Recombinant Plasmid Construction. (a) A restriction endonuclease recognizes and cleaves DNA at its specific recognition site. Cleavage produces sticky ends that accept complementary tails for gene splicing. (b) The sticky ends can be used to join DNA from different organisms by cutting it with the same restriction enzyme, ensuring that all fragments have complementary ends.

MICRO INQUIRY Why might two DNA fragments inadvertently be cloned into a single vector when using this cloning strategy?

Figure 17.5 Synthesis of cDNA. A poly-dT primer anneals to the 3' end of mRNAs. Reverse transcriptase then catalyzes the synthesis of a complementary DNA strand (cDNA). RNaseH digests the mRNA into short pieces that are used as primers by DNA polymerase to synthesize the second DNA strand. The 5' to 3' exonuclease function removes all of the RNA primers except the one at the 5' end (because there is no primer upstream from this site). This RNA primer can be removed by the subsequent addition of another RNase. After the double-stranded cDNA is made, it can be inserted into vectors, as described in figure 17.4.

MICRO INQUIRY Why must introns be removed from eukaryotic DNA before it can be expressed in a bacterium?

migration rate is determined by its molecular weight so that the smaller a fragment is, the faster it moves through the gel. Migration rate is also a function of gel density. In practice, this means that higher concentrations of gel material (agarose or acrylamide) provide better resolution of small fragments and vice versa. DNA that has not been digested with restriction enzymes is usually supercoiled and does not migrate to a position that corresponds to

its molecular weight. For this and other reasons, DNA is usually cut with restriction enzymes prior to electrophoresis.

Southern Blotting

Another problem early biotechnologists faced was the inability to distinguish the fragment of DNA possessing the gene of interest from the numerous chromosomal fragments produced by restriction enzyme digestion of an organism's genome. In 1975 Edwin Southern solved this problem with his **Southern blotting technique**. This procedure enables the detection of specific DNA fragments from a mixture of DNA molecules (figure 17.7). Southern blotting is a three-step process: separate DNA molecules by electrophoresis, transfer separated DNA molecules to a membrane, and hybridize to a labeled probe specific for the gene of interest.

After the DNA fragments are separated by agarose gel electrophoresis, they are rendered single-stranded (i.e., denatured). The denatured DNA molecules are next transferred and bound to a nylon membrane. The DNA of interest is identified by bathing the filter in a solution containing a radioactive **probe**, which is a fragment of labeled, single-stranded nucleic acid complementary to the DNA of interest. The DNA to which the probe hydrogen bonds is now radioactive and is readily detected by **autoradiography**. In autoradiography, a sheet of photographic film is placed over the membrane. When the film is developed, bands appear wherever the radioactive probe is bound because the energy released by the isotope causes the formation of dark-silver grains. Nonradioactive probes may also be used to detect specific DNAs. A common label is the small molecule biotin, as discussed in **Techniques & Applications 17.1**. Nonradioactive labels often are more rapidly detected and are safer to use than radioisotopes. **Southern Blotting**

By the late 1970s the techniques for cloning DNA were harnessed to produce recombinant human insulin, and by 1982 commercial production of insulin from genetically engineered *E. coli* began. This was an important development for several reasons: first, diabetic individuals no longer had to depend on insulin from pigs or other animals; second, it demonstrated the commercial feasibility of using recombinant DNA to make a better product.

►► **Biotechnology and industrial microbiology (chapter 42)**

Retrieve, Infer, Apply

1. Describe restriction enzymes, sticky ends, and blunt ends. Can you think of a cloning situation where blunt-ended DNA might be more useful than DNA with sticky ends?
2. What is cDNA? Why is it necessary to generate cDNA before cloning and expressing a eukaryotic gene in a bacterium?
3. You want to visualize a digested plasmid that yields fragments of 100 bp, 400 bp, and 3,000 bp. You have another plasmid digested with the same endonuclease that yields two fragments, 4,000 bp and 5,500 bp. How many recognition sites are there for this enzyme in each plasmid? For which plasmid would you use a 1.5% agarose gel? For which would a 0.8% gel be best? Explain your answer.
4. What is the purpose of Southern blotting? How is a probe selected? Why do you think the Southern blotting technique was an important breakthrough when it was introduced?

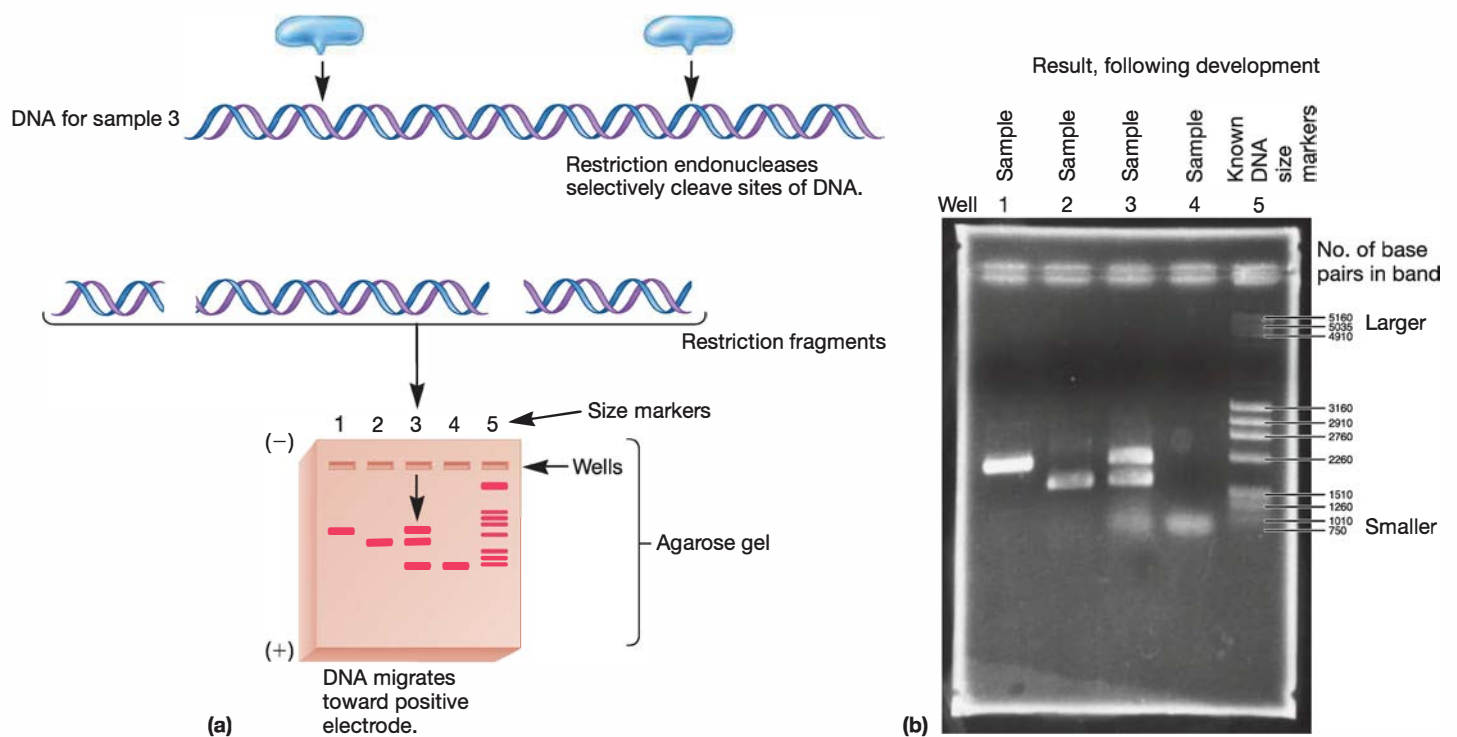

Figure 17.6 Gel Electrophoresis of DNA. (a) After cleavage into fragments, DNA is loaded into wells on one end of an agarose gel. When an electrical current is passed through the gel (from the negative pole to the positive pole), the DNA, being negatively charged, migrates toward the positive pole. The larger fragments, measured in numbers of base pairs, migrate more slowly and remain nearer the wells than the smaller (shorter) fragments. (b) Developed and stained gel revealing the separation pattern of the fragments of DNA. The size of a given DNA band can be determined by comparing it to a known set of molecular weight markers (lane 5) called a ladder.

MICRO INQUIRY If a linear piece of DNA is cut with a restriction enzyme for which it has four recognition sites, how many bands would be visible on a gel if the products of digestion were electrophoresed? (Hint: Make a drawing of the DNA and its restriction sites.)

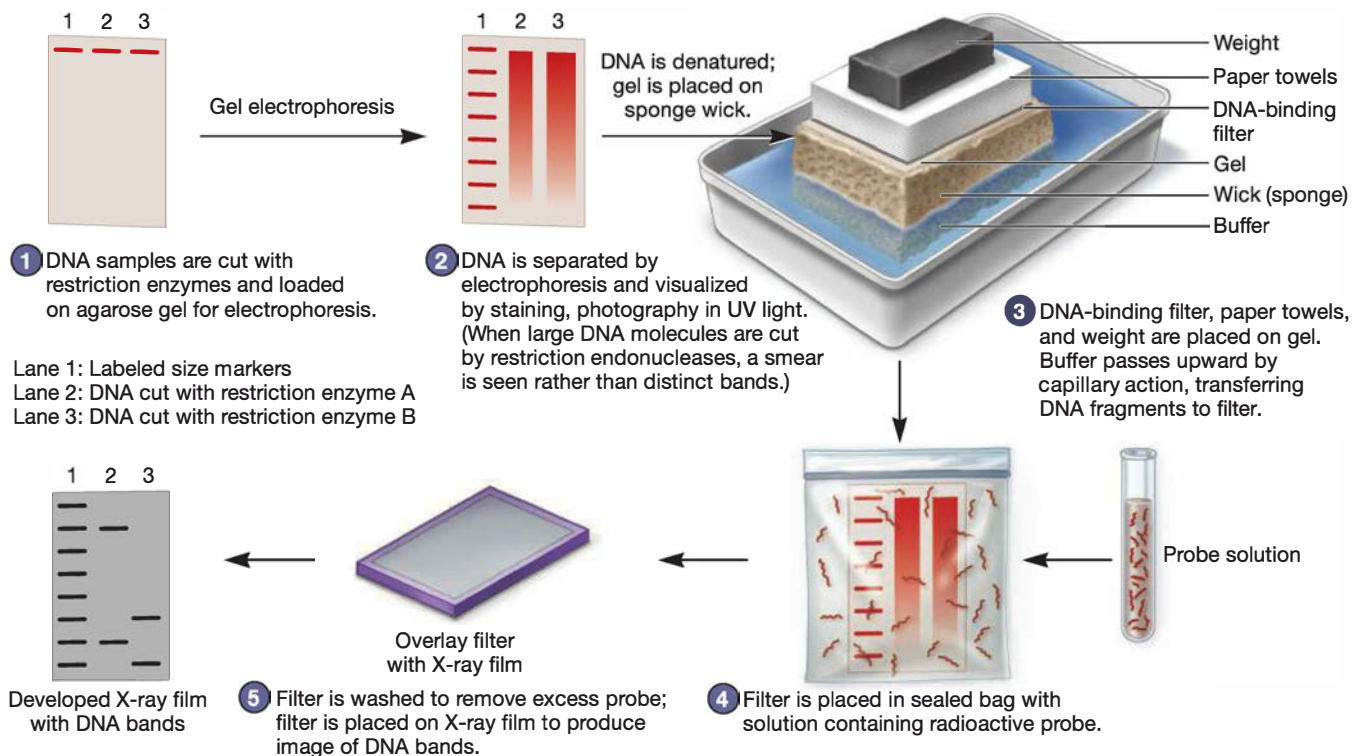

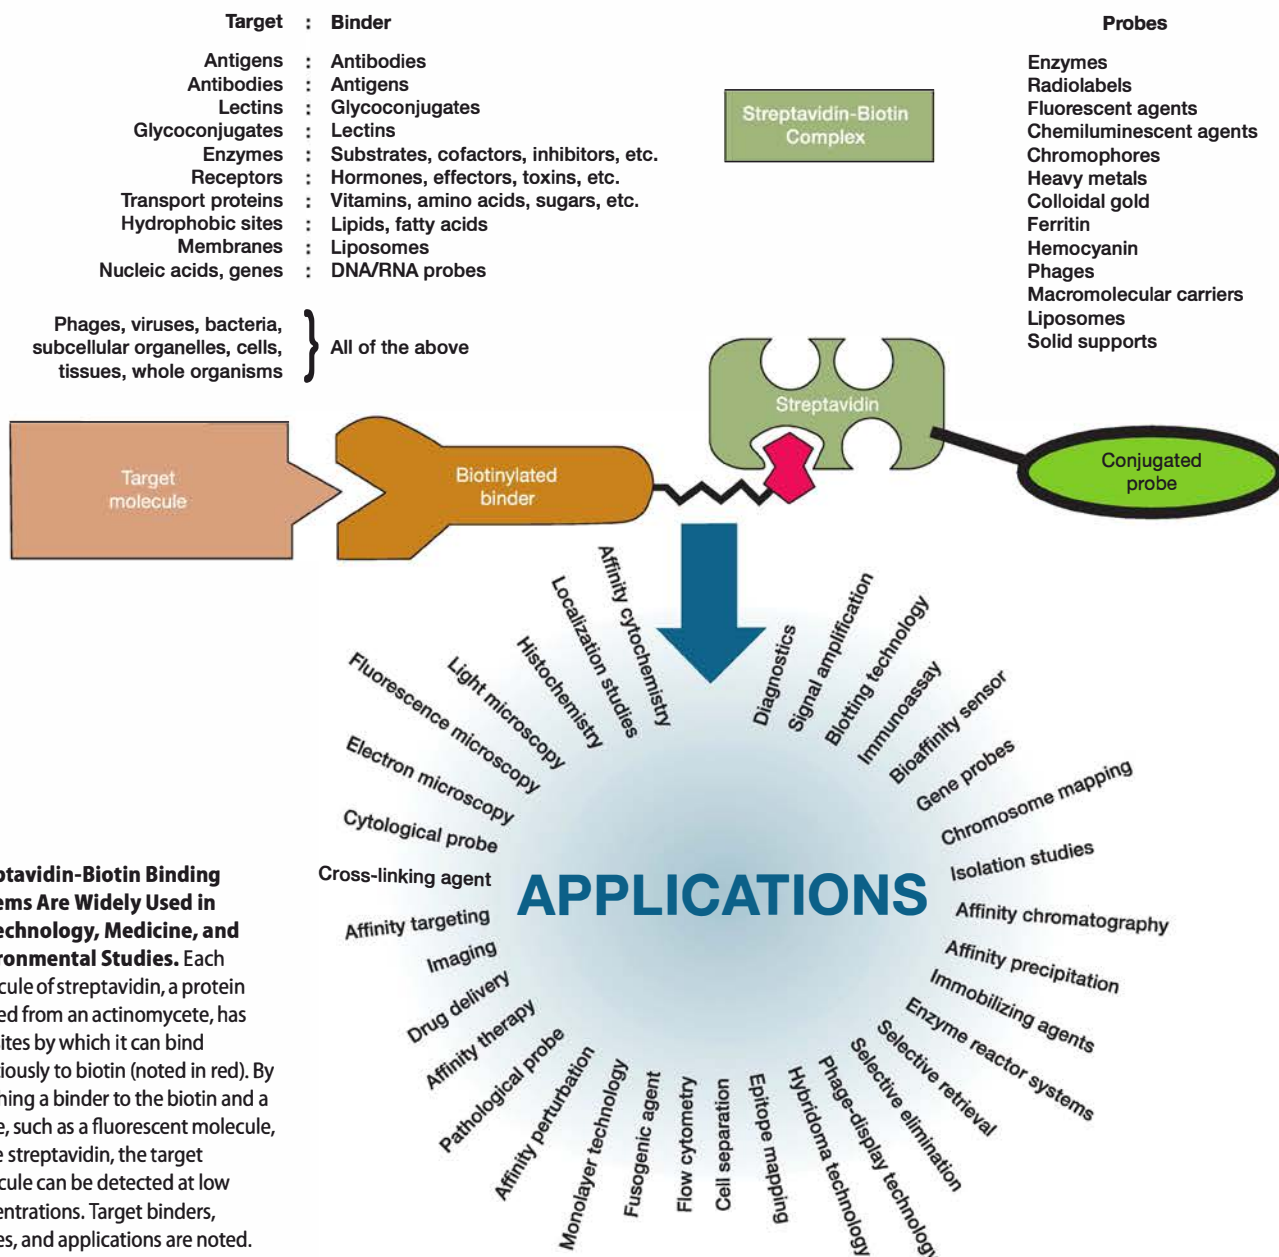

Figure 17.7 The Southern Blotting Technique.

17.1 Streptavidin-Biotin Binding and Biotechnology

Egg white contains many proteins and glycoproteins with unique properties. One of the most interesting, which binds tenaciously to biotin, was isolated in 1963. This glycoprotein, called avidin due to its “avid” binding of biotin, was suggested to play an important role: making egg white antimicrobial by “tying up” the biotin needed by many microorganisms. Avidin, which functions best under alkaline conditions, has the highest known binding affinity between a protein and a ligand. Several years later, scientists at Merck & Co., Inc., discovered a similar protein produced by the actinomycete *Streptomyces avidinii*, which binds biotin at a neutral pH and does not contain carbohydrates. These characteristics make this protein, called streptavidin, an ideal binding agent for biotin, and it

has been used in an almost unlimited range of applications, as shown in the **box figure**. The streptavidin protein is joined to a probe. When a sample is incubated with the biotinylated binder, the binder attaches to any available target molecules. The presence and location of target molecules can be determined by treating the sample with a streptavidin probe because the streptavidin binds to the biotin on the biotinylated binder, and the probe is then visualized. This detection system is employed in a wide variety of biotechnological applications, including use as a nonradioactive probe in hybridization studies and as a critical component in biosensors for a wide range of environmental monitoring and clinical applications.

17.2 Polymerase Chain Reaction

After reading this section, you should be able to:

- Differentiate between a PCR cycle and step, and define the function of each of the three steps used in a PCR cycle
- Explain why PCR results in the amplification of a specific DNA sequence despite many competing sequences
- Explain why PCR generates billions of products that are all the same size
- Contrast real-time, quantitative PCR to end-point collection PCR and identify an application for each
- Summarize the importance of PCR in biology

The **polymerase chain reaction (PCR)**, invented by Kary Mullis in the early 1980s, exploded onto the biotechnology landscape. It changed the way genes are cloned, nucleic acids sequenced, diseases diagnosed, and crimes solved. Why is PCR so versatile and important? Quite simply, it enables the rapid synthesis of billions of copies of a specific DNA fragment from a complex mixture of DNA. Researchers can thus obtain large quantities of specific pieces of DNA for experimental and diagnostic purposes.

Figure 17.8 outlines how PCR works. Suppose that one wishes to make large quantities of a particular DNA sequence, a process known as **gene or DNA amplification**. The first step is to synthesize **oligonucleotides** (Greek *oligo*, few or scant)—single-stranded DNA fragments with sequences complementary to those flanking the targeted sequence. Oligonucleotides are made with a DNA synthesizer and are generally between 15 and 30 nucleotides long. Oligonucleotides serve as DNA **primers**, providing the 3'-OH needed for DNA synthesis during PCR. The primers are

Figure 17.8 The Polymerase Chain Reaction (PCR) Technique.

During each cycle, oligonucleotides that are complementary to the ends of the targeted DNA sequence bind to the DNA and act as primers for the synthesis of this DNA region. The primers are usually 15 to 20 nucleotides in length. The region between the two primers is typically hundreds of nucleotides in length, not just several nucleotides as shown here. The net result of PCR is the synthesis of many copies of DNA in the region that is flanked by the two primers.

MICRO INQUIRY Why, after three cycles, are the vast majority of amplified DNA molecules (i.e., PCR products) the size defined by the distance between the forward and reverse primers?

added to the reaction mixture, along with the template DNA (often copies of an entire genome), a thermostable DNA polymerase, and each of the four deoxyribonucleoside triphosphates (dNTPs).

PCR requires a series of repeated reactions, called cycles. Each cycle has three steps that are precisely executed in a machine called a thermocycler. In the first step, the DNA containing the sequence to be amplified is denatured by raising the temperature to about 95°C. Next the temperature is lowered to about 50°C so that the primers can hydrogen bond (anneal) to the DNA on both sides of the target sequence. Finally, the temperature is raised, usually to 68 to 72°C, so that DNA polymerase can extend the primers and synthesize copies of the target DNA sequence using dNTPs. Only polymerases that function at the high temperatures can be used. The most commonly used thermostable enzyme is **Taq polymerase** from the thermophilic bacterium *Thermus aquaticus*.

At the end of one PCR cycle, the targeted sequences on both strands have been copied. When the three-step cycle is repeated (figure 17.8), the two strands from the first cycle are copied to produce four fragments. These are amplified in the third cycle to yield eight double-stranded products. Thus, each cycle increases the number of target DNA molecules exponentially. Depending on the initial concentration of the template DNA and other parameters such as the G + C content of the DNA to be amplified, it is theoretically possible to produce about 1 million copies of targeted DNA sequence after 20 cycles and over 1 billion after 30 cycles. Pieces ranging in size from less than 100 base pairs to several thousand base pairs in length can be amplified, and the initial concentration of target DNA can be as low as 10^{-20} to 10^{-15} M. ◀◀ *DNA replication in bacteria (section 13.3)*

🌀 Polymerase Chain Reaction

PCR is most frequently used in two ways. If large quantities of a specific piece of DNA are needed, the reaction products are collected and purified at the end of a designated number of cycles. This is sometimes called end-point PCR, and the final number of DNA fragments amplified is not quantitative. This means that the amount of final product does not always reflect the amount of template DNA present. In contrast, **real-time PCR** is quantitative; in fact, it is referred to as qPCR. That is, the amount of DNA or RNA template (which is converted to DNA with reverse transcriptase prior to starting PCR) present in a given sample can be determined. This is accomplished by adding a fluorescently labeled probe to the reaction mixture and measuring its signal during the initial cycles. This is when the rate of DNA amplification is logarithmic. However, as the PCR cycles continue, substrates are consumed and polymerase efficiency declines. So although the amount of product increases, its rate of synthesis is no longer exponential (this is why end-point collection of PCR products is not quantitative). Specially designed thermocyclers record the amount of PCR product generated as it occurs, thus the term real-time PCR. Gene expression studies often rely on real-time PCR because mRNA transcripts can be copied by reverse transcriptase to cDNA, which is then quantified. Therefore the procedure monitors transcription of the gene targeted by the primers.

PCR is an essential tool in many areas of molecular biology, medicine, and biotechnology. As shown in **figure 17.9**, when PCR

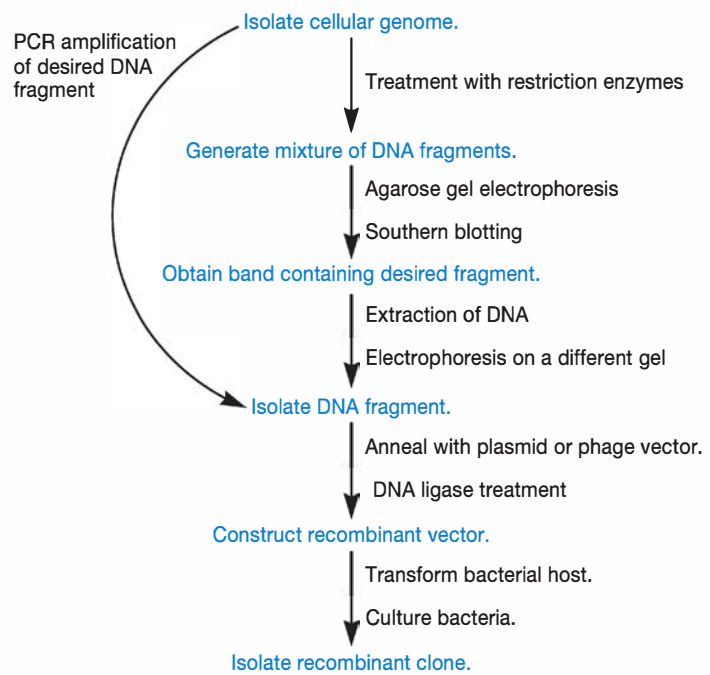

Figure 17.9 The Use of PCR in Cloning DNA Fragments. The use of PCR to synthesize DNA bypasses several steps traditionally used in cloning procedures. In addition, primers can be designed so that the restriction enzyme site of choice is present at each end of the DNA fragment to be cloned.

is used to obtain DNA for cloning, a number of steps in traditional cloning procedures are no longer required. PCR is also used to generate DNA for nucleotide sequencing. Because the primers used in PCR target specific DNA, PCR can isolate particular fragments of DNA (e.g., genes) from solutions that contain many different genomes, such as soil, water, and blood. For instance, PCR is used to amplify specific genes from the environment without first culturing members of the microbial community. It has also become an essential part of certain diagnostic tests, including those for AIDS, Lyme disease, chlamydia, tuberculosis, hepatitis, human papillomavirus, and other infectious agents and diseases. The tests are rapid, sensitive, and specific. PCR is also employed in forensic science, where it is used in criminal cases as part of DNA fingerprinting technology. ▶▶ *Metagenomics (section 18.8); Genomic fingerprinting (section 19.3)*

17.3 Cloning Vectors and Creating Recombinant DNA

After reading this section, you should be able to:

- List the three features of a cloning vector and why these elements are needed
- Differentiate between plasmids, phage-based cloning vectors, cosmids, and artificial chromosomes in terms of structure and application
- Explain how a piece of foreign DNA is recombined in vitro into a cloning vector

Table 17.3 Recombinant DNA Cloning Vectors

| Vector | Insert Size (kb, 1 kb = 1,000 bp) | Example | Characteristics |
|---|--------------------------------------|--|--|
| Plasmid | <20 kb | pBR322, pUC19 | Replicates independently of microbial chromosome so many copies may be maintained in a single cell |
| Bacteriophage | 9–25 kb | λ 1059, λ gt11, M13mp18, EMBL3 | Packaged into lambda phage particles; single-stranded DNA viruses such as M13 have been modified (e.g., M13mp18) to generate either double- or single-stranded DNA in the host |
| Cosmids | 30–47 kb | pJC720, pSupercos | Can be packaged into lambda phage particles for efficient introduction into bacteria, then replicates as a plasmid |
| BACs (bacterial artificial chromosomes) | 75–300 kb | pBAC108L | Modified F plasmid that can carry large DNA inserts; very stable within the cell |
| YACs (yeast artificial chromosomes) | 100–1,000 kb | pYAC | Can carry largest DNA inserts; replicates in <i>Saccharomyces cerevisiae</i> |

Recombinant DNA technology depends on the propagation of many copies of the nucleotide sequence of choice. To accomplish this, genes or other genetic elements to be cloned are inserted into **cloning vectors** that replicate in a host organism. There are four major types of vectors: plasmids, bacteriophages and other viruses, cosmids, and artificial chromosomes (table 17.3). Each type has its own advantages, so the selection of the proper cloning vector is critical to the success of any cloning experiment. Most cloning vectors share three important features: an origin of replication; a region of DNA that bears unique restriction sites, called a multicloning site or polylinker; and a selectable marker. These elements are described in the context of plasmids, the most frequently used cloning vectors. 🌱 *Construction of a Plasmid Vector*

Plasmids

Plasmids make excellent cloning vectors because they replicate autonomously (i.e., independently of the chromosome) and are easy to purify. They can be introduced into microbes by conjugation or transformation. Many different plasmids are used in

biotechnology, all derived from naturally occurring plasmids that have been genetically engineered (figure 17.10). ◀◀ *Plasmids* (section 3.6); *Bacterial conjugation* (section 16.6); *Bacterial transformation* (section 16.7)

Origin of Replication

The **origin of replication** (*ori*) allows the plasmid to replicate in the microbial host independently of the chromosome. pUC19, an *E. coli* plasmid, has an *ori* that generates a “high copy number” because it directs about 50–100 replications in the course of one generation. High copy number is often important because it facilitates plasmid purification and can dramatically increase the amount of cloned gene product produced by the cell. Some plasmids have two origins of replication, each recognized by different host organisms. These plasmids are called **shuttle vectors** because they can move, or “shuttle,” from one host to another. YEp24 is a shuttle vector that can replicate in yeast (*Saccharomyces cerevisiae*) and in *E. coli* because it has the 2 μ circle yeast replication element and the *E. coli* origin of replication (figure 17.10).

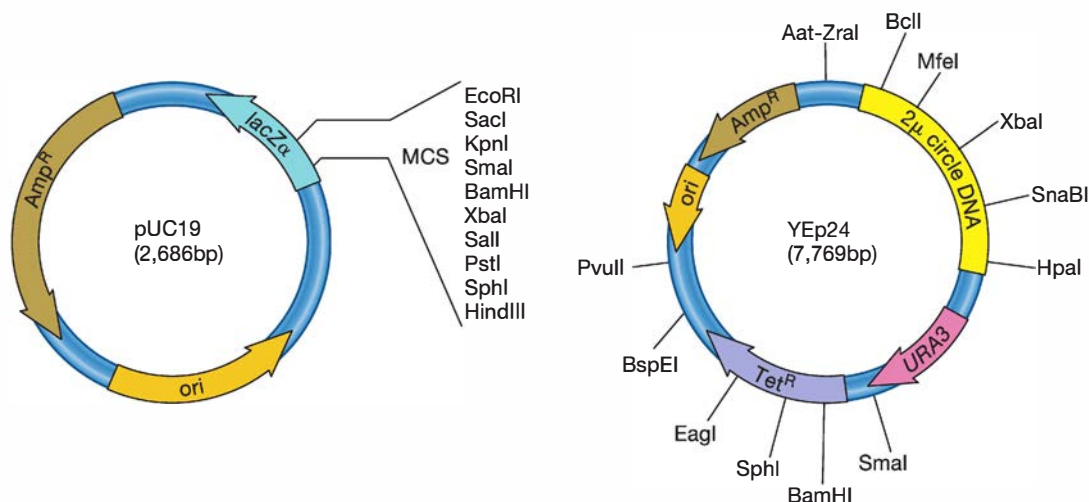

Figure 17.10 The Cloning Vectors pUC19 and YEp24.

Restriction sites that are present only once in each vector are shown. pUC19 replicates only in *E. coli*, while YEp24 replicates in both *E. coli* and *S. cerevisiae*.

MICRO INQUIRY Which plasmid is a shuttle vector? Why?

Selectable Marker

Following the uptake of vector by host cells, it is necessary to discriminate between cells that successfully obtained vector (transformants) from those that did not (nontransformants). Furthermore, selective conditions for the presence of plasmid must be maintained, otherwise the host cell may stop replicating it. This is achieved by the presence of a gene that encodes a protein that is needed for the cell to survive under certain, selective conditions. Such a gene is called a **selectable marker**. In the case of pUC19, the selectable marker encodes the ampicillin-resistance enzyme (*amp^R*, sometimes called *bla*, for β -lactamase). The shuttle vector YEp24 bears both the *amp^R* gene for selection in *E. coli* and URA3, which encodes a protein essential for uracil biosynthesis in yeast. Therefore this plasmid will only be maintained by strains of *S. cerevisiae* that are uracil auxotrophs.

Multicloning Site or Polylinker

In order to clone a fragment of DNA into a plasmid, both the fragment and plasmid are cut with the same restriction enzyme (or enzymes) so that compatible sticky ends are generated. It is essential that these restriction enzymes cut at only one place in the plasmid. Cleavage at a unique restriction site generates a linear plasmid. Alternatively, two different, unique sites may be cleaved and the DNA sequence between the two sites replaced with cloned DNA. Plasmids used for cloning have been designed with many unique restriction sites clustered in a single region called the **multicloning site** (MCS) (figure 17.10). When the plasmid and the DNA to be inserted are incubated in the presence of the enzyme DNA ligase, the compatible sticky ends hydrogen bond and phosphodiester bonds are generated between the cloned DNA fragment and the vector (figure 17.11).

Unfortunately, the ligation of foreign DNA into a vector is never 100% efficient. Thus when the ligation mixture is introduced into host cells, one must distinguish cells that carry just plasmid from those that carry plasmid into which DNA was successfully inserted. To accomplish this, the MCS in plasmids such as pUC19 is located within the 5' end of the *lacZ* gene. *lacZ* encodes β -galactosidase (β -Gal), an enzyme that cleaves the disaccharide lactose into galactose and glucose (see figure 14.2). When DNA has been cloned into the MCS, the *lacZ* gene is interrupted and a functional enzyme is not produced. This can be detected by the color of colonies: cells turn blue when β -Gal splits the alternative substrate, X-Gal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside), which is included in the medium (figure 17.11c). This is important because all *E. coli* cells that take up plasmid (with or without insert) are selected by their resistance to ampicillin (*Amp^R*); that is to say, only pUC19 transformants grow. Among these, colonies with plasmid lacking the desired DNA insert will be blue (due to the presence of functional *lacZ* gene), while those with pUC19 into which DNA was successfully cloned will be white. There are a number of other clever ways in which cells with vector versus those with vector plus insert can be differentiated; the detection of blue versus white colonies, though, is a common approach.

Phage Vectors

Phage vectors are engineered phage genomes that have been genetically modified to include useful restriction enzyme recognition sites for the insertion of foreign DNA. Once DNA has been inserted, the recombinant phage genome is packaged into viral capsids and used to infect host cells. The resulting phage lysate consists of thousands of phage particles that carry cloned DNA as well as the genes needed for host lysis. Two commonly used vectors are derived from the *E. coli* bacteriophages T7 and lambda (λ), both of which have double-stranded DNA genomes. In addition, phage vectors have been engineered for a number of different bacterial host species. ◀◀ *Virion structure* (section 6.2) ▶▶ *Bacteriophage lambda* (section 27.2)

Cosmids

Cosmids can maintain fragments of cloned DNA that are too large for plasmids and phage vectors (table 17.3). These engineered vectors have a *cos* site from phage and a selectable marker, origin of replication, and MCS from plasmids (thus the term “cos-mid”). These hybrid vectors replicate as plasmids within the host cell, but the presence of the *cos* sites means that the vector can be packaged into phage capsids and transferred to new host cells by transduction.

Artificial Chromosomes

Artificial chromosomes are special cloning vectors used when particularly large fragments of DNA must be cloned, as when constructing a genomic library or sequencing an organism's entire genome. In fact, **bacterial artificial chromosomes** (BACs) were crucial to the timely completion of the human genome project and the construction of a synthetic genome (**Techniques & Applications 17.2**). Like natural chromosomes, artificial chromosomes replicate only once per cell cycle. **Yeast artificial chromosomes** (YACs) were developed first and consist of a yeast telomere (TEL) at each end, a centromere sequence (CEN), a yeast origin of replication (ARS, autonomously replicating sequence), a selectable marker such as URA3, and an MCS to facilitate the insertion of foreign DNA (figure 17.12a). YACs are used when extraordinarily large DNA pieces (up to 1,000 kb; table 17.3) are to be cloned. BACs were developed, in part, because YACs tend to be unstable and may recombine with host chromosomes, causing mutations and rearrangement of the cloned DNA. Although BACs accept smaller DNA inserts than do YACs (up to 300 kb), they are generally more stable. BACs are based on the F fertility factor of *E. coli* (see figure 16.16). The example shown in figure 17.12b is typical in that it includes genes that ensure a replication complex will be formed (*repE*), as well as proper partitioning of one newly replicated BAC to each daughter cell (*sopA*, *sopB*, and *sopC*). It also includes features common to many plasmids such as an MCS within the *lacZ* gene for blue/white colony screening and a selectable marker, in this case for resistance to the antibiotic chloramphenicol (*Cm^R*).

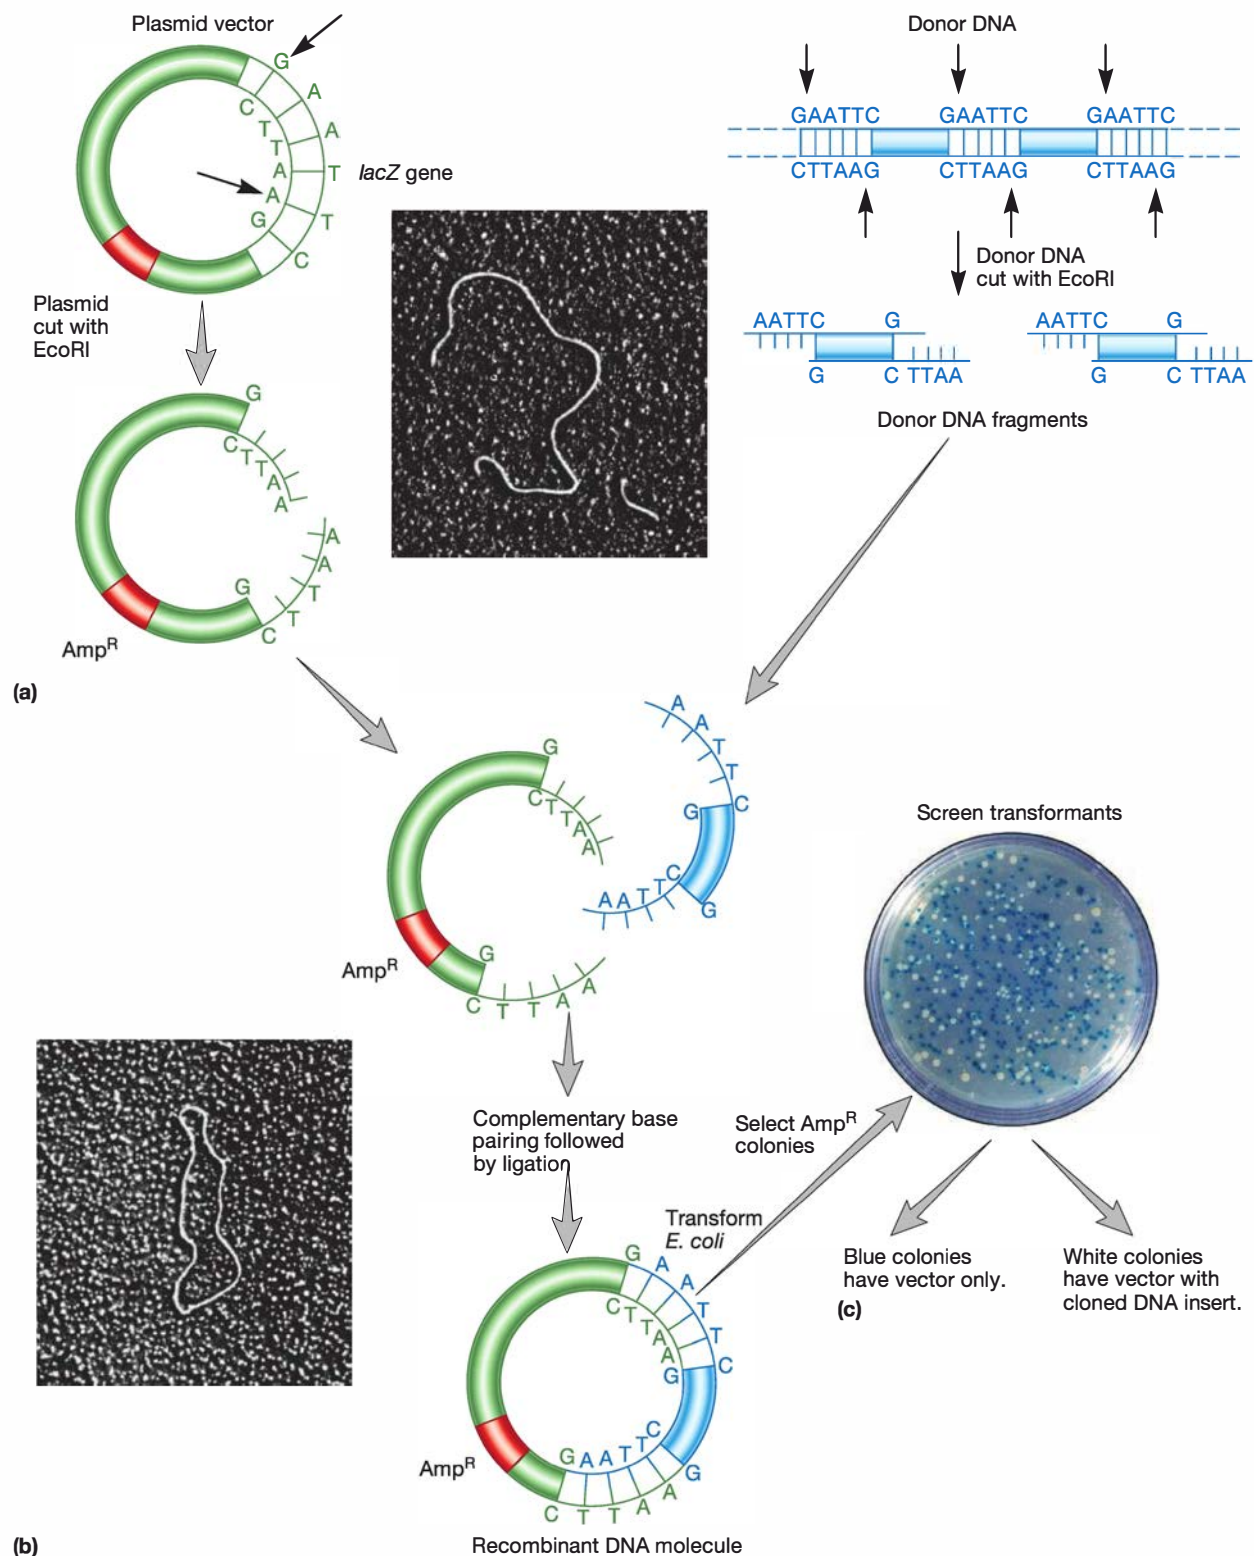

Figure 17.11 Recombinant Plasmid Construction and Cloning. The construction and cloning of a recombinant plasmid vector using an antibiotic-resistance gene to select for the presence of the plasmid. The interruption of the *lacZ* gene by cloned DNA is used to detect vectors with insert. The scale of the sticky ends of the fragments and plasmid has been enlarged to illustrate complementary base pairing. (a) The electron micrograph shows a plasmid that has been cut by a restriction enzyme and a donor DNA fragment. (b) The micrograph shows a recombinant plasmid. (c) After transformation, *E. coli* cells are plated on medium containing ampicillin and X-Gal so that only ampicillin-resistant transformants grow; X-Gal enables the visualization of colonies that were transformed with recombinant vector (vector + insert, white colonies).

MICRO INQUIRY What would you conclude if you obtained only blue colonies after cloning into a vector that enables blue/white screening of transformants? Why might such a result occur?

Techniques & Applications

17.2 How to Build a Microorganism

Biotechnology has repeatedly demonstrated how useful the genetic modification of an organism can be. From the production of recombinant human insulin to recombinant indigo (the dye used in blue jeans), it is clear that “gene juggling” can potentially be used for the production of a wide range of products. But what if, rather than modifying one gene at a time, it were possible to design the ideal genome? The construction of such a genome would enable synthesis of the precise genotype best suited for the application at hand, whether that is generating biofuels or pharmaceuticals.

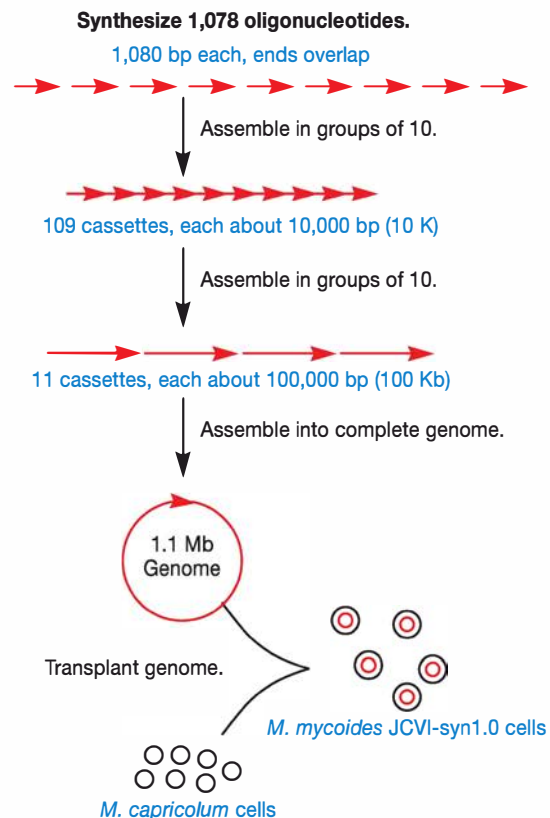

The first step in reaching this goal was to build a genome from scratch. Molecular biologists at the J. Craig Venter Institute (JCVI) accomplished this in 2008 with the one of the smallest bacterial genomes, that of *Mycoplasma genitalium*. The assembly of chemically synthesized DNA was performed in a series of BACs and then YACs to generate the entire bacterial chromosome in a yeast host. A year later, JCVI scientists showed it was possible to “transplant” a bacterial genome from a yeast host into a bacterium. So by 2010 the team was ready to go the distance and construct a synthetic genome and transplant it into a bacterial host.

The JCVI researchers used *M. mycoides* as their model genome. At 1.1 million base pairs (Mb), this microbe’s genome is about twice the size of *M. genitalium*. The first step was to chemically synthesize 1,078 oligonucleotides, each 1080 bp long (**box figure**). If lined up end to end, these oligonucleotides would represent the entire genome. Importantly, 80 bp at each end of every oligonucleotide overlapped with its neighbor, so within an *E. coli* host, these could be assembled in the same order as that found in the native chromosome. Assembly in groups of 10 generated 109 chromosomal fragments, each about 10,000 bp. These were then transformed into yeast, where they were joined into 11 larger cassettes of 100,000 bp each. Finally, these were recombined to yield the entire genome. In addition to the native genes, four nucleotide sequences, called watermarks, were included. Just as a watermark is used to identify the origin of a piece of stationary or currency, these nucleotide sequence watermarks were added to identify the genome as artificial.

The final step was to transplant the synthetic genome from the yeast host to the final bacterial host, *M. capricolum*. Just as in any other cloning experiment, this depended on the

presence of a selectable marker. In this case, a gene that conferred resistance to the antibiotic tetracycline was included in the synthetic genome. Upon selection of tetracycline-resistant *M. capricolum* cells bearing the *M. mycoides* genome, a series of verification tests were performed. These involved PCR and analysis of restriction endonuclease digestion patterns. Once it was confirmed that the host cell was carrying the synthetic genome, all that was left to do was to name the new organism. The JCVI scientists dubbed their new organism *M. mycoides* JCVI-syn1.0.

MICRO INQUIRY In what ways does the BAC shown here differ from the plasmid pUC19 shown in figure 17.10?

Retrieve, Infer, Apply

1. Briefly describe the polymerase chain reaction. What is the difference between a step and a cycle?
2. Why is PCR used to detect infectious agents that are often hard to diagnose?
3. How would you use PCR to measure the concentration of a specific gene's mRNA?
4. Why is it possible to visualize a PCR product on an agarose gel even if the template genome is present at such a low concentration that it cannot be seen?
5. You want to clone a 6,000 bp DNA fragment in *E. coli*. Which cloning vectors would be appropriate? How will you select transformants?

17.4 Construction of Genomic Libraries

After reading this section, you should be able to:

- Explain why genomic libraries are useful
- Outline the construction of a genomic library and how the gene of interest might be selected

The DNA to be cloned can be isolated in several ways. It can be synthesized by PCR, or it can be located on the chromosome by Southern blotting. Both these methods require some knowledge of the nucleotide sequence of the DNA to be cloned. However, what if researchers want to clone a gene based on the function of its product but have no idea what its DNA sequence might be? A genomic library must then be constructed and screened.

The goal of **genomic library** construction is to have an organism's genome cut into many fragments with each fragment cloned into a separate vector and each vector carried by a different microbial cell. Ideally the entire genome is represented in the collection of recombinant vectors; that is, the sum of the different fragments equals the whole genome. In this way, isolated groups of genes can be analyzed and isolated. The construction of a genomic library begins with cleaving the genome into small pieces by a restriction endonuclease (figure 17.13). These genomic DNA fragments are then either cloned into vectors and introduced into a microbe or packaged into phage particles that are used to infect the host. In either case, many thousands of different clones—each with a different genomic DNA insert—are created.

To select the desired clone from the library, it is necessary to know something about the function of the target gene or genetic element. If the genomic library has been inserted into a microbe that expresses the foreign gene, it may be possible to assay each clone for a specific protein or phenotype. For example, if one is studying a newly isolated soil bacterium and wants to find genes that encode enzymes needed for the biosynthesis of the amino acid alanine, the library could be expressed in an *E. coli* or *Bacillus subtilis* alanine auxotroph (figure 17.13). Recall that the growth of alanine auxotrophs requires the addition of this amino acid to the medium. Following introduction of the genomic library into host cells, those that now grow without alanine would be good candidates for the genomic library fragment that possesses the alanine biosynthetic genes. Success with this approach depends on the assumption that the activity of the cloned gene product is similar in both organisms. If this is not the case, the host must be the same species from which the library was prepared. In this example, a soil bacterial mutant lacking the trait in question (e.g., an alanine auxotroph) is used as the genomic library host. The genetic complementation of a deficiency in the host cell is sometimes called **phenotypic rescue** or **genetic complementation**. ◀◀ *Detection and isolation of mutants (section 16.2)*

If a genomic library is prepared from a eukaryote, a cDNA library is usually constructed. In this way, introns are not present in the genomic library. Instead, only the protein-coding regions of the genome are cloned. cDNA is prepared (figure 17.5) and cloned into a suitable vector. After the library is introduced into the host microbe, the host cell carrying the gene of interest may be identified by PCR, phenotypic rescue, or hybridization of plasmid DNA to an oligonucleotide. In some cases, neither phenotypic rescue nor hybridization with a probe is possible. Then the researcher must develop a novel approach that suits the particular set of circumstances to screen the genomic library.

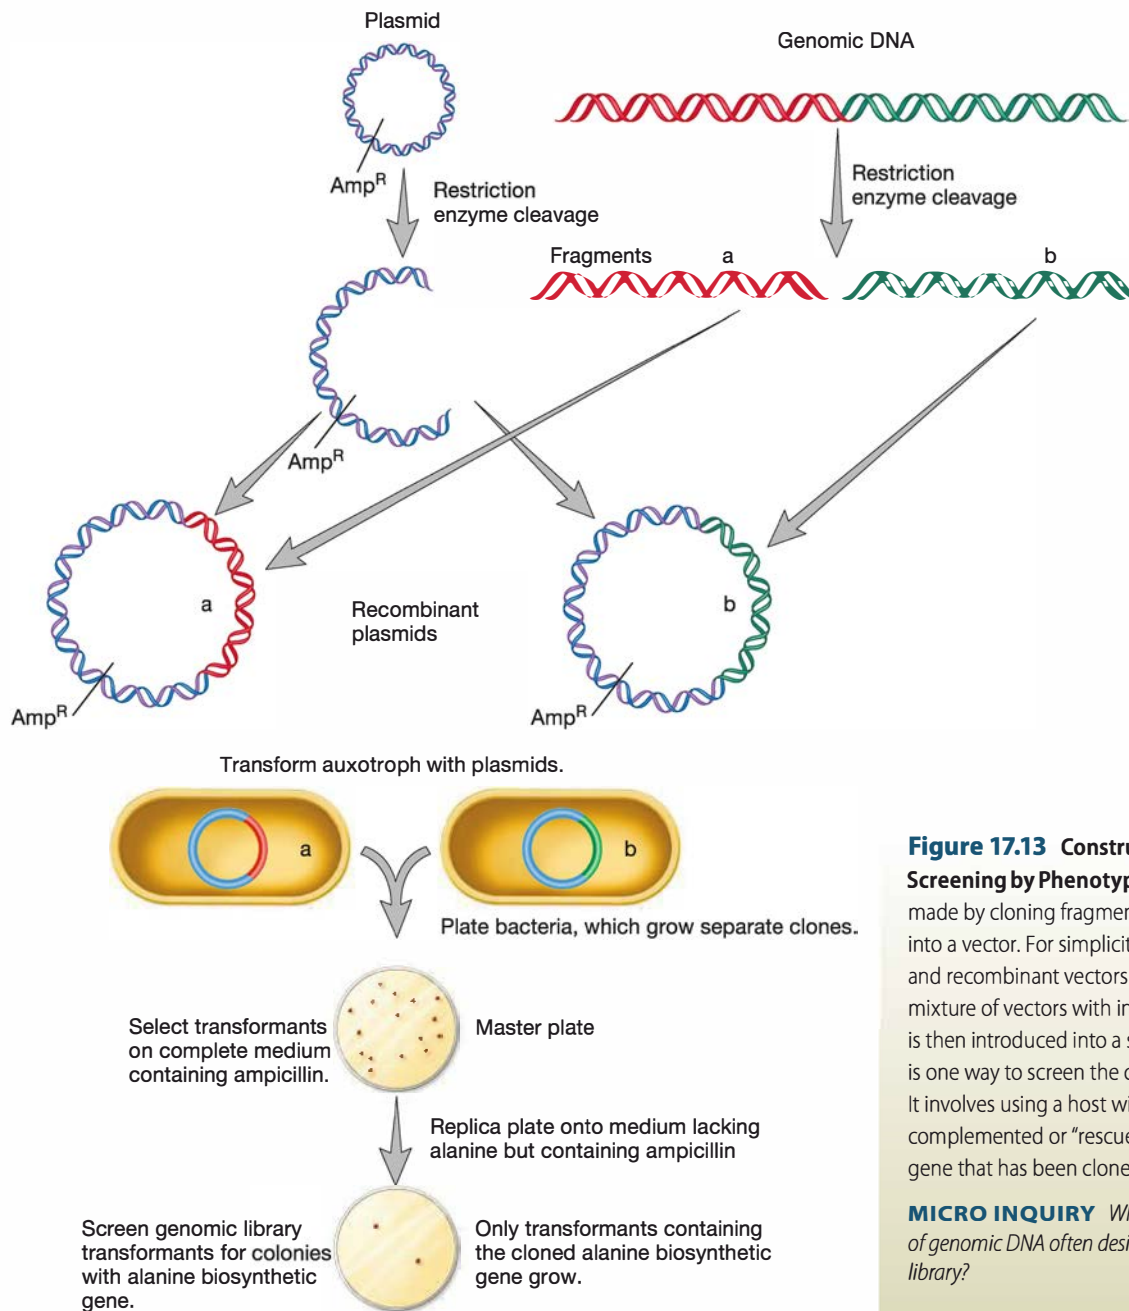

Figure 17.13 Construction of a Genomic Library and Screening by Phenotypic Rescue.

A genomic library is made by cloning fragments of an organism's entire genome into a vector. For simplicity, only two genomic fragments and recombinant vectors are shown. In reality, a large mixture of vectors with inserts is generated. This mixture is then introduced into a suitable host. Phenotypic rescue is one way to screen the colonies for the gene of interest. It involves using a host with a genetic defect that can be complemented or "rescued" by the expression of a specific gene that has been cloned.

MICRO INQUIRY Why are long fragments (e.g., 20,000 bp) of genomic DNA often desired when constructing a genomic library?

17.5 Introducing Recombinant DNA into Host Cells

After reading this section, you should be able to:

- Identify commonly used host cells
- Compare two common techniques by which recombinant DNA constructed in vitro is introduced into host cells

In cloning procedures, the selection of a host organism is as important as the choice of cloning vector. *E. coli* is the most frequent bacterial host and *S. cerevisiae* is most common among eukaryotes. Host microbes engineered to lack restriction enzymes and the recombination enzyme RecA make better hosts because it is less likely that the newly acquired DNA will be degraded or recombined with the host chromosome. There are several ways to introduce recombinant DNA into a host microbe. Chemical transformation and electroporation are two commonly

employed techniques when the host microbe does not have the capacity to be transformed naturally. This is the case with *E. coli* and most Gram-negative bacteria as well as many Gram-positive bacteria and archaea. In these cases, the host cells may be rendered competent by treatment with divalent cations and artificially transformed by heat shocking the cells. ◀◀ *Bacterial transformation (section 16.7)*

Electroporation is a simple technique that has wide application to a number of host organisms, including bacteria, plant, and animal cells. In this procedure, cells are mixed with the recombinant DNA and exposed to a brief pulse of high-voltage electricity. The plasma membrane becomes temporarily permeable and DNA molecules are taken up by some of the cells. The cells are then grown on media that select for the presence of the cloning vector, as described in section 17.4.

17.6 Expressing Foreign Genes in Host Cells

After reading this section, you should be able:

- Explain the utility of expression vectors
- Outline the procedure by which a His-tagged protein is generated in vivo and purified in vitro
- Summarize the role of GFP in protein analysis, and differentiate between a transcriptional and a translational GFP fusion

When a gene from one organism is cloned into another, it is said to be a **heterologous gene**. Many heterologous genes cannot be expressed in the host cell without further modification of the recombinant vector. To be transcribed, the recombinant gene must have a promoter that is recognized by the host RNA polymerase. Translation of its mRNA depends on proper ribosome binding. For instance, if the host is a bacterium and the gene has been cloned from a eukaryote, a bacterial promoter and leader must be provided and introns removed.

The problems of expressing recombinant genes in host cells are largely overcome with the help of specially constructed cloning vectors called **expression vectors**. These vectors contain promoters that result in high-level transcription of the gene cloned under the control of a particularly “strong” promoter. Often expression vectors contain regulatory regions of the *lac* operon (or another inducible promoter) so that expression of the cloned genes can be controlled by the addition of inducer molecules. This is important because sometimes high-level expression of a heterologous protein can be toxic to the host cell. The presence of an inducible promoter allows the biotechnologist to grow the cells to a certain density before inducing the expression of the cloned gene. ◀◀ *Regulation of transcription initiation (section 14.2)*

Purification and Study of Recombinant Proteins

It is often necessary to isolate the protein product of the cloned gene so that its structure and activity can be studied. In

addition, it is sometimes desirable to determine the subcellular localization of a protein. Finally, as discussed in chapter 42, heterologous genes are often expressed for the production of commercially prepared recombinant proteins. Here we discuss some clever ways in which proteins can be purified and visualized in living cells.

Protein Purification

A common method by which proteins are purified is called **polyhistidine tagging**, or simply **His-tagging**. His-tagging involves adding a series of histidine amino acid residues to either the N- or C-terminus of the protein. Most often six residues are added, and this is called a 6xHis-tag. Because histidine has a high affinity for metal ions, a protein bearing multiple histidine residues will bind preferentially to a solid-phase material, called a resin, which has exposed nickel or cobalt atoms. This permits the separation of the His-tagged protein from other cellular constituents. The tagged protein is then removed from the resin, and the histidine residues may be removed with a specific protease.

The process of purifying a His-tagged protein begins by adding the histidine residues to the protein. This is most commonly accomplished by cloning the protein into an expression vector that already has the histidine-encoding sequence present (**figure 17.14**, step 1). Alternatively, the histidine-encoding sequence can be amplified by PCR and added to the gene of interest. Once the protein-coding nucleotide sequence is fused to the histidine codons, the vector is introduced into the microbe of choice, usually *E. coli* (step 2). As *E. coli* grows, the His-tagged protein is produced (step 3). When the cells reach a sufficiently high density, they are lysed by treatment with detergent or enzymes, and all the soluble protein within the cell—including the His-tagged protein—is collected. These proteins are mixed with the metal resin that is bound to a column (step 4) so that only the His-tagged protein sticks to the resin. The remaining, unwanted material is washed from the resin (step 5). The His-tagged protein is then removed by passing the aromatic compound imidazole through the column (step 6). Depending on the purification system used, the His-tag can be cleaved from the protein when it is detached from the resin, or it can be removed following its release. Often the protein is functional with the His-tag, so it may not be removed. His-tagging is used if the protein is soluble and remains in the cytoplasm. While His-tagging is certainly the most popular approach to purifying recombinant proteins, other approaches exist, especially for purifying membrane-associated proteins.

Fluorescence Labeling

What if the goal of cloning a gene is to study the regulation or function of the protein product in vivo? It is possible to visualize the activity of a specific promoter as well as observe the localization of a protein by fluorescence. The development of fluorescent labeling of living cells began when it was discovered

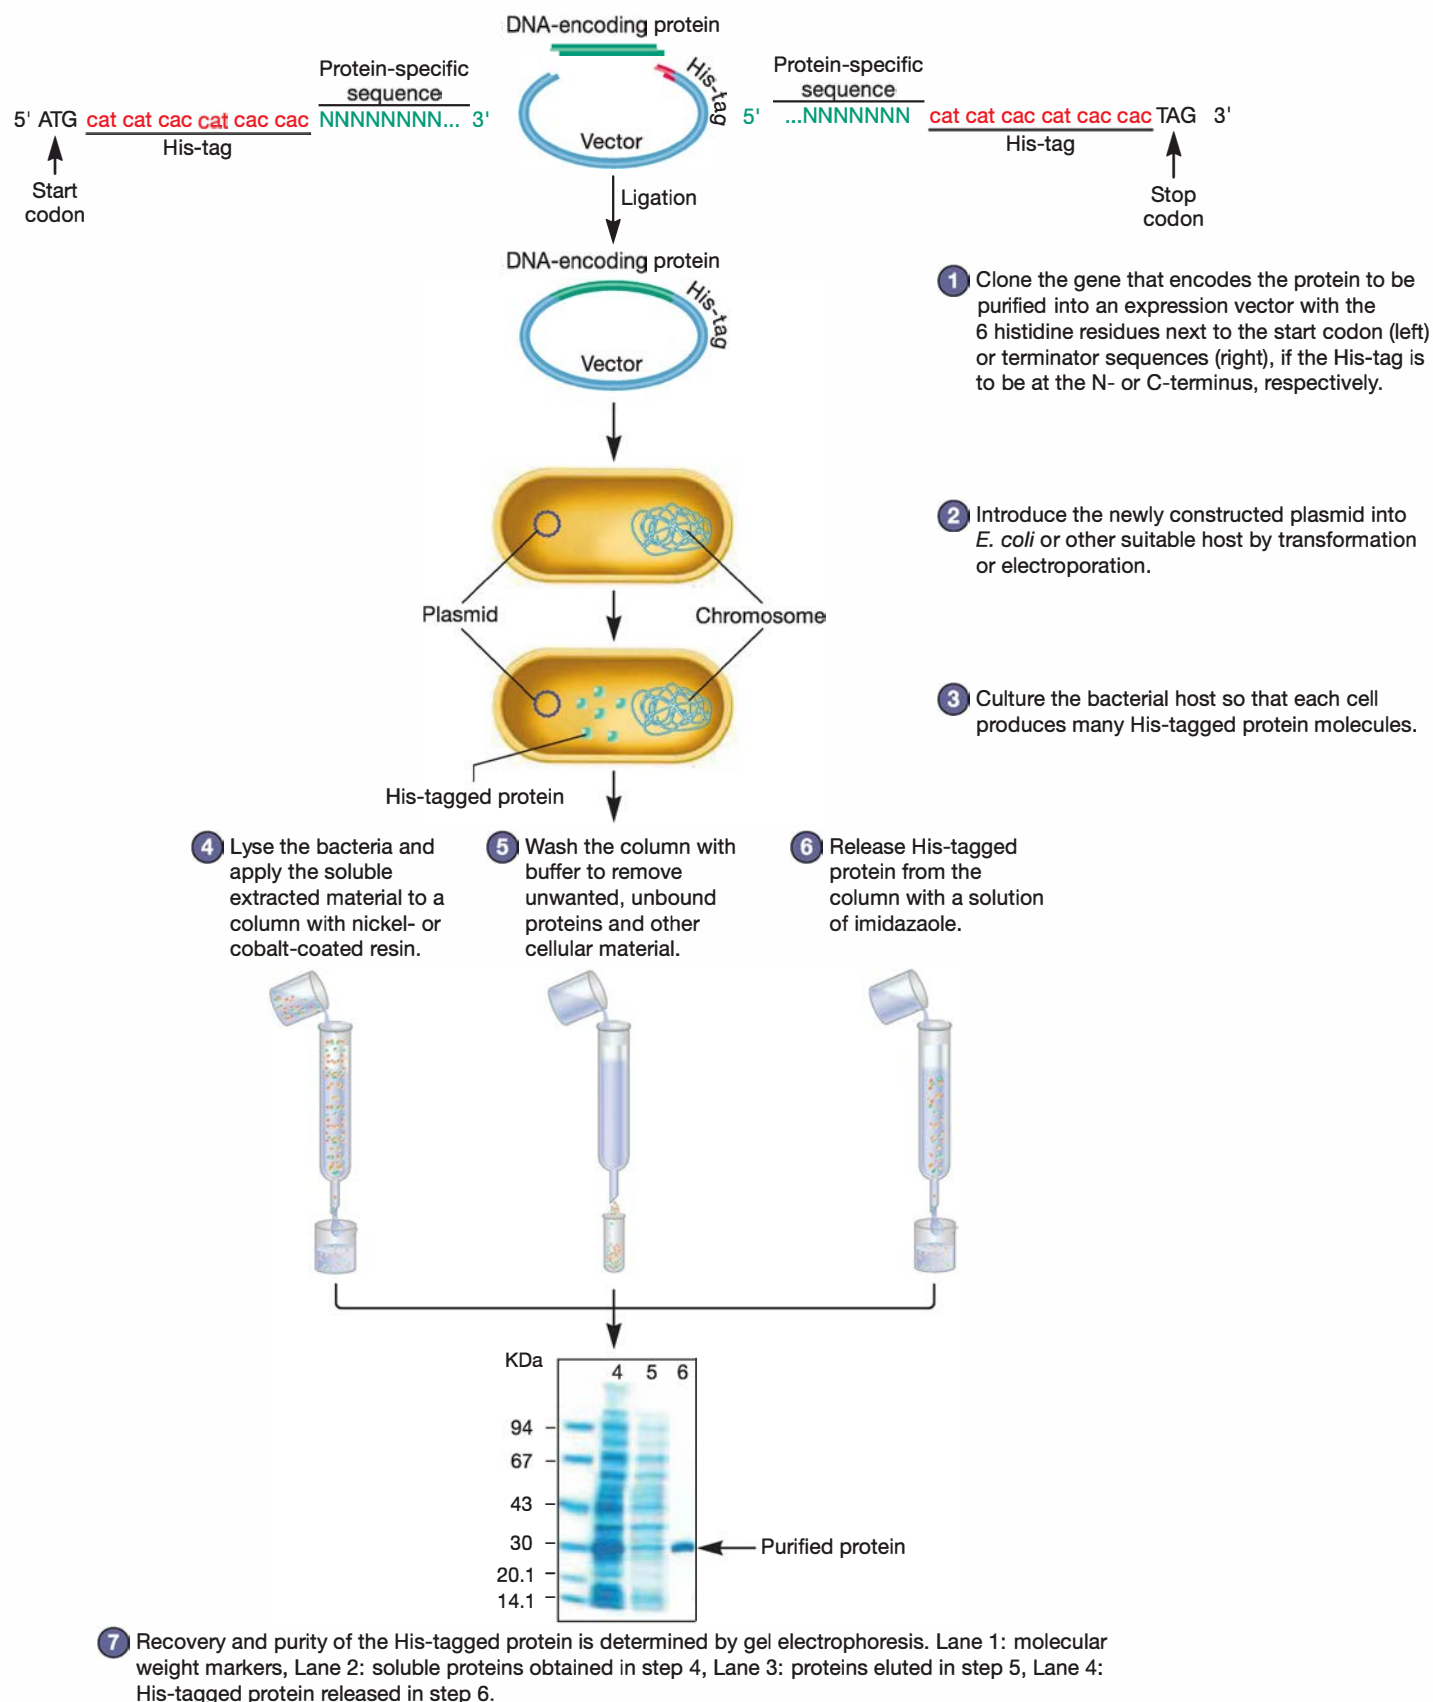

Figure 17.14 Construction and Purification of a Polyhistidine-Tagged Protein.

Figure 17.15 Fluorescent Protein Labeling. (a) A transcriptional fusion places the gene encoding a fluorescent peptide under the control of a promoter, replacing the coding sequence of the gene. In this case, the mCherry gene is controlled by the promoter that normally governs transcription of a gene in the actinomycete *Streptomyces coelicolor* that is expressed only when aerial hyphae form cross walls (septa) that give rise to a chain of spores. Thus red fluorescence is seen uniformly throughout the chain of spores but not in hyphae without septae. (b) A translational fusion generates a chimeric protein consisting of the normal protein attached to the GFP label. Here the FtsZ gene has been fused to GFP. This shows that FtsZ localizes at the septa. Notice that the filament to the right is not forming septae, so FtsZ is not present.

MICRO INQUIRY What special considerations are necessary if one is constructing a translational fusion of a protein known to be exported?

that the jellyfish *Aequorea victoria* produces a protein called **green fluorescent protein (GFP)**. GFP is encoded by a single gene that, when translated, undergoes self-catalyzed modification to generate a strong, green fluorescence. This means that it is easily cloned and expressed in any organism. In fact, an entire palette of fluorescent labels is now available. These include mutant versions of the GFP protein that glow throughout the blue-green-yellow spectrum. In addition, other fluorescent peptides that likewise undergo self-catalyzed light production have been developed.

There are two ways in which the amino acid sequence that encodes fluorescent peptides can be attached to a gene. A transcriptional fusion is used to study gene regulation. Transcriptional fusions replace the entire coding sequence of the gene of interest with the fluorescence-encoding gene (figure 17.15a). Because the expression of the fluorescence gene is now governed by the promoter of the replaced gene, promoter activity can be visualized. That is, when the promoter is turned “on,” the cells glow. If the transcriptional fusion has been made in a multicellular organism, then not only is the timing of promoter activity seen but the specific cell type in which the gene is normally expressed is also determined. On the other hand, a translational fusion is used to determine where a particular protein is localized in the cell. Translational fusions add the GFP-encoding sequence to the structural gene of interest. This creates a chimeric protein—a protein that consists of two parts: the protein being studied and GFP. Of course, care must be taken to ensure that the protein fusion still functions like the original protein. One way to do this is to test for phenotypic rescue of a mutant lacking the structural gene

of interest. Once it has been determined that the chimeric protein is fully functional, the cellular “address” of the protein can be determined (figure 17.15b).

Retrieve, Infer, Apply

1. Describe how a genomic library might be screened for a gene that confers the production of an extracellular enzyme that degrades casein, a protein found in milk. (Hint: Agar with skim milk loses its opacity when casein is degraded.)
2. Explain the selection for antibiotic resistance followed by blue versus white screening of colonies containing recombinant plasmids. Why must both antibiotic selection and color screening be used? What would you conclude if, after transforming a ligation mixture into *E. coli*, only blue colonies were obtained?
3. How can one prevent recombinant DNA from undergoing recombination in a bacterial host cell?
4. List several reasons why a cloned gene might not be expressed in a heterologous host cell.
5. Think of a situation in which you might want to keep the His-tag on a recombinant protein and a situation in which it would be important to remove it.
6. You are studying chemotaxis proteins in a newly described bacterium. You have cloned a gene that encodes the CheA protein. You need to be sure that this protein localizes to the inside of the plasma membrane (see figure 14.21). Will you use a transcriptional or translational fusion? Explain your choice.

Key Concepts

17.1 Key Developments in Recombinant DNA Technology

- Genetic engineering became possible after the discovery of restriction enzymes and reverse transcriptase, and the development of essential methods in nucleic acid chemistry such as the Southern blotting technique.
- Restriction enzymes are important because they cut DNA at specific sequences, thereby releasing fragments of DNA that can be cloned or otherwise manipulated (**figure 17.3** and **table 17.2**).
- Gel electrophoresis is used to separate molecules according to charge and size.
- DNA fragments are separated on agarose and acrylamide gels. Because DNA is acidic, it migrates from the negative to the positive end of a gel (**figure 17.6**).

17.2 Polymerase Chain Reaction

- The polymerase chain reaction (PCR) allows small amounts of specific DNA sequences to be increased in concentration thousands of times (**figure 17.8**).
- PCR has numerous applications. It often is used to obtain genes for cloning and in diagnostic and forensic science.

17.3 Cloning Vectors and Creating Recombinant DNA

- There are four types of cloning vectors: plasmids, viruses, cosmids, and artificial chromosomes. Cloning vectors generally have at least three components: an origin of replication, a selectable marker, and a multicloning site or polylinker (**table 17.3**; **figures 17.10** and **17.12**).
- The most common approach to cloning is to digest both vector and DNA to be inserted with the same restriction enzyme or enzymes so that compatible sticky ends are generated. The vector and DNA to be cloned are then incubated in the presence of DNA ligase, which catalyzes the formation of phosphodiester bonds once the DNA fragment inserts into the vector.
- Once the recombinant plasmid has been introduced into host cells, cells carrying vector must be selected. This is often accomplished by allowing the growth of only

antibiotic-resistant cells because the vector bears an antibiotic-resistance gene. Cells that took up vector with inserted DNA must then be distinguished from those that contain only vector. Often a blue-versus-white colony phenotype is used; this is based on the presence or absence, respectively, of a functional *lacZ* gene (**figure 17.11**).

17.4 Construction of Genomic Libraries

- It is sometimes necessary to find a gene without the knowledge of the gene's DNA sequence. A genomic library is constructed by cleaving an organism's genome into many fragments, each of which is cloned into a vector to make a unique recombinant plasmid.
- Genomic libraries are often screened for the gene of interest by either phenotypic rescue (genetic complementation) or DNA hybridization with an oligonucleotide probe (**figure 17.13**).

17.5 Introducing Recombinant DNA into Host Cells

- The bacterium *E. coli* and the yeast *S. cerevisiae* are the most common host species.
- DNA can be introduced into microbes by transformation or electroporation.

17.6 Expressing Foreign Genes in Host Cells

- An expression vector has the necessary features to express any recombinant gene it carries.
- If a eukaryotic gene is to be expressed in a bacterium, cDNA is used because it lacks introns; a bacterial leader must also be fused to the 5' end of the gene.
- Purification of recombinant proteins is often accomplished by fusing the coding sequence of a protein to six histidine residue codons found on some expression vectors. When introduced and expressed in bacteria, the His-tagged protein can be selectively purified (**figure 17.14**).
- Green fluorescent protein can be used to study the regulation of gene expression (transcriptional fusions) and protein localization (translational fusions) (**figure 17.15**).

Compare, Hypothesize, Invent

1. You are performing a PCR to amplify a gene encoding a tRNA from a bacterium that has only recently been grown in pure culture. You are expecting a product of 954 bp. However, you generate three different products; only one is the expected size. List at least two possible explanations (excluding experimental error).
2. You have cloned a structural gene required for riboflavin synthesis in *E. coli*. You find that an *E. coli* riboflavin auxotroph carrying the cloned gene on a vector makes less riboflavin than does the wild-type strain. Why might this be the case?

3. Suppose that you inserted a plasmid vector carrying a human interferon gene into *E. coli* but none of the transformed bacteria produced interferon. Give as many plausible reasons as possible for this result.
4. You are interested in the activity and regulation of a protease made by the Gram-positive bacterium *Geobacillus stearothermophilus*. What would be the purpose of constructing each of the following: a His-tagged protease, a transcriptional GFP fusion to the protease gene, and a translational GFP fusion to the protease gene?
5. Rapid and accurate identification of pathogens in clinical samples is paramount for effective patient care. To that end, the identification of microbes in human tissue and blood using PCR is used for some infectious agents. However, before a PCR approach can be adopted by clinical microbiologists, it must be shown that it is specific and

accurate. Fungal infections are particularly difficult to treat and have become more widespread as the population of patients with compromised immune systems grows. A PCR protocol for the identification of several important fungal pathogens, including *Aspergillus*, *Candida*, and *Cryptococcus*, has been described. This assay is based on the amplification of the 28S large subunit ribosomal RNA gene from each microbe. Recall that as a eukaryote, the human host also has a homologous gene. Outline how you think these researchers performed the PCRs and what they did to control for false positive and false negatives. Why do you think real-time PCR was used, rather than end-point PCR?

Microbial Genomics

“Synthetic Life”: Oxymoron or the Future?

To live, to err, to fall, to triumph, to recreate life out of life!” When James Joyce wrote these words in 1916 in *A Portrait of the Artist as a Young Man*, he could never have imagined that they would be encrypted in the genetic code inserted in the synthetic genome of a novel bacterium. But 94 years later, Daniel Gibson and his co-workers at the J. Craig Venter Institute (JCVI) did just that. Building on 15 years of investigation, the JCVI researchers used a computer to design a genome and a DNA synthesizer to make short stretches of DNA. These were then stitched together to create a 1.08 million base pair genome based on the chromosome of *Mycoplasma mycoides* (see *Techniques & Applications* 17.2). The genome was then transplanted into *M. capricolum*, which after a few rounds of replication consisted entirely of molecules whose synthesis was directed by a chromosome that started as a computer program and four bottles of deoxynucleotides.

Clearly, this feat raises lots of questions. Is this a synthetic cell? Some say yes, some say no; it is a synthetic genome inside a naturally produced cell. Why construct this microbe? Craig Venter views it as a \$30 million proof of concept that can (will?) lead to the construction of genomes specifically designed for the development of vaccines, pharmaceuticals, clean water and food products, and biofuels. In fact, Dr. Venter is working with Exxon Mobil Corporation to construct a biofuel-producing algal cell.

Is synthetic life ethical? Depends on whom you ask. Some environmental groups say synthetic genome research should stop until specific regulations are in place. Most scientists and bioethicists take a more measured view, envisioning two ways such a microbe might be released: bioterror and bioerror. Protection against bioterror relies on a host of security measures, many of which are already in place. Bioerror brings us back to James Joyce. The scientists who designed the genome inserted a “watermark”—sequences unique to this microbe—into the genome so

The science of genomics began in the mid-1990s with the sequencing of viral, then bacterial, and finally mammalian genomes. The new frontier of genomics is the construction of completely synthetic genomes so that organisms can be designed to perform a particular suite of functions.

that if it were to escape the lab, its identity could be determined. They developed a cipher to convert the genetic code so that when “translated,” the watermark spells out the Joyce quote, as well as “See things not as they are, but as they might be,” from the book *American Prometheus* (about Robert Oppenheimer, who oversaw the Manhattan Project), and perhaps most fittingly, the words of the late physicist Richard Feynman, “What I cannot create, I do not understand.”

The construction of this bacterium, *M. mycoides* JCVI-syn1.0, represents the culmination of decades of work. In order to understand how we have arrived in a world where a computer is the starting point for a new organism, we need to review the individual technologies required as well as some other applications. This involves the integration of a number of genetic and biotechnology principles; be sure you succeed in the readiness check, because the world of genomics is a vast and amazing place well worth exploring.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Identify the key structural elements of DNA, RNA, and protein (section 13.2)
- ✓ Discuss what is meant by the term genome
- ✓ Explain the process and utility of PCR (section 17.2)
- ✓ Diagram the fundamental principles of gel electrophoresis (section 17.1)
- ✓ Summarize the purpose, construction, and screening of a genomic library (section 17.4)

18.1 Determining DNA Sequences

After reading this section, you should be able to:

- Explain how DNA is sequenced by the Sanger chain termination method
- Contrast and compare the advantages and disadvantages of the Sanger method with massively parallel sequencing methods

The genomic era is considered a 21st-century phenomenon. One of the most crucial steps leading to the genomic revolution was figuring out how to sequence DNA. This was accomplished in 1977 by Alan Maxam and Walter Gilbert (collaborating on one technique), and Frederick Sanger. Sanger's method is most commonly used and is now discussed.

Sanger DNA Sequencing

The Sanger method involves the synthesis of a new strand of DNA using the DNA to be sequenced as a template. The reaction begins when single strands of template DNA are mixed with a primer (a short piece of DNA complementary to the region to be sequenced), DNA polymerase, the four deoxynucleoside triphosphates (dNTPs), and dideoxynucleoside triphosphates (ddNTPs). ddNTPs differ from dNTPs in that the 3' carbon lacks a hydroxyl group (figure 18.1). In such a reaction mixture, DNA synthesis will continue until a ddNTP, rather than a dNTP, is added to the growing chain. Without a 3'-OH group to attack the 5'-PO₄ of the next dNTP to be incorporated, synthesis

stops (see figure 13.10). Indeed, Sanger's technique is frequently referred to as the **chain-termination DNA sequencing** method.

To obtain sequence information, four separate synthesis reactions must be prepared, one for each ddNTP (figure 18.2).

Figure 18.1 Dideoxyadenosine Triphosphate (ddATP). Note the lack of a hydroxyl group on the 3' carbon, which prevents further chain elongation by DNA polymerase.

MICRO INQUIRY What is the function of the 3'-OH during DNA synthesis?

1 Isolated unknown DNA fragment

2 DNA is denatured to produce single template strand.

3 Labeled specific primer molecule hybridizes to the DNA strand.

4 DNA polymerase and regular nucleotide mixture (dATP, dCTP, dGTP, and dTTP) are added; ddGTP, ddATP, ddCTP, and ddTTP are placed in separate reaction tubes with the regular nucleotides. The dd nucleotides are labeled with some type of tracer, which allows them to be visualized.

Incubate

5 Newly replicated strands are terminated at the point of addition of a dd nucleotide.

6 Schematic view of how all possible positions on the fragment are occupied by a labeled nucleotide

7 Running the reaction tubes in four separate gel lanes separates them by size and nucleotide type. Reading from bottom to top, one base at a time, provides the correct DNA sequence.

Figure 18.2 The Sanger Method of DNA Sequencing. Steps 1–6 are used for both manual and automated sequencing. Step (7) shows preparation of a gel for manual sequencing in which radiolabeled ddNTPs are used.

When each DNA synthesis reaction is stopped, a collection of DNA fragments of varying lengths has been generated. The reaction prepared with ddATP produces fragments ending with an A, those with ddTTP produce fragments with T termini, and so forth. If the DNA is to be manually sequenced, radioactive dNTPs are used and each reaction is separated by electrophoresis in a separate lane on a polyacrylamide gel. Recall that each fragment's migration rate is inversely proportional to the log of its molecular weight. Simply put, the smaller a fragment is, the faster it moves through the gel. Because synthesis proceeds with the addition of a nucleotide to the 3'-OH of the primer, the dideoxynucleotide at the end of the shortest fragment is assigned as the 5' end of the DNA sequence, while the largest fragment is the 3' end. In this way, the DNA sequence can be read directly from the gel from the smallest to the largest fragment.

◀◀ Gel electrophoresis (section 17.1) ▶ Sanger Sequencing

DNA is more often prepared for automated sequencing (figure 18.3). Here the four reaction mixtures can be combined and loaded into a single lane of a gel because each ddNTP is labeled with a different colored fluorescent dye. These fragments are then separated by electrophoresis, and a laser beam detects the order in which they exit the bottom of the gel. A chromatogram documenting the fragment order is generated in which the amplitude of each spike represents the fluorescent intensity of each particular fragment (figure 18.3b). The corresponding DNA sequence is listed above the chromatogram.

Next-Generation DNA Sequencing

Using Sanger's chain termination method, the cost of sequencing the human genome (completed in 2001) was about \$300 million and took about a decade to finish. One reason for this was sample preparation; as discussed in section 18.2, Sanger sequencing requires the construction of a genomic library. However, scientists want to sequence genomes faster and more cheaply, so innovative, newer DNA sequencing techniques have been developed that do not require prior genomic library construction. ▶◀ Construction of genomic libraries (section 17.4)

Here we review three “next generation” technologies. All of these approaches start by shearing the DNA into short pieces to be sequenced and attaching oligonucleotides called adapters to the ends of the resulting fragments (figure 18.4). The adapter at one end of each DNA fragment attaches it to a solid substrate, and the adapter at the other end anneals to a primer used to initiate the polymerase chain reaction (PCR). PCR results in the production of many copies of the same fragment, which are sequenced simultaneously. These methods are therefore sometimes called **massively parallel sequencing techniques**. In addition to making genomic sequencing faster and cheaper, as we discuss later in this chapter, these techniques are also used to study gene regulation (i.e., mRNA), small, noncoding RNAs, and environmental sequencing. ▶◀ Polymerase chain reaction (section 17.2)

A widely used technology is that of 454 Life Sciences Corporation. Their approach, called **pyrosequencing**, or just 454 sequencing, uses a series of enzymatic reactions that results in the generation of visible light. The intensity of the light produced is proportional to the number of nucleotides added to a growing DNA strand. As shown in figure 18.4, one DNA fragment is attached per microscopic plastic bead and then amplified by PCR within an oil-water emulsion so the bead is covered with about a million copies of each fragment. After denaturing the PCR products, individual beads are deposited into picoliter-sized wells; one plate can have as many as 1.6 million wells, with one bead per well. Each well receives the reagents necessary for a cascade of three critical enzymatic reactions. In the first, DNA synthesis is catalyzed by DNA polymerase, primer, and a single species of unlabeled dNTP (e.g., dATP, dGTP, dCTP, or dTTP):

This lengthens some DNA strands by one nucleotide and releases pyrophosphate (PP_i). The PP_i is then converted to ATP in a reaction catalyzed by ATP sulfurylase:

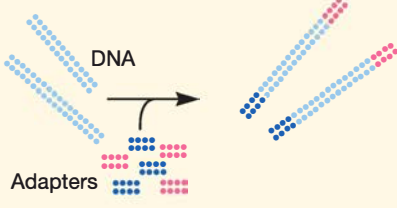

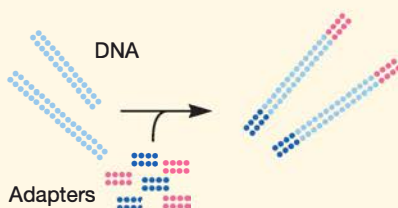

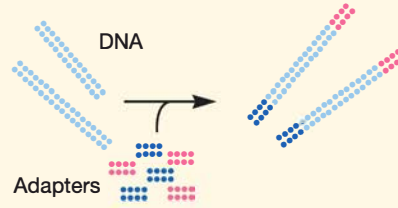

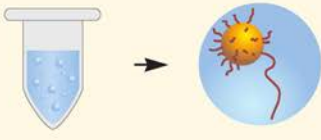

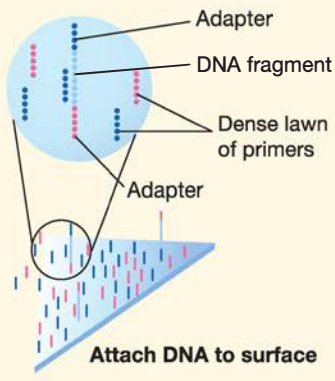

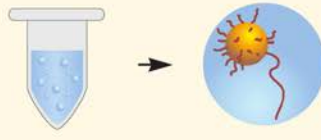

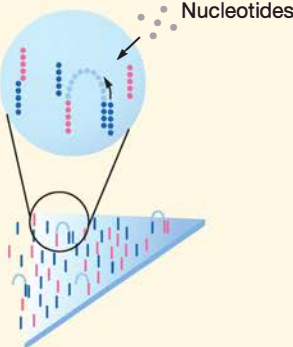

Figure 18.3 Automated Sanger DNA Sequencing. (a) Part of an automated DNA sequencing run. Here the ddNTPs are labeled with fluorescent dyes. (b) Data generated during an automated DNA sequencing run. Bases 538 to 580 are shown.

| Process or step | 454 | Solexa/Illumina | SOLiD |
|--|--|---|--|
| Adapters - synthetic fragments of DNA with a known sequence added to both ends of genomic fragments | One adapter will attach fragment to a bead for PCR; the other will serve to hybridize primer.  | One adapter will attach fragment to a glass slide for PCR; the other will serve to hybridize primer, also attached to glass slide.  | One adapter will attach fragment to a bead for PCR; the other will serve to hybridize primer.  |
| PCR platform - provides a solid substrate for PCR to occur; products are tethered to substrate | Bead: a single genomic DNA fragment is bound to bead via adapter  | Flow cell surface coated with oligonucleotides that complement adapters  Attach DNA to surface | Bead: a single genomic DNA fragment is bound to bead via adapter  |
| PCR - copies of each genomic fragment are synthesized so the signal created during sequencing reaction is large enough to be detected | Beads and PCR reagents are mixed in oil and water microreactors.  DNA on beads | Complementary primer attached to flow cell surface primes PCR.  Nucleotides | Similar to 454  DNA on beads |

(a)

Figure 18.4 Comparison of Massively Parallel DNA Sequencing Methodologies.

MICRO INQUIRY Why is it important that the DNA to be sequenced is immobilized in all three of these techniques?

(Continued)

Figure 18.4 (Continued)

(b)

ATP is then converted to light by firefly luciferase:

The amount of light is directly proportional to the number of ATP hydrolyzed. Thus light intensity measures the amount of PP_i released. Each well is provided with an excess of one of the four dNTPs; however, a dATP analogue must be used to prevent dATP conversion into light. As the nucleotides are sequentially added, a flash of light is generated by the liberated PP_i . Each flash is correlated with the nucleotides present on a well-by-well basis, and the intensity of the flash depends on how many nucleotides were added; one PP_i is released for each nucleotide incorporated. For instance, the incorporation of three Cs in a row will produce a light signal that is three times brighter than if only one is added (figure 18.5). Computer software tracks the growth of newly synthesized DNA one nucleotide at a time. At the completion of one round of nucleotide incorporation, unincorporated nucleotides are removed and the cycle repeats.

In **Solexa sequencing**, adapters attach the genomic fragments to a glass slide coated with oligonucleotides whose sequences complement the adapters (figure 18.4). The adapter at the other end will find its complement and hydrogen bond, causing the fragment to double over like a hairpin. So-called “bridge PCR” results in clusters of linear fragments of DNA scattered over the surface of the slide. Once the fragments are rendered single-stranded, the DNA is ready for a Sanger-type sequencing reaction. All four dNTPs, each with a different fluorescent label, are added along with polymerase and other reagents. The sequencing reaction takes place on the glass slide within a flow cell.

A somewhat different approach is called **sequencing by ligation** or **SOLiD technology**, for supported oligo ligation detection. The PCR amplification of genomic fragments is very similar to the process used in 454 (figure 18.4). After denaturing the amplified fragments, a primer complementary to

the adapter is added. Next eight-base oligonucleotides (octamers) are hybridized to each fragment and the enzyme ligase attaches them to the primer. This is possible because the octamers are made in every possible combination of A-C-T-G, so it is simply a matter of each octamer finding its complementary sequence on the genomic fragment. Importantly, the identity of the bases in the fourth and fifth positions can be determined by a fluorescent label at the end of the octamer. After exciting the fluorescent labels with laser light to identity the bases, the ligated octamer is cleaved after the fifth base to remove the fluorescent label. Another round of ligation and cleavage is then repeated. In this way, the sequence is determined in a ladderlike fashion.

18.2 Genome Sequencing

After reading this section, you should be able to:

- List the steps used in whole-genome shotgun cloning
- Describe the multiple strand displacement method and how this technique is used

Efficient methods for sequencing entire genomes were not available until 1995, when J. Craig Venter, Hamilton Smith, and their collaborators developed whole-genome shotgun sequencing and the computer software needed to assemble sequence data into a complete genome. They used their new method to sequence the genomes of the bacteria *Haemophilus influenzae* and *Mycoplasma genitalium*. This was a significant accomplishment because prior to this, only a few smaller viral genomes had been fully sequenced. Venter and Smith ushered in what has been called the genomic era. Within 15 years, the number of complete genomes published grew from 2 to over 700 with thousands of additional genome sequencing projects underway.

Whole-Genome Shotgun Sequencing

When Sanger sequencing is used, genomic fragments must be cloned into vectors, most commonly bacterial artificial chromosomes (BACs; see figure 17.12). This process, known as **whole-genome shotgun sequencing**, may be broken into four stages: library construction, random sequencing, fragment alignment and gap closure, and editing.

1. **Library construction.** The DNA molecules are randomly broken into fragments using ultrasonic waves; the fragments are then purified (figure 18.6). These fragments are next inserted into cosmid or bacterial artificial chromosome (BAC) vectors and isolated. *Escherichia coli* strains lacking restriction enzymes are transformed with the cosmids or BACs to produce a library of clones. **◀ Cloning vectors and creating recombinant DNA (section 17.3)**
2. **Random sequencing.** DNA is purified from each clone, and thousands of DNA fragments are sequenced with

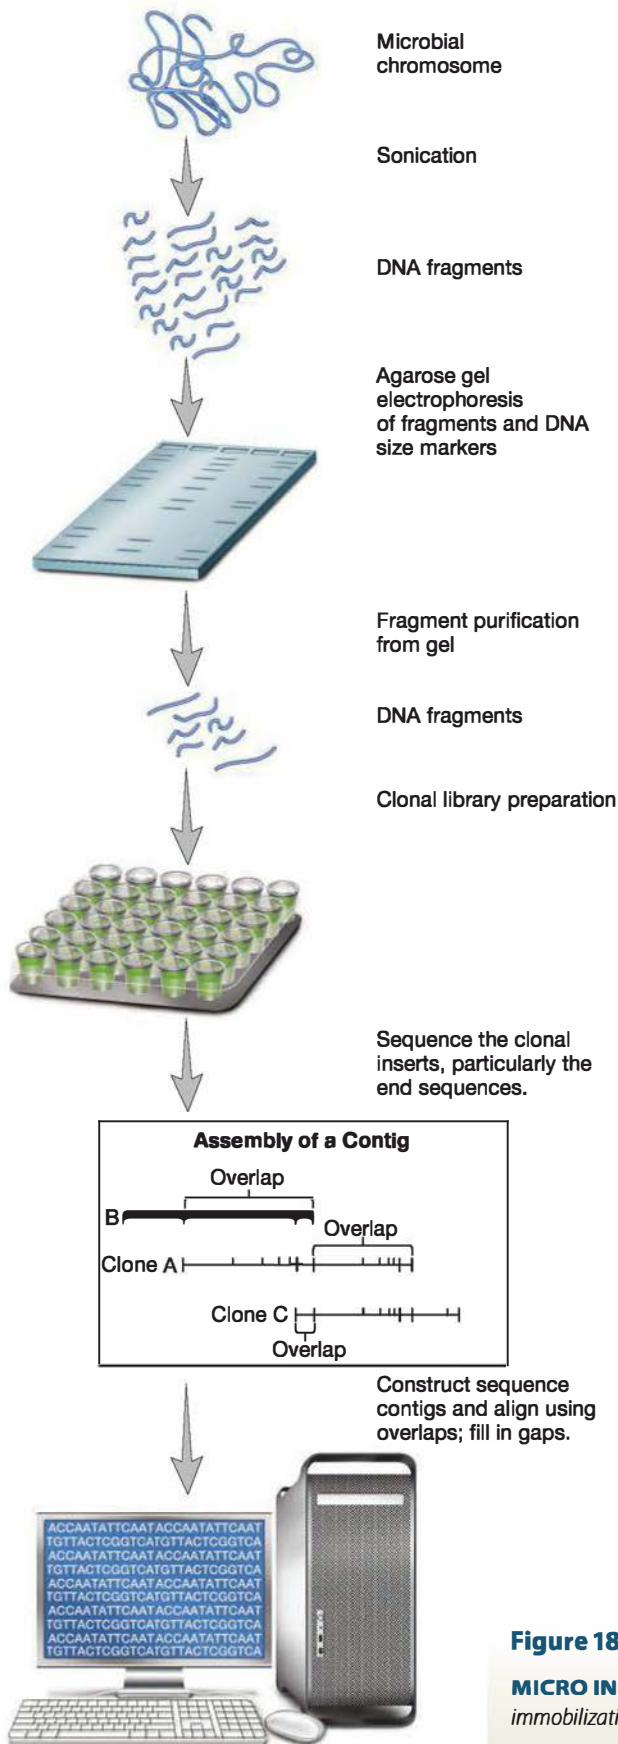

Figure 18.5 A Pyrogram Displays Raw Data from

Pyrosequencing. The amplitude (height) of each signal is proportional to the number of nucleotides incorporated. The order of nucleotide addition is listed below the pyrogram, and the sequence (indicating the number of each nucleotide incorporated) is listed above the pyrogram.

automated sequencers, employing dye-labeled primers that recognize the plasmid DNA sequences adjacent to the cloned, chromosomal insert. The sequencing machines are very fast and can run for 24 hours without operator attention. As many as 96 samples can be sequenced simultaneously, making it possible to sequence as many as 1 million bases per day, per sequencer. All stretches of the genome are sequenced multiple times to increase the accuracy of the final results. The number of times a region is sequenced is called “coverage,” so for a genome with at least $8\times$ coverage, all regions of the genome have been sequenced a minimum of eight times.

3. **Fragment alignment and gap closure.** Using computer analysis, the DNA sequence of each fragment is assembled into longer stretches of sequence. Two fragments are joined together to form a larger stretch of DNA if the sequences at their ends overlap and match. This comparison process results in a set of larger, contiguous nucleotide sequences called **contigs**. Finally, the contigs are aligned in the proper order to form the complete genome sequence. If gaps exist between two contigs, sometimes fragments with ends in two adjacent contigs are available. These fragments are analyzed and the gaps filled in with their sequences. When this approach is not possible, a variety of other techniques are used to align contigs and fill gaps.
4. **Editing.** The sequence is then carefully proofread to resolve any ambiguities or frameshift mutations in the sequence. Proofreading is accomplished by ensuring that the sequences of the two DNA strands are complementary.

Single-Cell Genomic Sequencing

Only a decade ago, genomic sequencing of a single cell would have seemed a preposterous idea to most. However, it is now possible to amplify the few femtograms (10^{-15} gram) of DNA to the several micrograms (10^{-6} gram) needed for sequencing. This is an important breakthrough because the vast majority of microbes cannot be cultured axenically (i.e., as the only species present in the culture) and thus otherwise could not be studied from a genomic perspective. The capacity to sequence the DNA from a single cell extracted from its natural environment is prompting new research strategies in microbial genetics, ecology, and infectious disease.

The process of **single-cell genomic sequencing** is based on a method called multiple strand displacement or **multiple displacement amplification (MDA)** (figure 18.7). In this

Figure 18.6 Whole-Genome Shotgun Sequencing.

MICRO INQUIRY Which step (or steps) in this process is (are) replaced by PCR amplification and immobilization of fragments to a solid support in massively parallel sequencing techniques?

Figure 18.7 Single-Cell Genomic Sequencing. Many copies of DNA extracted from a cell are generated by multiple displacement amplification. Random hexamer primers (red) bind to complementary template sequences, and DNA polymerase from bacteriophage phi29 is used to catalyze synthesis in the 5' to 3' direction (purple arrowheads). When the end of a newly synthesized strand meets double-stranded DNA, one strand is displaced by the growing DNA.

reaction, the DNA extracted from a single cell is synthesized using DNA polymerase from the bacteriophage phi29. In addition, a collection of primers of random sequence, all six bases in length (hexamers), is added to the reaction along with dNTPs. The primers hydrogen bond to complementary sequences scattered throughout the genome. As DNA synthesis proceeds from each primer, the growing 3' end of one newly made strand will eventually bump into and then displace the 5' end of another newly growing strand. In this way, many new strands are rapidly synthesized. The new strands have an average length of about 12,000 bases (12 kb) but can be as long as 100 kb. This makes them suitable for cloning and DNA sequencing.

MDA has been used to amplify the genomes of a variety of microbes, including a single filament of an uncultured species of *Beggiatoa* and a single spirochete *Borrelia burgdorferi*, the causative agent of Lyme disease, from a tick's midgut. In practice, MDA is performed on genomes from several cells of the same species collected from the same sample. Bacteriophage phi29 DNA polymerase rarely incorporates the wrong base, that is, it has a high fidelity, so the sequence data has fewer mistakes than that obtained from DNA amplified by PCR. ►► *Methods in microbial ecology (chapter 29)*

Retrieve, Infer, Apply

1. Why is the Sanger technique of DNA sequencing also called the chain-termination method?
2. How would one recognize a gap in the genome sequence following whole-genome shotgun sequencing?
3. Compare whole-genome shotgun sequencing with one of the emergent sequencing approaches. What do you think are the advantages of the new sequencing methodologies besides reduced cost? What are the disadvantages?
4. Suggest a medical and an ecological application of single-cell genomic sequencing.

18.3 Bioinformatics

After reading this section, you should be able to:

- Explain how a potential protein-coding gene is recognized within a genome sequence
- Compare the meaning of the terms orthologue and paralogue
- Differentiate between a conserved hypothetical protein and a putative protein of unknown function

The analysis of entire genomes generates a rapidly growing volume of information regarding genome content, structure, and arrangement as well as data detailing protein structure and function. This has led to the development of the field of **bioinformatics**, which combines biology, mathematics, computer science, and statistics. Determining the location and nature of genes or presumed genes on a newly sequenced genome is a complex process called **genome annotation**. Once genes have been identified, bioinformaticists can perform computer or **in silico analysis** to further examine the genome.

Obviously, obtaining nucleotide sequences without any understanding of the location and nature of individual genes would be a pointless exercise. The goal of genome annotation is to identify every potential (putative) protein-coding gene as well as each rRNA- and tRNA-coding gene. A protein-coding gene is usually first recognized as an **open reading frame (ORF)**; to find all ORFs, both strands of DNA must be analyzed in all three reading frames (**figure 18.8**). A bacterial or archaeal ORF is generally defined as a sequence of at least 100 codons that it is not interrupted by a stop codon and has terminator sequences at the 3' end. The 5' end of the gene should also bear a ribosome-binding site. Only if these elements are present is an ORF considered a putative protein-coding gene. This process is performed by gene prediction programs designed to find genes that encode proteins or functional RNA products. In most cases, the computer-identified genes are then manually inspected by bioinformaticists to

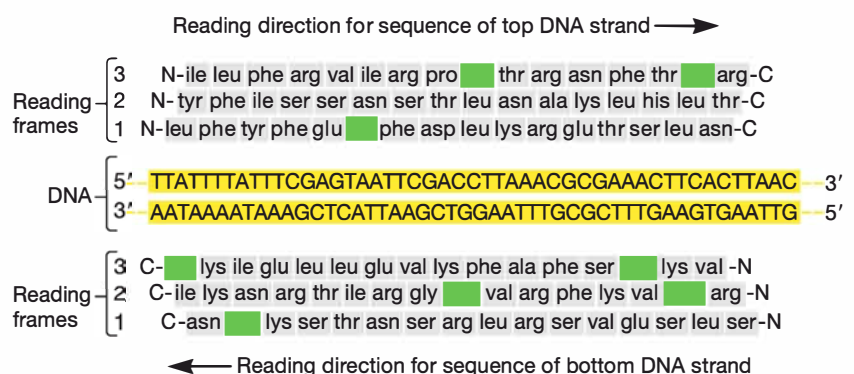

Figure 18.8 Finding Potential Protein-Coding Genes. Annotation of genomic sequence requires that both strands of DNA be translated from the 5' to 3' direction in each of three possible reading frames. Stop codons are shown in green.

verify the computer-generated assignment. This process is called genome curation.

ORFs presumed to encode proteins are called **coding sequences** (CDS). Bioinformaticists have developed algorithms to compare the sequence of predicted CDS with those in large databases containing nucleotide and amino acid sequences of known proteins. The base-by-base comparison of two or more gene sequences is called **alignment**. Scientists most often use **BLAST** (**b**asic **l**ocal **a**lignment **s**earch **t**ool) programs to perform this task. These programs compare the amino acid or nucleotide sequence of interest (the query sequence) to all other sequences entered in the database. The results (“hits”) are ranked in order of decreasing similarity. An E-value is assigned to each alignment; this value measures the possibility of obtaining the alignment by chance; thus highly homologous sequences have very low E-values.

The translated amino acid sequences are almost always used to annotate potential genes or CDSs to gain an understanding of potential protein structure and function. Often a short pattern of amino acids, called a motif or domain, will represent a functional unit within a protein, such as the active site of an enzyme. For instance, **figure 18.9** shows the C-terminal domain of the cell division protein MinD from a number of microbes. Because these amino acids are found in such a wide range of organisms, they are considered phylogenetically well conserved. In this case, the conserved region is predicted to form a coil needed for proper localization of the protein to the membrane. Finding this high level of conservation allows the genome curator to assign a function to the domain. ◀◀ *Cytokinesis* (section 7.2)

Only if a CDS aligns above a certain threshold level with one or more genes in the database is it presumed to encode a protein of similar function. Pairs of such similar ORFs are called **orthologues**. Often a CDS will align with other genes over only a portion of its length, but depending on the degree of similarity and the overall percent of sequence that matches, this may be sufficient to assign the product of that CDS a putative (presumed) function. As the number of sequenced genomes has expanded, so has the need to constrain the vocabulary by which new genes are named. The use of a structured vocabulary is called ontology, and a standard **gene ontology** (GO) has been adopted as the means by which genes, or motifs within genes, are commonly named. This is based on the similarities of amino acid sequences among orthologous proteins. A GO term not only reflects protein function but also defines the cellular process in which the protein participates (e.g., motility) and the cellular location of the protein (e.g., flagellum).

CDSs that do not align with known amino acid sequences fall into two classes: (1) **Conserved hypothetical proteins** are encoded by genes that have matches in the database but no function has yet been assigned to any of the sequences. (2) **Proteins of unknown function** are the products of genes unique to that organism. However, as more genomes are published, future comparisons may reveal a match in another organism. Finally, alignment of nucleotides on the same genome (i.e., from a single organism) may show that the nucleotide sequences of two or more genes are so alike that they most probably arose through gene duplication; such genes are called **paralogues**.

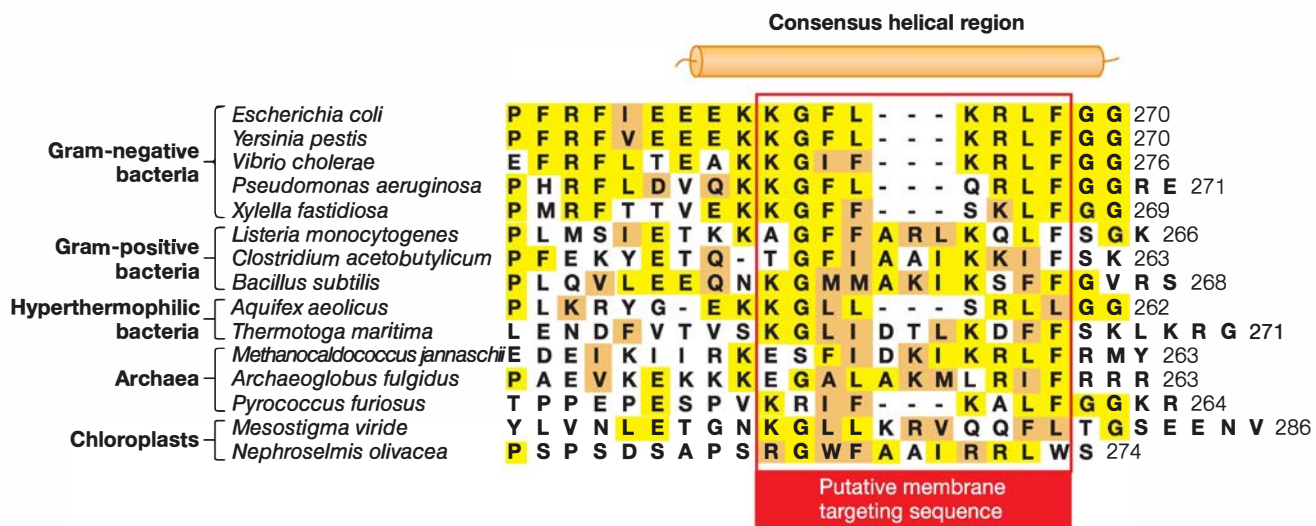

Figure 18.9 Analysis of Conserved Regions of Phylogenetically Well-Conserved Proteins. C-terminal amino acid residues of MinD from 15 organisms and chloroplasts are aligned to show strong similarities. Amino acid residues identical to *E. coli* are boxed in yellow, and conservative substitutions (e.g., one hydrophobic residue for another) are boxed in orange. Dashes indicate the absence of amino acids in those positions; such gaps may be included to maintain an alignment. The number of the last residue shown relative to the entire amino acid sequence is shown at the extreme right of each line.

MICRO INQUIRY Which amino acids are most highly conserved?

18.4 Functional Genomics

After reading this section, you should be able to:

- Describe the construction of a physical genome map
- Explain how genome annotation can be used to graphically represent the metabolism, transport, motility, and other key features of a microbe
- Contrast and compare microarray analysis with RNA-seq in the study of transcriptomes

Once the putative identities of the genes in a given genome have been identified and classified, **functional genomics** seeks to place the information in a biological context. A microbial genome is often drawn as a **physical map** (figure 18.10). It is helpful to color-code genes according to category. For instance,

when the *H. influenzae* genome was first annotated, about one-third of the genes were of unknown function (denoted by white regions on the map) and about 65 genes were assigned regulatory functions (dark-blue regions). However, the *H. influenzae* was only the second bacterial genome sequenced. With over 700 complete bacterial and archaeal sequences now available for comparison, the number of genes with unknown function has fallen dramatically and will continue to decline as additional genome sequences are made publicly available.

The careful annotation of a microbe's genome can be used to piece together metabolic pathways, transport systems, and potential regulatory and signal transduction mechanisms. A common outcome of a genome project is to use the genes present to infer the functional metabolic pathways, transport mechanisms, and other physiological features of the microbe (figure 18.11). This is of special interest for the causative agent of syphilis, *Treponema pallidum*. Because it is not possible to grow *T. pallidum* outside

Figure 18.10 Physical Map of the *Haemophilus influenzae* Genome.

The predicted coding regions in the outer concentric circle are indicated with colors representing their functional roles. The outer perimeter shows the *NotI*, *RsrII*, and *SmaI* restriction sites. The inner concentric circle shows regions of high G + C content (red and blue) and high A + T content (black and green). The third circle shows the coverage by λ clones (blue). The fourth circle shows the locations of rRNA operons (green), tRNAs (black), and the Mu-like prophage (blue). The fifth circle shows simple tandem repeats and the probable origin of replication (outward pointing green arrows). The red lines are potential termination sequences.

Figure 18.11 Metabolic Pathways and Transport Systems of *Treponema pallidum*. This depicts *T. pallidum* metabolism as deduced from genome annotation. Note the limited biosynthetic capabilities and extensive array of transporters. Although glycolysis is present, the TCA cycle and respiratory electron transport are lacking. Question marks indicate where uncertainties exist or expected activities have not been found.

MICRO INQUIRY Based on this genomic reconstruction, can you determine if *T. pallidum* has a respiratory or fermentative metabolism?

the human body, we know little about its metabolism or the way it avoids host defenses. This has prevented the development of a syphilis vaccine. The sequencing and annotation of the *T. pallidum* genome reveal that *T. pallidum* is metabolically crippled. It can use carbohydrates as an energy source but lacks TCA cycle and oxidative phosphorylation enzymes. *T. pallidum* also lacks many biosynthetic pathways (e.g., for enzyme cofactors, fatty acids, nucleotides, and some electron transport proteins) and must rely on molecules supplied by its host. In fact, about 5% of its genes code for transport proteins. The genes for surface proteins are of particular interest. *T. pallidum* has a family of surface protein genes characterized by many repetitive sequences. Some have speculated that these genes might undergo recombination to generate new surface proteins, enabling the organism to avoid attack by the immune system. It may be possible to develop a vaccine for syphilis using some of these surface proteins. It may also be possible to identify strains of *T. pallidum* using these surface proteins, which would be of great importance in syphilis epidemiology. The annotated genome should ultimately help us understand how *T. pallidum* causes syphilis. ►► *Phylum Spirochaetes* (section 21.7)

Transcriptome Analysis

Once the identity and function of the genes that comprise a genome have been analyzed, the key question remains, “Which genes are expressed at any given time?” The entire collection of mRNAs that are produced at any one time by an organism is its **transcriptome**, which is studied in the field of transcriptomics. Prior to the genomic era, researchers could identify only a limited number of genes whose expression was altered under specific circumstances. However, the development of **DNA microarrays** allows scientists to look at the expression level of a vast collection of genes at once. DNA microarrays are solid supports, usually of glass or silicon, upon which DNA is attached in an organized grid fashion. Each spot of DNA, called a **probe**, represents a single gene or CDS. The location of each gene on the grid is carefully recorded so that when analyzed, the genetic identity of each spot is known.

Commercially prepared microarrays can be purchased or custom arrays can be made. The preparation of custom, or spotted, arrays relies on the robotic application of a probe to the microarray. The probe may be a polymerase chain reaction (PCR)

product, complementary DNA (cDNA), or a short DNA fragment within the gene or CDS. Spotted arrays are especially useful in the study of bacteria and archaea that are studied by a relatively small number of researchers. Commercial microarrays are available for many pathogenic and widely studied model microbes such as *E. coli* and the yeast *Saccharomyces cerevisiae*.

The analysis of gene expression using microarray technology, like many other molecular genetic techniques, is based on hybridization between the single-stranded probe DNA and the nucleic acids to be analyzed, often called the targets, which are typically single-stranded cDNAs made from mRNA (figure 18.12). The target nucleotides are labeled with fluorescent dyes and incubated with the chip under conditions that ensure proper binding of target cDNA to its complementary probe. Unbound target is washed off and the chip is then scanned with laser beams. Fluorescence at each spot or probe indicates that cDNA hybridized. Analysis of the color and intensity of each probe quantifies the level of expression of each gene represented by a probe.

DNA Probe
DNA microarray analysis can be used to determine which genes are expressed at specific times during growth or how a mutation influences gene expression. One common application of microarray technology is to determine the genes whose expres-

sion is changed (either up- or downregulated) in response to environmental changes (figure 18.12). For instance, the microbe *Deinococcus radiodurans* has the remarkable ability to survive intense desiccation and γ -radiation at doses many times above that needed to kill humans. Scientists want to know which *D. radiodurans* genes are repressed or induced upon exposure to ionizing radiation. To determine this, total cellular mRNA from bacteria grown under normal conditions can be isolated and converted to cDNA by reverse transcription (see figure 17.5). This cDNA is tagged with a green fluorochrome to serve as a control or reference, while cDNA made from mRNA recovered from cells exposed to γ -radiation is labeled red. The green (reference) and red (experimental) cDNAs are then mixed and hybridized to the same microarray. During incubation, the red and green cDNAs for any given gene must compete with each other for binding to the same probe. After the unattached cDNA is washed off, the microarray is scanned and the image is computer analyzed. A yellow spot or probe indicates that roughly equal numbers of green and red cDNA molecules were bound, so there was no change in the level of gene expression for that gene. If a target is red, more mRNA from irradiated bacteria was present, thus this gene was induced. Conversely, a green target indicates that the gene was repressed upon exposure to radiation. Careful image analysis is

Figure 18.12 A Microarray System for Monitoring Gene Expression. Cloned genes from an organism are amplified by PCR, and after purification, samples are applied by a robotic printer to generate a spotted microarray. To monitor enzyme expression, mRNA from test and reference cultures is converted to cDNA by reverse transcriptase and labeled with two different fluorescent dyes. The labeled mixture is hybridized to the microarray and scanned using two lasers with different excitation wavelengths. The fluorescence responses are measured as normalized ratios that show whether the test gene response is higher or lower than that of the reference.

used to determine the relative intensity of each spot so that the magnitude of induction or repression of each gene whose expression is altered can be approximated.  **Microarrays**

Microarray experiments yield a vast amount of information that must be organized in some meaningful fashion. One common approach is to use **hierarchical cluster analysis**, which groups genes according to function or in terms of level of expression: induced genes (red spots) are grouped separately from repressed genes (green spots); genes whose expression remains unaltered are shown in black. The hierarchical cluster analysis shown in **figure 18.13** was generated when *D. radiodurans* was exposed to γ -radiation. Ionizing radiation causes double-stranded breaks in DNA—the most lethal form of DNA damage. *D. radiodurans* is able to reassemble its genome after it has been fragmented into thousands of pieces. It was thought that sequencing this bacterium's genome would reveal that *D. radiodurans* is superb in executing DNA repair. But, surprisingly, *D. radiodurans* was discovered to have fewer DNA repair genes than *E. coli*.

To understand these unexpected findings, microbiologists used microarrays with about 94% of *D. radiodurans* genes represented to examine the transcriptome following radiation

treatment. These results were then scanned for genes with similar functions and then grouped by relatedness (degree of relatedness is statistically quantified by a correlation coefficient, or “r value”). Such analysis confirmed that the DNA repair gene *recA* and genes involved in DNA replication and recombination are dramatically upregulated following irradiation. However, unlike repair found in other cells in which one strand serves as a template for synthesis of a new strand, *Deinococcus* uses an unusual DNA polymerase to synthesize two new strands. The newly synthesized fragments are then pieced together in a process that depends on RecA. The newly repaired genome thus becomes a mosaic of old and new DNA fragments.  *Deinococcus-Thermus* (section 21.2)

Although microarrays gave birth to transcriptome analysis, they present three principal drawbacks. First, mRNA must be converted to cDNA, and this may introduce a bias because not all mRNA molecules are reverse transcribed with the same efficiency. Second, the mRNAs identified are only those that have a corresponding probe on the array. This means that noncoding RNAs and coding sequences that may have been missed during annotation will go undetected. Finally, nonspecific hybridization of some cDNAs to probe sequences can introduce a high

level of background noise, making analysis difficult. The advent of next-generation sequencing techniques has made it possible to directly sequence total cellular mRNA, a process known as RNA-seq. Quantification of mRNA is accomplished by measuring the amount of data (“reads”) matching each CDS. Because RNA-seq generates data without the limitations encountered in microarray analysis, it is expected to gradually replace microarrays as the transcriptomic tool of choice.

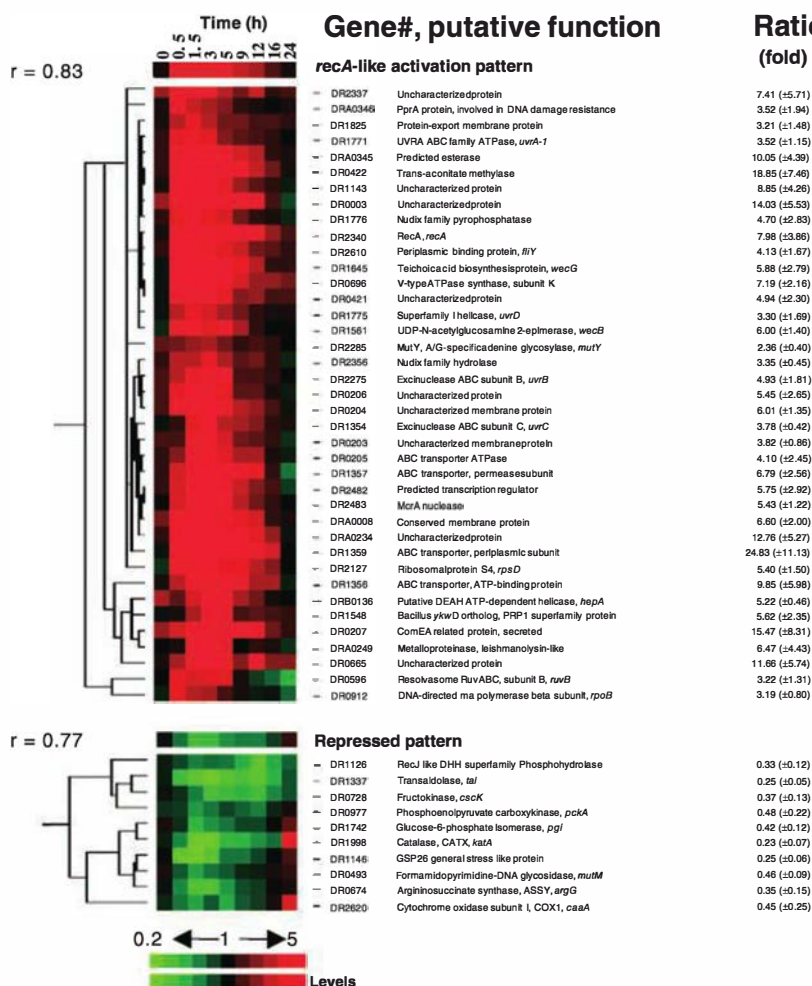

Figure 18.13 Hierarchical Cluster Analysis of Gene Expression of *D. radiodurans* Following Exposure to γ -Radiation.

Each row of colored strips represents a single gene, and the color indicates the level of expression over nine time intervals. The far-left column is the control and thus is black (at control levels of expression). The level of induction or repression relative to the control value is indicated as the ratio (fold). Each group of genes has been scored for relatedness, and a “tree” has been generated on the far left of the clusters, with the indicated correlation coefficient (r value). A large number of genes encoding DNA repair, synthesis, and recombination proteins is induced upon radiation. These are grouped separately from repressed genes involved in other aspects of metabolism.

MICRO INQUIRY Based on your interpretation of the data, identify two genes that are strongly induced and two genes that are strongly repressed.

18.5 Proteomics

After reading this section, you should be able to:

- Explain how 2-D gel electrophoresis is able to resolve two proteins of identical molecular weight
- Summarize the importance of mass spectrometry in analyzing protein structure
- Explain why DNA-protein interactions are of interest and how they can be experimentally identified

Genome function can be studied at the translation level as well as the transcription level. The entire collection of proteins that an organism produces is called its **proteome**. Thus **proteomics** is the study of the proteome or the array of proteins an organism can produce. Proteomics provides information about genome function that mRNA studies cannot because a direct correlation between mRNA and the pool of cellular proteins does not always exist. Much of the research in this area is referred to as **functional proteomics**. It is focused on determining the function of different cellular proteins, how they interact with one another, and the ways in which they are regulated.

Although new techniques in proteomics are continuously being developed, we will focus briefly only on the most common approach, **two-dimensional gel electrophoresis**. In this procedure, a mixture of proteins is separated using two different electrophoretic procedures (dimensions). This permits the visualization of thousands of cellular proteins that would not otherwise be separated in a single electrophoretic dimension. As shown in **figure 18.14a**, the first dimension makes use of **isoelectric focusing**, in which proteins move through a pH gradient (e.g., pH 3 to 10). First, the protein mixture is applied to an acrylamide gel in a tube with a stable pH gradient and electrophoresed. Each protein moves along the pH gradient until the protein's net charge is zero and the protein stops moving. The pH at this point is equal to the protein's **isoelectric point**. Thus the first dimension separates proteins based on the content of ionizable amino acids. The second dimension is SDS **polyacrylamide gel electrophoresis** (SDS-PAGE). SDS (sodium dodecyl sulfate) is an anionic detergent that denatures proteins and coats them with a negative

(a) The technique of two-dimensional gel electrophoresis

(b) An autoradiograph of a two-dimensional gel. Each protein is a discrete spot.

Figure 18.14 Two-Dimensional Gel Electrophoresis.

charge. After the isoelectric gel has been completed, the tube gel is soaked in SDS buffer and then placed at the edge of an SDS-PAGE gel. A voltage is then applied. Because all the proteins are negatively charged thanks to SDS treatment, they will migrate from the negative pole of the gel to the positive. In this way, polypeptides are separated according to their molecular weight; that is, the smallest polypeptide will travel fastest and farthest. Two-dimensional gel electrophoresis can resolve thousands of proteins; each protein is visualized as a spot of varying intensity, depending on its cellular abundance (figure 18.14b). Radiolabeled proteins are often used, enabling greater sensitivity so that newly synthesized proteins can be distinguished. Computer analysis is used to compare two-dimensional gels from microbes grown under different conditions or to compare wild-type and mutant strains. Websites have been developed for the deposition of such images, allowing researchers access to ever-growing databases.

Two-dimensional gel electrophoresis is even more powerful when coupled with **mass spectrometry (MS)**. The unknown protein spot is cut from the gel and the protein is cleaved into fragments by treatment with proteolytic enzymes. Then the fragments are analyzed by a mass spectrometer and the mass of the fragments is plotted. This mass fingerprint can be used to estimate the probable amino acid composition of each fragment and tentatively identify the protein. Sometimes proteins or collections of fragments are run through two mass spectrometers in sequence, a process known as **tandem MS (figure 18.15)**. The first spectrometer separates proteins and fragments, which are further fragmented. The second spectrometer then determines the amino acid sequence of each smaller fragment. The sequence of a whole protein often can be determined by analysis of such fragment sequence data. Alternatively, if the genome of the organism has been sequenced, only a partial amino acid sequence is needed. Computer analysis is then used to compare this amino acid sequence with the predicted translated sequences of all the annotated CDSs on the organism's genome. In this way, both the protein and the gene that encodes it can be identified.

A second branch of proteomics is called **structural proteomics**. Here the focus is on determining the three-dimensional structures of many proteins and using these to predict the structures of other proteins and protein complexes. The assumption is that proteins fold into a limited number of shapes and can be grouped into families of similar structures. When a number of protein structures are determined for a given family, the patterns of protein structure organization or protein-folding rules will be known. Then computational biologists use this information to predict the most likely shape of a newly discovered protein; a process known as **protein modeling**.

Not surprisingly, a variety of other “-omics” are studied. For instance, **lipidomics** investigates a cell's lipid profile at a particular time, and **glycomics** is the systematic study of the cellular pool of carbohydrates. The goal of **metabolomics** is to identify all the small-molecule metabolites, regardless of chemical structure, present in the cell at a given point in time. Because many metabolites are used in multiple pathways, the overview

Figure 18.15 The Use of Tandem Mass Spectrometry to Determine the Amino Acid Sequence of a Peptide.

MICRO INQUIRY How would determining the amino acid sequence of a 30 amino acid residue peptide differ from determining the amino acid sequence of a 200,000 dalton protein?

presented by a complete metabolome enables a researcher to discern which pathways are functional under a given set of conditions. Thus metabolomics provides a high-resolution means to evaluate physiological status. These “-omics” rely heavily on the use of chromatography and as such are beyond the scope of this chapter. Nonetheless, the development of these fields illustrates the dynamic and ever-changing nature of microbiology and the need to take a holistic view if one seeks to understand the structure, function, and behavior of cells.

Probing DNA-Protein Interactions

As described in chapters 13 and 15, many proteins directly interact with DNA; for example, regulatory proteins and proteins involved in replication and transcription. Until recently, the most common way to study protein-DNA interaction was through a procedure known as electrophoretic mobility shift assays (EMSA). This technique is also called a gel shift assay because when a DNA-binding protein is added to a mixture of purified target DNA, the mobility of the DNA is slowed in an agarose gel. When compared to the same DNA without protein, the DNA-protein complex is shifted to a higher molecular weight. The magnitude of the shift is usually related to the protein:DNA ratio such that when sufficient protein is added, the largest shift is seen. To perform EMSA, the target protein must be purified and the DNA to which it binds must be amplified. ◀◀ *Gel electrophoresis (section 17.1)*

What if an investigator suspects a DNA-binding protein binds to more than one target DNA? The use of **chromatin immunoprecipitation (ChIP)** coupled with microarray technology, called the ChIP-chip technique, can be used. In contrast to EMSA, which is entirely *in vitro* and uses one protein and one amplified fragment of DNA, ChIP surveys the living cell. First, cells are treated with a cross-linking agent such as formaldehyde, which “fixes” any DNA-binding proteins to their genomic targets (**figure 18.16**). The cells are then broken open and the DNA (with bound proteins) is cut into small pieces. Antibodies, which are molecules that bind to specified proteins, are used to tag the DNA-binding proteins of interest and the antibody-protein-DNA complexes are precipitated. At this point, any region of DNA to which the protein binds can be identified by PCR using primers specific for the DNA regions that the protein of interest is thought to bind. ▶▶ *Antibodies (section 34.7)*

In ChIP-chip analysis, the proteins are removed from the precipitated protein-DNA complexes and the DNA is denatured so it is now single-stranded. After the DNA strands are labeled, they are hybridized to a microarray that bears all or part of the microbe’s genome (**figure 18.12**). In this way, the whole genome

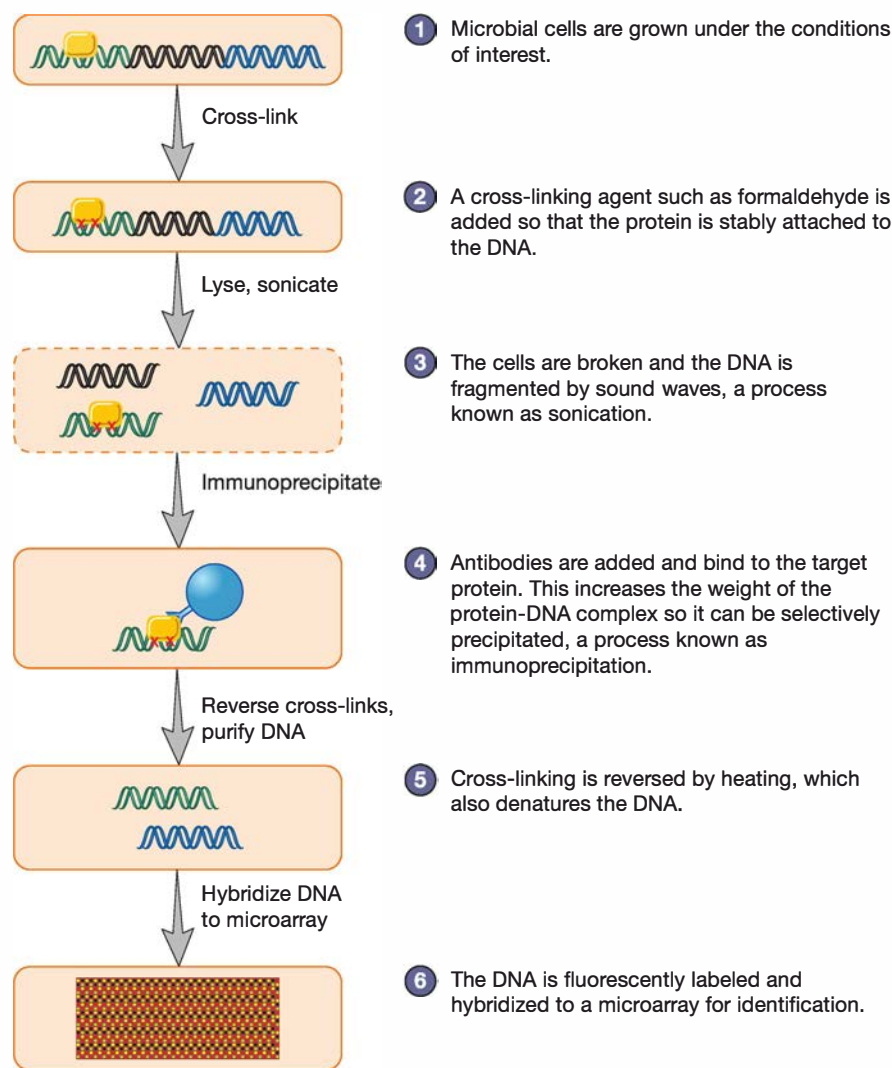

Figure 18.16 ChIP-Chip Analysis. This technology can be used to identify the DNA to which a protein binds.

is scanned for sites to which the protein of interest binds. Regardless of whether ChIP is performed with PCR or a microarray, this technology enables the identification of DNA-protein interactions under different conditions. The same microbial strain can be treated with cross-linking agents when grown in different situations or at different phases of growth, so the DNA-binding profile of a protein can be followed.

Retrieve, Infer, Apply

1. Why does two-dimensional gel electrophoresis allow the visualization of many more cellular proteins than seen in single-dimension electrophoresis (i.e., SDS-PAGE)?
2. What is the difference between mass spectrometry and tandem mass spectrometry?
3. Describe a ChIP-chip experiment in which you want to identify the promoters to which the stationary phase sigma factor RpoS binds in *E. coli*. Could you also determine when RpoS binds? Explain your answer.

18.6 Systems Biology

After reading this section, you should be able to:

- Explain the role of genomics in shaping systems biology
- Suggest two areas of investigation that would benefit from a systems biology approach

Imagine the following experiment: You have created a microbial strain in which you have deleted, or “knocked out,” a single gene; it doesn’t really matter what the gene encodes. You want to compare the transcriptome and proteome of the knockout mutant with its parent strain, which is identical to it in every way except the presence of this particular gene. To evaluate the transcriptome, you perform RNA-seq, and to assess the proteome, you run two-dimensional gels. You find that the loss of just one gene has huge ramifications with regard to gene expression and protein synthesis. Not only is the pathway that you knew your gene product was involved in altered, but the expression of many more genes and proteins has also been affected.

This scenario has been repeated many times for numerous microorganisms. Life scientists now realize that most of the genes and proteins that have been widely investigated have a vastly broader role in cellular physiology than previously thought. Gone are the days of reductionist biology, when a single metabolic or regulatory pathway could be considered in isolation. Systems biology seeks to integrate the “parts list” of cells—mRNA, proteins, small molecules—with the molecular interactions that become pathways for catabolism, anabolism, regulation, behavior, responses to environmental signals, etc. To accomplish this, systems biology must be interdisciplinary, requiring the expertise of physiologists, biochemists, bioinformaticists, mathematicians, geneticists, ecologists, and others.

One area where systems biology has been applied to microbiology is the study of metabolism (figure 18.17). Here genome sequencing and annotation leads to one set of predictions that can be tested by transcriptomics, proteomics, and metabolomics. The interactions between the individual

products—RNA, protein, metabolites—can then be linked in a predictive network and used to construct testable hypotheses. Like most science, systems biology is an interactive process involving data collection, analysis, and hypothesis building. What sets it apart, however, is the volume of data, the depth of sampling, and the use of sophisticated predictive models to guide the development of new hypotheses.

18.7 Comparative Genomics

After reading this section, you should be able to:

- Discern the general relationship between genome size and organism complexity
- Describe the genomic differences that distinguish intracellular parasites from free-living microbes

A natural consequence of the tremendous number of recently sequenced genomes is the increased ability to make meaningful genome comparisons. **Comparative genomics** is a useful set of analyses by which gene function and evolution can be inferred by studying similar nucleotide and amino acid sequences found among organisms. Perhaps the most fundamental comparison is the relative sizes of microbial genomes. Several generalizations can be deduced from such analysis. Inspection of figure 18.18 reveals that the smallest genomes published to date, across all three domains, belong to parasitic microbes. These organisms depend on their hosts for many metabolites and have lost the genes encoding the enzymes needed for their assembly. Also note that as the genome size increases, the trend is toward more open reading frames per nucleotide; that is, they have a higher gene density. Bacterial and archaeal genomes tend to have more open reading frames per nucleotide; that is, they have a higher gene density. This is because they lack introns and much of the other non-coding sequences found in eukaryotes. Indeed, some archaea and bacteria have reduced noncoding sequence to a minimum and have many overlapping genes. This is particularly true for those that live in nutrient-limited environments; synthesizing

DNA, which requires both phosphate and nitrogen, is costly.

When comparing microbes of different domains, we see that archaea tend to have smaller genomes than many bacteria (figure 18.18). The largest known archaeal genome, that of the methanogen *Methanosarcina acetivorans*, falls in the middle of the genome size range for bacteria. Bacterial genomes range from the very small (about 500,000 base pairs) to over 9 million base pairs (Mb). In general, genome size reflects metabolic and morphological complexity. For instance, the two largest genomes listed in figure 18.18

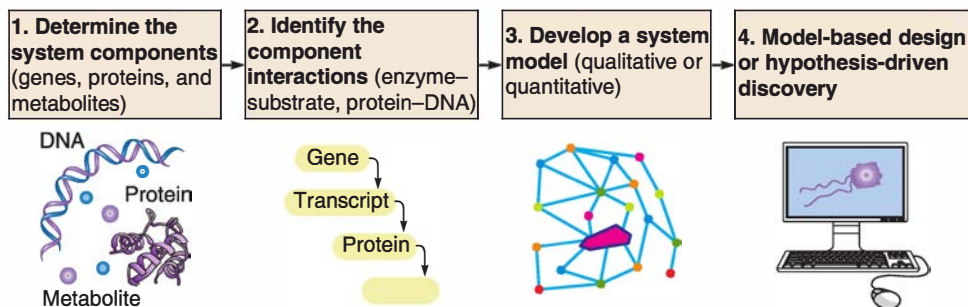

Figure 18.17 Systems-Based Biology. Microbial metabolism is an active area of systems biology research. It can involve (1) identifying the system components, (2) recognizing their interactions, and (3) developing a model that predicts how they interact, which then (4) informs the synthesis of hypotheses that can be tested either by further modeling or by experimentation.

belong to *Bradyrhizobium japonicum*, which produces plant-associated nodules in which differentiated bacteria fix nitrogen, and *Streptomyces coelicolor*, which has a complex life cycle and produces a number of specialized metabolites, including antibiotics. Eukaryotic microbes have the largest range of genome sizes. The genome of the intracellular pathogenic microsporidian fungus *Encephalitozoon cuniculi* is smaller than many bacterial and archaeal genomes, yet the ciliated protist *Paramecium tetraurelia* has a tremendously large genome. It is thought that this protist underwent multiple rounds of genomic duplication. ▶▶ Suborder Streptomycineae (section 24.1); Alveolata (section 25.5); Nitrogen-fixing bacteria (section 31.3)

Comparing genome sequences between genera, species, and strains has revealed a high level of **horizontal gene transfer (HGT)**. As detailed in chapter 16, HGT is the exchange of genetic material between organisms that need not be of similar evolutionary lineages. Surprisingly, many genes involved in a myriad of cellular functions reside on mobile genetic elements, including transposons, plasmids, and phages. Genome analysis has revealed that HGT is frequently mediated by viruses and that lysogeny may be the rule, rather than the exception. In fact, some bacteria and archaea carry multiple proviruses. Some temperate phages carry lysogenic conversion genes, so called because they change the phenotype of their hosts. For instance, the virulence genes for some important pathogens, including the bacteria that cause diphtheria and cholera, are encoded by phages. ◀◀ Infections of bacterial and archaeal cells (section 6.4)

When mobile genetic elements are permanently integrated into a microbial genome, they are called **genomic islands**. When these new genes encode proteins that contribute to or confer virulence, they

Figure 18.18 Microbial Genome Sizes. The distribution of genome sizes in millions of base pairs (Mb) among some archaea, bacteria, and eukaryotic microbes. Asterisk denotes that the microbe is parasitic.

MICRO INQUIRY Two *E. coli* strains are shown in this figure. One is a pathogen and one is not. Explain why genome size cannot be used to determine which is pathogenic.

are known as **pathogenicity islands**. How is it known that certain genes were obtained by HGT? Genomic islands provide evidence of transfer such as a G + C content and a codon bias that differs from the remainder of the genome. This is most easily explained by example. The genomes of *Streptomyces* spp. are about 72% G + C. In these microbes, codons that are AT-rich are rarely used (e.g., the cysteine codon ACG is used much more frequently than ACA). Therefore, a region of the genome that has a low G + C ratio coupled with AT-rich codons suggests the presence of a genomic island and the acquisition of the genes by HGT. Genomic islands also sometimes retain inverted repeat sequences or other elements needed for transfer or integration. It has become clear that HGT is a major evolutionary force in short-term microbial evolution and long-term speciation.

It follows that phylogenetic relationships between microbes can be explored by comparative genomics. One approach is to examine how similar the organization of orthologous genes are in the genomes of the microbes being compared. This is called **synteny**, and closely related microbes generally have a high degree of synteny. It may be easiest to understand synteny by first considering the order of genes in similar operons found in two different microbes. For instance, one would not be surprised to learn that the order of tryptophan biosynthetic genes is the same (conserved) in the *E. coli* and *Salmonella* spp. genomes. Analysis of synteny takes this comparison to the level of whole genomes. As shown in **figure 18.19**, when the order of genes in the genome of the plant symbiont *Sinorhizobium meliloti* is compared with that of the plant pathogen *Agrobacterium tumefaciens*, it is clear that the gene order is very similar. This is in contrast to *E. coli* and *S. meliloti*. Although these two bacteria belong to the same phylum, the *Proteobacteria*, they are not sufficiently related to show synteny.

▶▶ **Class Alphaproteobacteria (section 22.1); Microbe-plant interactions (section 31.3)**

Comparative genomics can also provide great insight into genes and gene products that are associated with virulence when pathogen genomes are analyzed. Such insights are particularly needed in understanding *Mycobacterium tuberculosis*, the causative agent of tuberculosis (TB). About one-third of the human population has TB. After establishing residence in immune cells in the lung, *M. tuberculosis* often remains in a dormant state until the host's immune system is compromised. It then goes on to cause active disease, killing about 2 million people annually. The *M. tuberculosis* genome has been compared to the genomes of two relatives—*M. leprae*, which causes leprosy, and *M. bovis*, the causative agent of TB in a wide range of animals, including cows and humans. The genomes of *M. bovis* and *M. tuberculosis* are most similar—about 99.5% identical at the sequence level. However, the *M. bovis* genome is missing 11 separate regions, making its genome slightly smaller (4.3 Mb versus 4.4 Mb). The sequence dissimilarities involve the inactivation of some genes, leading to major differences in the way the two bacteria respond to environmental conditions. This may account for the host range differences between these two closely related pathogens.

▶▶ **Suborder Corynebacterineae (section 24.1); *Mycobacterium* infections (section 39.1)**

The divergence between *M. tuberculosis* and *M. leprae* is even more striking. The *M. leprae* genome is a third smaller than that of *M. tuberculosis*. About half the genome is devoid of functional genes. Instead, there are over 1,000 degraded, nonfunctional genes called **pseudogenes** (**figure 18.20**). In total, *M. leprae* seems to have lost more than 1,000 genes during its career as an intracellular parasite. *M. leprae* even lacks some of the enzymes required for energy production and DNA replication. This might explain why the bacterium has such a long doubling

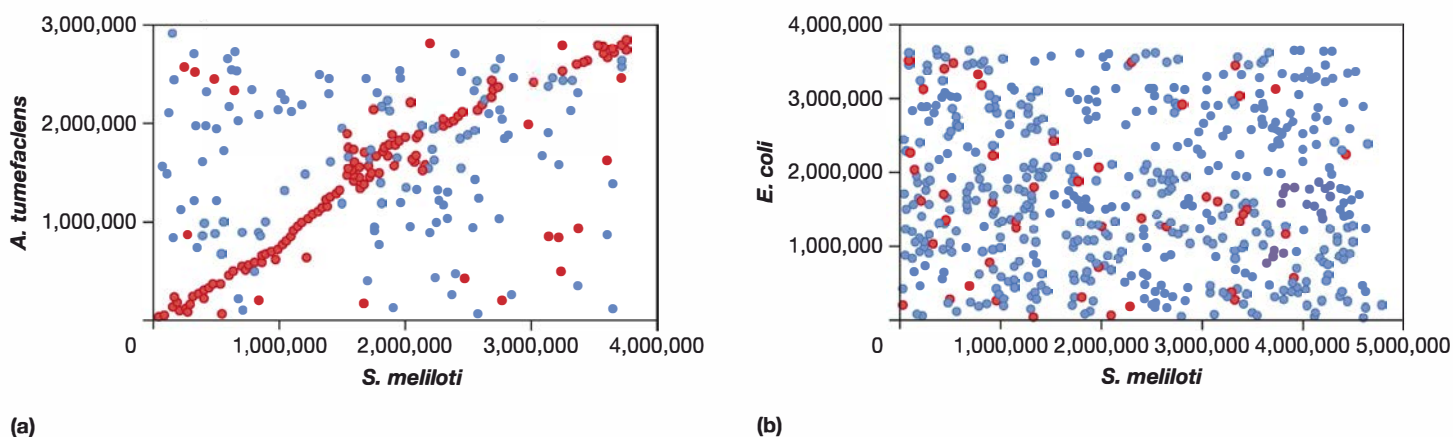

Figure 18.19 Synteny. Each axis on the graphs maps the genes on each organism's genome. For instance, each number on the X axis in both (a) and (b) indicates the position of genes (blue dots) on the 3.7 Mb *S. meliloti* genome. (a) When the genomes of *S. meliloti* and *A. tumefaciens* are compared, it is evident that the distribution of orthologous genes on the genome is quite similar, as shown by the red line indicating similar placement on the genome (red dots represent *A. tumefaciens* genes). (b) *E. coli* and *S. meliloti* are not closely related; thus their genomes show no synteny (red dots represent *E. coli* genes).

Figure 18.20 Comparative Genomic Analysis Between Two *Mycobacterium* Species. The genome of *M. leprae* is significantly smaller than that of *M. tuberculosis*. Over one-third of its genes are nonfunctional pseudogenes that will presumably be lost as genome reduction continues.

time, about 2 weeks in mice. One hope from genomic analysis is that critical surface proteins can be discovered and used to develop a sensitive test for early detection of leprosy. This would allow immediate treatment of the disease before nerve damage occurs. ►► *Leprosy* (section 39.3)

18.8 Metagenomics

After reading this section, you should be able to:

- Differentiate between the construction and screening of a genomic library (chapter 17) and a metagenomic library
- List two applications of metagenomics in any field of microbial biology
- Define the human microbiome and explain the role metagenomics plays in its investigation

It is clear that structural, functional, and comparative genomics have revolutionized the study of microbial physiology and genetics. Equally important is the growing field of environmental genomics, also called **metagenomics**. While the dominant role of microorganisms in driving the nutrient cycles that support life on Earth has long been recognized, efforts to comprehensively understand microbial communities have been

stymied by the fact that only about 1 to 2% of all microbial species have so far been cultured in laboratories. New genomic techniques offer cultivation-independent approaches to studying microbial biodiversity. Environmental genomics can be used to take a census of microbial populations as well as to discern the presence and abundance of certain classes of genes. That is to say, genomics can ask, “Who is there and what are they doing?” To do this, DNA fragments are extracted directly from the environment and cloned into plasmid vectors. In this way, a library of environmental DNA fragments can be maintained and amplified (**figure 18.21**). Alternatively, certain genes may be obtained by PCR amplification of DNA fragments derived from environmental samples. In either case, a stable source of nucleotide sequences is generated that reflects the

diversity of microbes growing in nature, not just those that can be grown in the laboratory. The nucleotides are then sequenced and analyzed, or expressed in a microbial host and screened for a specific function, such as the production of novel antimicrobial compounds. ◀◀ *The polymerase chain reaction* (section 17.2) ►► *Exploring microbial taxonomy and phylogeny* (section 19.3); *Assessing microbial community activity* (section 29.3)

Metagenomics has dramatically transformed our understanding of microbial diversity. Metagenomic libraries prepared from DNA extracted from natural samples, such as seawater, soil, and the human body, have generated billions of nucleotide sequences. Most often massively parallel sequencing (p. 426) is used because it is not necessary to first construct a DNA library. This avoids bias that may be introduced by cloning efficiency. When sequences are examined for the presence of genes that indicate taxonomy (e.g., 16S rRNA encoding genes), genomic species, called **phylotypes**, can be determined. As described in chapter 29, microarrays called phylochips have been developed so that community diversity can be assessed. Amazingly, a single gram of pristine soil harbors more phylotypes than the number of currently catalogued bacterial and archaeal species. When analyzed for function, the metabolic activities of a microbial community can be explored.

One ambitious metagenomics project was performed by J. Craig Venter, Hamilton Smith, and colleagues. They wanted to determine the bacterial and archaeal biodiversity of the Sargasso Sea, that portion of the Atlantic Ocean that surrounds Bermuda. They collected seawater and used filtration to exclude viruses (using 0.2 μm cutoff filters) and eukaryotes (using 0.8 μm cutoff filters). An environmental genomic library was prepared from DNA extracted from the remaining seawater. After sequencing over 1 billion base pairs, followed by manual and computer analysis to determine sequence relatedness, it was determined that at least 1,800 phylotypes were represented. Among these, about 145 phylotypes were previously unknown and most likely represent new species. Phylogenetic diversity was further evaluated by PCR amplification of genes,

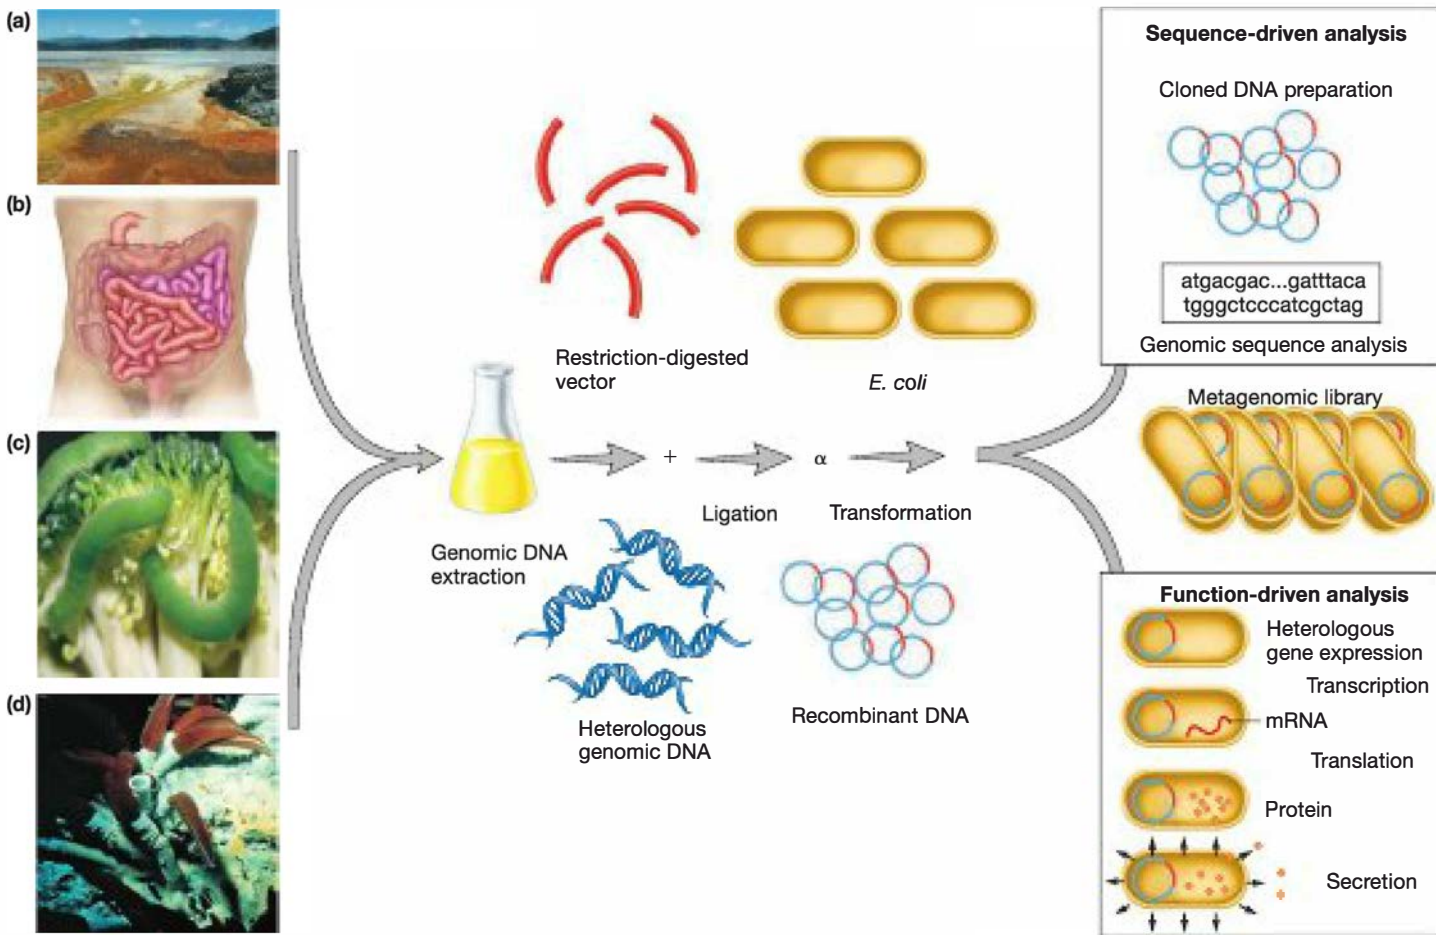

Figure 18.21 Construction and Screening of Genomic Libraries Directly from the Environment. DNA has been extracted directly from environments such as (a) bacterial mats at Yellowstone National Park, (b) the human colon, (c) cabbage white butterfly larvae, and (d) tube worms from hydrothermal vents. The DNA is cloned into suitable vectors and transformed into a bacterial host. Sequences or gene products are then analyzed.

such as the recombinase gene *recA*, the 16S rRNA gene, and the gene that encodes RpoB (*rpoB*; a subunit conserved in all RNA polymerases). The sequences for these genes are highly conserved, making them good candidates for assessing species diversity (figure 18.22). Amazingly, Venter, Smith, and their collaborators report the discovery of 1.2 million previously unknown genes (although this number is controversial), including over 700 new proteorhodopsin-like photoreceptors from taxa not previously known to possess light-harvesting capabilities. These results demonstrate that metagenomic analysis opens the door to more study so that we can ultimately fully appreciate the biological diversity in the world's oceans.

Metagenomics is also changing our understanding of human biology. In 2007 the National Institutes of Health initiated the Human Microbiome Project. The **human microbiome** refers to the community of microorganisms present in and on the human body. Metagenomic analysis is being used to explore the microbial communities from human skin and respiratory, gastrointestinal, and urogenital tracts. An international team of scientists has

also focused on the metagenomics of the human gut. Results from both of these projects have revolutionized the study of human health and disease. It is now recognized that the human body is dependent on its normal microbiota for normal function. Conditions as disparate as obesity and irritable bowel syndrome are influenced by the makeup of the human microbiome. Clearly, metagenomics is a powerful field that will change how we view the world and ourselves. ►► *Human-microbe interactions* (section 32.2)

Retrieve, Infer, Apply

1. What is a phylotype?
2. Massively parallel sequencing techniques are considered well suited for metagenomics because a genomic library does not have to be constructed. Apart from convenience, explain why this is important for metagenomic analysis.
3. Examine figure 18.21. How might metagenomics be used to isolate a novel antifungal compound?

Figure 18.22 Phylogenetic Diversity of Sargasso Sea Microbes. The relative abundance (weight % of clones) of each group of microbes is shown according to the specific conserved gene that was used for genetic analysis. The genes used were those encoding elongation factor G (EFG), elongation factor Tu (EFTu), heat-shock protein 70 (HSP70), recombinase A (RecA), a conserved subunit of RNA polymerases (RpoB), and the gene that encodes 16S rRNA.

Key Concepts

18.1 Determining DNA Sequences

- Genomics is the study of the molecular organization of genomes, their information content, and the gene products they encode.
- DNA fragments are normally sequenced using dideoxynucleotides and the Sanger chain termination technique (**figures 18.2 and 18.3**).
- Three newer sequencing methodologies include pyrosequencing (454), Solexa sequencing, and sequencing by ligation. These technologies are faster and cheaper than the Sanger method but generate shorter reads (**figures 18.4 and 18.5**).

18.2 Genome Sequencing

- When using the Sanger sequencing technique, the whole-genome shotgun technique is used. Four stages are involved: library construction, sequencing of randomly produced fragments, fragment alignment and gap closure, and editing the final sequence (**figure 18.6**).
- It is now possible to use the multiple strand displacement technique to copy the genome of a single microbial cell so there is sufficient DNA for sequencing. In this way, the genomes of uncultivated microbes can be studied (**figure 18.7**).

18.3 Bioinformatics

- Analysis of vast amounts of genome data requires sophisticated computer software; these analytical procedures are a part of the discipline of bioinformatics.
- An open reading frame is a putative protein-coding gene; the identity of the gene and its product are inferred by aligning the translated amino acid sequence with other genes like it in the database (**figures 18.8 and 18.9**).
- Bioinformatics enables the comparison of genes within genomes to identify paralogues and of genes between different organisms to identify orthologues.

18.4 Functional Genomics

- Functional genomics is used to reveal genome structure and function relationships.
- The physical map of a microbe's genome is often displayed so the location of genes with related functions are easily identified (**figure 18.10**).
- The presence of genes whose products are known to function in specific metabolic processes such as catabolic pathways and transport enables the genomic reconstruction of the organism—a type of map that illustrates these processes within the cell (**figure 18.11**).

- Two techniques are used to study transcriptomes: DNA microarrays and RNA-seq. Both assess gene expression as a measure of individual gene transcripts (mRNA). Gene expression can be determined for mutant versus wild-type strains or for a given organism under specific environmental conditions (**figure 18.12**).

18.5 Proteomics

- The entire collection of proteins that an organism can produce is its proteome, and its study is called proteomics.
- The proteome is often analyzed by two-dimensional gel electrophoresis, in which the total cellular protein pool can be visualized. In many cases, the amino acid sequence of individual proteins is determined by mass spectrometry; if this is coupled to genomics, both a protein of interest and the gene that encodes it can be identified (**figures 18.14 and 18.15**).
- Structural proteomics seeks to model the three-dimensional structure of proteins based on computer analysis of amino acid sequence data.
- Protein-DNA interactions can be analyzed by chromatin immunoprecipitation, which enables the identification of both the protein and its target DNA (**figure 18.16**).

18.6 Systems Biology

- Systems biology is an interdisciplinary field of study that combines experimentally derived data sets with predictive modeling to an organismal process.
- Systems biology is the opposite of reductionist biology because it integrates molecular networks with the goal of understanding the function of the cell as a whole.

18.7 Comparative Genomics

- Comparing genome sequences reveals information about genome structure and evolution, including the importance of horizontal gene transfer.
- Comparative genomics is an important tool in discerning how microbes have adapted to particular ecological niches and in developing new therapeutic agents.

18.8 Metagenomics

- Metagenomics enables the study of the biodiversity and metabolic potential of microbial communities without culturing individual microbes (**figure 18.21**).
- Metagenomics has been applied to many natural microbial habitats, including the human body.

Compare, Hypothesize, Invent

1. Propose an experiment that can be done easily with a DNA microarray or RNA-seq that would have required years to do before these technologies were developed.
2. You have discovered a new DNA-binding protein. You show by EMSA that it binds to the promoter of an operon that encodes enzymes required for carotenoid biosynthesis. You wonder if any other genes are controlled by this new protein. How will you find other regions of DNA to which the protein might bind? How will you determine if the new protein activates or represses transcription of the genes whose promoters it binds?
3. You are developing a new vaccine for a pathogen. You want your vaccine to recognize specific cell-surface proteins. Explain how you will use genome analysis to identify potential protein targets. What functional genomics approaches will you use to determine which of these proteins is produced when the pathogen is in its host?
4. You are annotating the genomic sequence of a new soil bacterium. You believe you have found a gene that encodes

nitrate reductase (*nar*). How did you arrive at this conclusion, and how will you strengthen this annotation using only in silico analysis?

5. The bacterial genus *Borrelia* is the cause of several tick-borne diseases. In addition, *B. recurrentis* causes louse-borne relapsing fever. In 2008 a team of scientists reported that the genome of *B. recurrentis* is a smaller, degraded version of the genome of *B. duttonii*, the cause of tick-borne relapsing fever. What do you think these researchers discovered when they compared these two genomes that enabled them to make this conclusion? In addition, it was found that *B. recurrentis* lacks genes encoding *recA* and *mutS*; refer to section 16.1 and explain why the loss of these genes may have accelerated the decay of this genome.

Read the original paper: Lescot, M., et al. 2008. The genome of *Borrelia recurrentis*, the agent of deadly louse-borne relapsing fever, is a degraded subset of tick-borne *Borrelia duttonii*. *PLoS Genetics* 4:e1000185.

Microbial Taxonomy and the Evolution of Diversity

Scientists Query: “Is the Microbial Universe Expanding?”

The more you know, the more you discover. Evolutionary biologist Dr. Jonathan Eisen wanted to discover as much as possible from the genomic sequences of previously unknown bacteria and archaea. However, he realized that the genome database was limited to the genomes of microbes already chosen for sequencing because they were pathogenic, industrially relevant, or had some other desired trait. So his research group, in collaboration with the Joint Genome Institute, set out to diversify the database by sequencing bacterial and archaeal genomes across the evolutionary spectrum. When computers were used to translate the nucleotide sequences into their protein and RNA products, the researchers were rewarded with the discovery of hundreds of novel protein families. This not only extends the limits of biological diversity, it also provides a source of inquiry for the development of new, useful microbial products, including medically important compounds. To make these data freely available, Dr. Eisen has spearheaded the development of the Genomic Encyclopedia of Bacteria and Archaea, or GEBA for short.

Dr. Eisen’s research team did not stop there, however. His former boss, Dr. Craig Venter, had collected millions of partial genome sequences from microbes sampled during several ocean voyages (see section 18.8). Dr. Eisen posed a fundamental (and possibly audacious) question: “Could there be an entirely undiscovered domain of life?” The only way to test this is to use PCR (see section 17.2). But here’s the catch: if a gene is really undiscovered, by definition it won’t contain the conserved sequences to which PCR primers must bind. Currently there is no way around this conundrum, but undeterred, Dr. Eisen’s team selected two protein-coding genes: the recombinase gene *recA* and the gene encoding the β subunit of RNA polymerase, *rpoB*. Both genes are abundant in all three domains as

There are more microbes on Earth than stars in the universe. This vast diversity reflects the roughly 3.5 billion years in which microbes have evolved to adapt to seemingly every environment on (and in) the planet, regardless of how inhospitable it may seem to a plant or animal.

well as some viruses, so there were plenty of known sequences for comparison. Over 4,600 *recA* and 1,800 *rpoB* genes were analyzed and subdivided into groups of protein subfamilies. Amazingly, members of one subfamily for each protein were found to be completely unrelated to any other known protein on Earth. So, is this evidence of a new domain? Perhaps. Alternatively, these sequences could be ancient relatives of the more familiar proteins, or they could be from some unusual viruses. But if they do represent a new domain, we would add to *Bacteria*, *Archaea*, and the *Eukarya* the ... well, it’s too early to choose a name. But time, and more scientific discovery, will tell.

In this chapter, we explore microbial taxonomy and evolution—how and why microorganisms are classified using an evolutionary framework. This was not always the case, and the move to an evolution-based system resulted in the reclassification of some genera, to the consternation of some scientists. Indeed, the fields of microbial taxonomy and evolution continue to present challenges and controversy. But ultimately, microbial taxonomy and phylogeny open the door to a degree of biological diversity unmatched by multicellular organisms.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Describe the structure of DNA (section 13.2) and summarize methods used in DNA sequencing (sections 18.1 and 18.2)
- ✓ Outline in general terms how small subunit rRNA has been used to define the three domains of life (section 1.2)
- ✓ Summarize the mechanisms of horizontal gene transfer (chapter 16)
- ✓ Differentiate between a microbial genus, species, and strain (section 1.2)
- ✓ Describe the rationale for the RNA world hypothesis of the origin of life (section 1.2)
- ✓ Summarize why the term prokaryote is controversial (section 3.1)
- ✓ Contrast and compare the structural differences between bacterial, archaeal, and eukaryotic microbes (chapters 3–5)

19.1 Introduction to Microbial Taxonomy

After reading this section, you should be able to:

- Explain the utility of taxonomy and systematics
- Draw a concept map illustrating the differences between phenetic, phylogenetic, and genotypic classification

Microbiologists are faced with the daunting task of understanding the diversity of life forms that cannot be seen with the naked eye but can live seemingly anywhere on Earth. Obviously a reliable classification system is paramount. **Taxonomy** (Greek *taxis*, arrangement or order, and *nomos*, law, or *nemein*, to distribute or govern) is defined as the science of biological classification. In a broader sense, it consists of three separate but interrelated parts: classification, nomenclature, and identification. Once a classification scheme is selected, it is used to arrange organisms into groups called taxa (s., **taxon**) based on mutual similarity. **Nomenclature** is the branch of taxonomy concerned with the assignment of names to taxonomic groups in agreement with published rules. Identification is the practical side of taxonomy—the process of determining if a particular isolate belongs to a recognized taxon and, if so, which one. The term **systematics** is often used for taxonomy, although it sometimes infers a more general scientific study of organisms with the ultimate objective of arranging them in an orderly manner. Thus systematics encompasses disciplines such as morphology, ecology, epidemiology, biochemistry, genetics, molecular biology, and physiology.

One of the oldest classification systems, called **natural classification**, arranges organisms into groups whose members share many characteristics. The Swedish botanist Carl von Linné, or Carolus Linnaeus as he often is called, developed the first natural classification in the middle of the eighteenth century. It was based largely on anatomical characteristics and was a great improvement over previously employed artificial systems because knowledge of an organism's position in the scheme provided information about many of its properties. For example, classification of humans as mammals denotes that they have hair, self-regulating body temperature, and milk-producing mammary glands in the female.

When natural classification is applied to higher organisms, evolutionary relationships become apparent simply because the morphology of a given structure (e.g., wings) in a variety of organisms (ducks, songbirds, hawks) suggests how that structure might have been modified to adapt to specific environments or behaviors. However, the traditional taxonomic assignment of microbes was not rooted in evolutionary relatedness. For instance, bacterial pathogens and microbes of industrial importance were historically given names that described the diseases they cause or the processes they perform (e.g., *Vibrio cholerae*, *Clostridium tetani*, and *Lactococcus*

lactis). Although these labels are of practical use, they do little to guide the taxonomist concerned with the vast majority of microbes that are neither pathogenic nor of industrial consequence. Our present understanding of the evolutionary relationships among microbes now serves as the theoretical underpinning for taxonomic classification.

In practice, determining the genus and species of a newly isolated microbe is based on **polyphasic taxonomy**. This approach includes phenotypic, phylogenetic, and genotypic features. To understand how all of these data are incorporated into a coherent profile of taxonomic criteria, we must first consider the individual components.

Phenetic Classification

For a very long time, microbial taxonomists had to rely exclusively on a **phenetic system**, which classifies organisms according to their phenotypic similarity. This system succeeded in bringing order to biological diversity and clarified the function of morphological structures. For example, because motility and flagella are always associated in particular microorganisms, it is reasonable to suppose that flagella are involved in at least some types of motility. Although phenetic studies can reveal possible evolutionary relationships, this is not always the case. Many traits are compared without assuming that some might be more phylogenetically important than others; that is, unweighted traits are employed in estimating general similarity. Obviously the best phenetic classification is one constructed by comparing as many attributes as possible.

Phylogenetic Classification

With the publication in 1859 of Charles Darwin's *On the Origin of Species*, biologists began developing **phylogenetic** or **phyletic classification systems** that sought to compare organisms on the basis of evolutionary relationships. The term **phylogeny** (Greek *phylon*, tribe or race, and *genesis*, generation or origin) refers to the evolutionary development of a species. Scientists realized that when they observed differences and similarities between organisms as a result of evolutionary processes, they also gained insight into the history of life on Earth. However, for much of the twentieth century, microbiologists could not effectively employ phylogenetic classification systems, primarily because of the lack of a good fossil record. When Carl Woese and George Fox proposed using small subunit (SSU) rRNA nucleotide sequences to assess evolutionary relationships among microorganisms, the door opened to the resolution of long-standing inquiries regarding the origin and evolution of the majority of life forms on Earth—the microbes. As discussed later (p. 453), the power of rRNA as a phylogenetic and taxonomic tool rests on the features of the rRNA molecule that make it a good indicator of evolutionary history and on the ever-increasing size of the rRNA sequence database.

Genotypic Classification

In general, **genotypic classification** seeks to compare the genetic similarity between organisms. Individual genes or whole genomes can be compared. Since the 1970s it has been widely accepted that bacteria and archaea whose genomes are at least 70% homologous belong to the same species (p. 453). However, there is now a consensus building to replace this metric with a genomics-based assay that measures the average nucleotide identity between organisms. The means by which microbes are genotypically classified is discussed further in section 19.3.

Retrieve, Infer, Apply

1. What is a natural classification? What microbial features might have been considered when devising a natural classification scheme?
2. What is polyphasic taxonomy, and what three types of data does it consider? Should each type of data be of equal weight?
3. Consider the finding that bacteria capable of anoxygenic photosynthesis belong to several different phylogenetic lineages. How do you think these bacteria were originally classified, and what types of data do you think were key in making the most recent taxonomic assignments?

19.2 Taxonomic Ranks

After reading this section, you should be able to:

- Outline the general scheme of taxonomic hierarchy
- Explain how the binomial system of Linnaeus is used in microbial taxonomy

The definition of a bacterial or archaeal species is widely debated, as discussed in section 19.5. Nonetheless, for practical reasons it is essential that the established rules of taxonomy are followed. As reviewed in chapter 1, microbes are placed in taxonomic levels arranged in a nonoverlapping hierarchy so that each level includes not only the traits that define the rank above it but also a new set of more restrictive traits (**figure 19.1**). Thus within each domain—*Bacteria*, *Archaea*, or *Eukarya*—each organism is assigned (in descending order) to a phylum, class, order, family, genus, and species epithet. Some microbes are also given a subspecies designation. Microbial groups at each level have a specific suffix indicative of that rank or level.

The most fundamental definition of a bacterial or archaeal **species** is a collection of strains that share many stable properties and differ significantly from other groups of strains. A **strain** consists of the descendants of a single, pure microbial culture. Strains within a species may be described in a number of different ways. **Biovars** are variant strains characterized by biochemical or physiological differences, **morphovars** differ morphologically, and **serovars** have distinctive antigenic (immunologically reactive) properties. For each species, one strain is designated as the **type strain**. It is usually one of the first strains studied and often is more fully characterized than other strains; however, it does not have to be the most representative member. The type strain is the holder of the species name. This ensures permanence of names when nomenclature revisions occur because the type species must remain within the original species. Only those strains very similar to the type strain or type species are included in a species. Each species is assigned to a **genus**, the next rank in the taxonomic hierarchy. A genus is a well-defined group of one or more species that is clearly separate from other genera. In practice, considerable subjectivity occurs in assigning species to a genus, and taxonomists may disagree about the composition of genera.

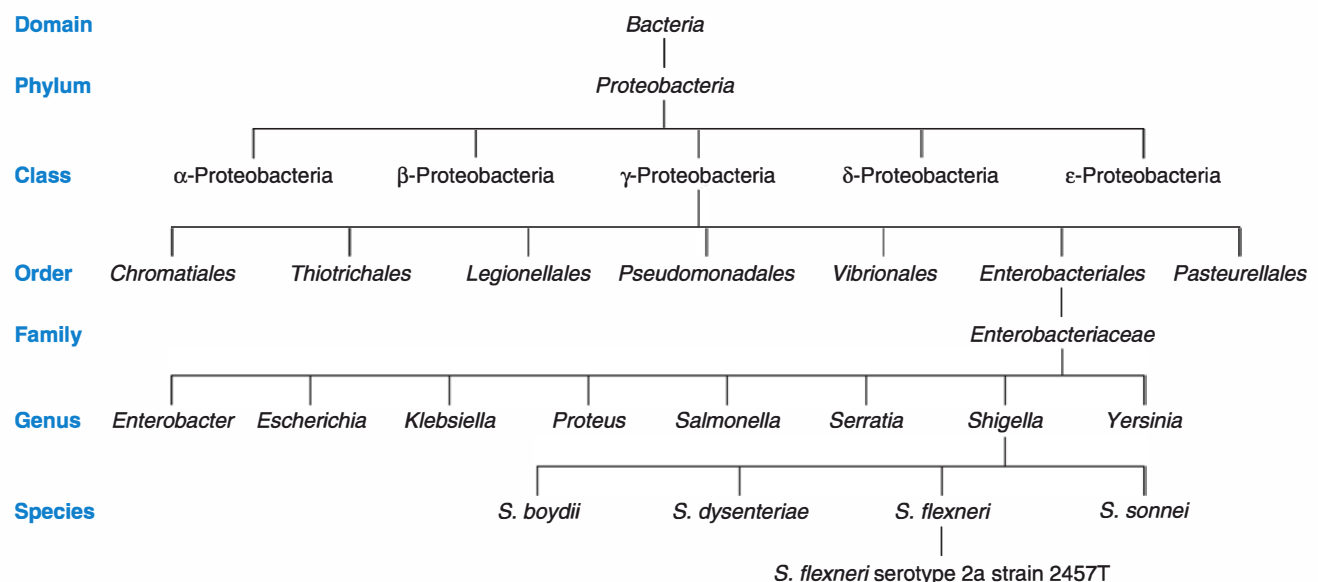

Figure 19.1 Hierarchical Arrangement in Taxonomy. In this example, members of the genus *Shigella* are placed within higher taxonomic ranks. Not all classification possibilities are given for each rank to simplify the diagram. Note that *-ales* denotes order and *-ceae* indicates family.

Microbiologists name microorganisms using the **binomial system** of Linnaeus. The Latinized, italicized name consists of two parts. The first part is the generic name (i.e., the genus), and the second is the species name (e.g., *Yersinia pestis*, the causative agent of plague). The species name is stable; the oldest epithet for a particular organism takes precedence and must be used. In contrast, a generic name can change if the organism is assigned to another genus. For example, some members of the genus *Streptococcus* were placed into two new genera, *Enterococcus* and *Lactococcus*, based on rRNA analysis and other characteristics. Thus *Streptococcus faecalis* is now *Enterococcus faecalis*. To be recognized as a new species, genomic, metabolic, morphological, reproductive, and ecological data must be accepted and published in the *International Journal of Systematic and Evolutionary Microbiology*; until that time, the new species name will appear in quotation marks. Microbes that have not been grown in pure culture but for which there is sufficient genetic characterization may be given a provisional genus and species name preceded by the term *Candidatus*, meaning candidate. For instance, a novel aerobic phototrophic member of the phylum *Acidobacterium* has been grown only in coculture with another isolate. It has been given the provisional name *Candidatus Chloracidobacterium thermophilum* (note that the genus and species are not italicized). *Bergey's Manual of Systematic Bacteriology* contains only recognized bacterial and archaeal species and is discussed in section 19.6. ▶▶ *Photosynthetic bacteria* (section 21.4)

Retrieve, Infer, Apply

- 1. What is the difference between a microbial species and a strain?
- 2. Why is it important to have a type strain for each species?
- 3. The genus *Salmonella* was once thought to contain five species. Most scientists now consider only two species valid: *S. bongori* and *S. enterica*. The latter contains six subspecies, and *S. enterica* subspecies *enterica* is further subdivided into eight serovars. Three of these, Enteritidis, Typhi, and Typhimurium, were once considered *Salmonella* species. (a) Inspect figure 19.1 and construct a similar lineage for *Salmonella*. (b) What criteria do you think were used to make these taxonomic changes?

19.3 Exploring Microbial Taxonomy and Phylogeny

After reading this section, you should be able to:

- Review the approaches commonly used to determine taxonomic classification
- Assess the impact molecular methods have had on the field of microbial taxonomy and phylogeny
- Compare and contrast nucleotide sequencing and nonsequencing-based molecular approaches used in microbial taxonomy and phylogeny
- Select an appropriate technique to identify a microbial genus, species, and strain
- Predict the basic biological as well as public health implications of microbial taxonomic identification

Many different approaches are used in classifying and identifying microorganisms that have been isolated and grown in pure culture. For clarity, we divide them into two groups: classical and molecular. The most durable identifications are those that are based on a combination of approaches. Methods often employed in routine laboratory identification of pathogenic bacteria are covered in chapter 36, Clinical Microbiology and Immunology.

Classical Characteristics

Classical approaches to taxonomy make use of morphological, physiological, biochemical, and ecological characteristics. These characteristics have been employed in microbial taxonomy for many years and form the basis for phenetic classification. When used in combination, they are quite useful in routine identification and may provide phylogenetic information as well.

Morphological Characteristics

Morphological features are important in microbial taxonomy for many reasons. Morphology is easy to study and analyze, particularly in eukaryotic microorganisms and more complex bacteria and archaea. In addition, morphological comparisons are valuable because structural features depend on the expression of many genes and are usually genetically stable. Thus morphological similarity often is a good indication of phylogenetic relatedness.

Many different morphological features are employed in the classification and identification of microorganisms (table 19.1). Although the light microscope has always been a very important tool, its resolution limit of about 0.2 μm reduces its usefulness in viewing smaller microorganisms and structures. The transmission

| Table 19.1 | Some Morphological Features Used in Classification and Identification |

and scanning electron microscopes, with their greater resolution, have immensely aided the study of all microbial groups.

◀◀ *Microscopy (chapter 2)*

Physiological and Metabolic Characteristics

Physiological and metabolic characteristics are very useful because they are directly related to the nature and activity of microbial enzymes and transport proteins. Because proteins are gene products, analysis of these characteristics provides an indirect comparison of microbial genomes. **Table 19.2** lists some of the most important of these properties.

Biochemical Characteristics

Among the more useful biochemical characteristics used in microbial taxonomy are bacterial fatty acids, which can be analyzed using a technique called *fatty acid methyl ester* (FAME) analysis. A fatty acid profile reveals specific differences in chain length, degree of saturation, branched chains, and hydroxyl groups. Microbes of the same species will have identical fatty acid profiles, provided they are grown under the same conditions; this limits FAME analysis to only those microbes that can be grown in pure

culture. Finally, because the identification of a species is done by comparing the results of the unknown microbe in question with the FAME profile of other, known microbes, identification is only possible if the species in question has been previously analyzed. Nonetheless, FAME analysis is particularly important in public health, food, and water microbiology. In these applications, microbiologists seek to identify specific microbial pathogens.

▶▶ *Microbiology of food (chapter 41); Water purification and sanitary analysis (section 43.1)*

Ecological Characteristics

The ability of a microorganism to colonize a specific environment is of taxonomic value. Some microbes may be very similar in many other respects but inhabit different ecological niches, suggesting they may not be as closely related as first suspected. Some examples of taxonomically important ecological properties are life cycle patterns; the nature of symbiotic relationships; the ability to cause disease in a particular host; and habitat preferences such as requirements for temperature, pH, oxygen, and osmotic concentration. Many growth requirements are considered physiological characteristics as well (table 19.2).

Molecular Characteristics

It is hard to overestimate how the study of DNA, RNA, and proteins has advanced our understanding of microbial evolution and taxonomy. Evolutionary biologists studying plants and animals draw from a rich fossil record to assemble a history of morphological changes; in these cases, molecular approaches supplement such data. In contrast, microorganisms have left almost no fossil record, so molecular analysis is the only feasible means of collecting a large and accurate data set that explores microbial evolution. When scientists are careful to make only valid comparisons, phylogenetic inferences based on molecular approaches provide the most robust analysis of microbial evolution.

Nucleic Acid Base Composition

Microbial genomes can be directly compared and taxonomic similarity can be estimated in many ways. The first, and possibly the simplest, technique to be employed is the determination of DNA base composition. Base-pairing rules dictate that the $(G + C)/(A + T)$ ratio or **G + C content**—the percent of G + C in DNA—reflects the base sequence and varies with sequence changes as follows:

$$\text{mol\% G + C} = \frac{G + C}{G + C + A + T} \times 100$$

The base composition of DNA can be determined in several ways. The most obvious is genome sequencing. However, for microbes whose genomes have not yet been sequenced, the G + C content often is determined from the **melting temperature** (T_m) of DNA. In double-stranded DNA, three hydrogen bonds join GC base

Figure 19.2 A DNA Melting Curve. The T_m is indicated.

MICRO INQUIRY Would this curve be shifted to the left or the right for a microbe with an exceptionally low G + C composition? Explain your answer.

pairs and two bonds connect AT base pairs. As a result, strands of DNA with a greater G + C content separate at higher temperatures; that is, the DNA has a higher melting temperature. For example, compare *Mycoplasma hominis*, with a mol% G + C of about 29 and a T_m of 65°C, with *Micrococcus luteus*, which is almost 79% G + C with a T_m of 85°C.

DNA melting can be easily followed spectrophotometrically because the absorbance of DNA at 260 nm increases during strand separation. When a DNA sample is slowly heated, the absorbance increases as hydrogen bonds are broken and reaches a plateau when all the DNA has become single-stranded (figure 19.2). The

midpoint of the rising curve gives the melting temperature, a direct measure of the G + C content. When a genome is sequenced, the T_m is determined mathematically.

The G + C content of thousands of organisms has been determined. The G + C content of DNA from animals and higher plants averages around 40% and ranges between 30 and 50%. In contrast, the G + C content of microorganisms varies greatly. Bacterial and archaeal G + C content ranges from about 25 to almost 80% and is more variable than that of fungi and protists. Despite such a wide range of variation, the G + C content of strains within a particular species is constant and varies very little within a genus (table 19.3). If two organisms differ in their G + C content by more than about 10%, their genomes have quite different base sequences, indicating that they are not closely related. On the other hand, it is not safe to assume that organisms with very similar G + C contents also have similar DNA base sequences because two very different base sequences can be constructed from the same proportions of A + T and G + C base pairs.

Nucleic Acid Hybridization

The similarity between genomes can be compared more directly by use of nucleic acid hybridization studies, also called **DNA-DNA hybridization (DDH)**. If the genomes of two microbial isolates are heated to become single-stranded (ss) DNA and then cooled and held at a temperature about 25°C below the T_m , strands with complementary base sequences will reassociate to form stable double-stranded (ds) DNA. However, noncomplementary strands will remain unpaired. Because strands with similar but not identical sequences form less

Table 19.3 Representative G + C Content of Microorganisms

| Organism | Percent G + C | Organism | Percent G + C | Organism | Percent G + C |
|-----------------------|---------------|----------------------------------|---------------|---------------------------------|---------------|
| Bacteria | | <i>Streptococcus</i> | 33–44 | <i>Paramecium</i> spp. | 29–39 |

temperature-stable dsDNA hybrids, incubation of the mixture at 30 to 50°C below the T_m allows hybrids of more diverse ssDNAs to form. Incubation at 10 to 15°C below the T_m permits hybrid formation only with almost identical strands.

In one of the more widely used hybridization techniques, nylon filters with bound nonradioactive DNA strands are incubated at the appropriate temperature with radioactive ssDNA fragments. After the fragments hybridize with the membrane-bound ssDNA, the membrane is washed to remove any nonhybridized ssDNA and its radioactivity is measured. The quantity of radioactivity bound to the filter reflects the amount of hybridization and thus the similarity of the DNA sequences. The degree of similarity is expressed as the percent of experimental DNA radioactivity retained on the filter compared with the percent of homologous DNA radioactivity bound under the same conditions. Two strains whose DNAs show at least 70% relatedness under optimal hybridization conditions and less than a 5% difference in T_m often, but not always, are considered members of the same species.  **DNA Probe (DNA-DNA Hybridization)**

The use of DDH has been considered a vital tool in microbial classification since its introduction in the late 1960s. However, DDH techniques are cumbersome and the results cannot be used on cumulative databases for comparative analysis. For these and other reasons, an alternate approach has been sought. Currently, **average nucleotide identity (ANI)**, which uses pairwise alignment between DNA from two organisms, is considered a promising replacement for DDH. ANI was initially used to compare complete genome sequences but has since been used to compare short stretches of nucleotides generated using massively parallel sequencing techniques, such as pyrosequencing. In general, an ANI value of 95% is comparable to

the 70% value as a minimum value needed for species delineation. Several other nucleotide sequencing-based approaches are also under development; although it unclear which will ultimately replace DDH as the part of the “gold standard,” there is no doubt that DDH has become outdated.  **Determining DNA sequences (section 18.1)**

Nucleic Acid Sequencing

The rRNAs from small ribosomal subunits (16S from bacterial and archaeal cells and 18S from eukaryotes) have become the molecules of choice for inferring microbial phylogenies and making taxonomic assignments at the genus level. The **small subunit rRNAs (SSU rRNAs)** are almost ideal for studies of microbial evolution, relatedness, and genus identification because they play the same role in all microorganisms. In addition, because the ribosome is absolutely necessary for survival and the SSU rRNAs are an integral part of the complex ribosome structure, the genes encoding these rRNAs cannot tolerate large mutations. Thus these genes change very slowly with time and do not appear to be subject to horizontal gene transfer, an important factor in comparing sequences for phylogenetic purposes. The utility of SSU rRNAs is extended by the presence of certain sequences that are variable among organisms and other regions that are quite similar. The variable regions enable comparison between closely related microbes, whereas the stable sequences allow the comparison of distantly related microorganisms.

Comparative analysis of SSU rRNA sequences from thousands of organisms has demonstrated the presence of **oligonucleotide signature sequences (figure 19.3)**. These are short, conserved nucleotide sequences that are specific for phylogenetically defined groups of organisms. Thus the signature sequences found in

Figure 19.3 Small Ribosomal Subunit RNA. bacterial rRNAs are rarely or never found in archaeal rRNAs and vice versa. Likewise, the 18S rRNA of eukaryotes bears signature sequences that are specific to the domain *Eukarya*. Either complete rRNAs or, more often, specific rRNA fragments can be compared. The Ribosomal Database Project website is a repository of hundreds of thousands of rRNA sequences and facilitates accurate comparative analysis.

The ability to amplify regions of rRNA genes (rDNA) by the polymerase chain reaction (PCR) and sequence the DNA using automated sequencing technology has greatly increased the efficiency by which SSU rRNA sequences can be obtained. PCR can be used to amplify rDNA from the genomes of organisms because conserved nucleotide sequences flank the regions of interest. In practice, this means that PCR primers are readily generated to amplify rDNA from both cultured and uncultured microbes. The validity of SSU rRNA sequences as a taxonomic marker has been evaluated in at least two ways. First, analysis of thousands of bacterial and archaeal 16S rRNA sequences reveals that no two microbes with 98.5% 16S rRNA sequence identity have been found with less than the 70% DNA-DNA hybridization cutoff value for the operational definition of a microbial species. Second, genome-based studies have demonstrated that 16S rRNA is a valid and robust measurement of taxonomic relatedness. ◀◀ *Polymerase chain reaction* (section 17.2)

Signature sequences are present in genes other than those encoding rRNA. Many genes have insertions or deletions of specific lengths and sequences at fixed positions. A particular insertion or deletion may be found exclusively among all members of one or more phyla; these are called conserved **indels** (for *insertion/deletion*). These signature sequences are particularly useful in phylogenetic studies when they are flanked by conserved regions. In such cases, changes in the signature sequence cannot be due to sequence misalignments. The signature sequences

located in some highly conserved housekeeping genes do not appear greatly affected by horizontal gene transfers and, like SSU rRNA, can be employed in phylogenetic analysis.

Genomic Fingerprinting

SSU rRNA can also be compared by two methods that do not require sequencing. Instead, the differences in rRNA gene sequences can be discerned by digestion with restriction enzymes. Recall that restriction enzymes cut only at their recognition sequences, so when these sequences vary (even by one nucleotide) in the SSU rRNA gene from different microbial isolates, bands of differing sizes (called restriction fragments) will be seen when the DNA is electrophoresed. There are two ways to examine SSU rRNA genes using restriction enzymes. The first method, called **restriction fragment length polymorphism (RFLP)**, requires PCR amplification of the gene encoding the rRNA. It is then digested with restriction enzymes and run on a gel (figure 19.4). The second method, termed **ribotyping**, omits the need for PCR as the microbe's entire genome is cut with one or more restriction enzymes. The digested DNA is run on a gel and transferred to a nylon filter, and the rRNA encoding DNA fragments are visualized after hybridization with a labeled rRNA gene probe. Thus ribotyping is much like a Southern blot. Importantly, each strain yields a reproducible pattern that can be deposited in a database; such databases are commonly used in clinical diagnostics and food and water analyses. Because both RFLP and ribotyping generate specific patterns that are used to reveal microbial identity, they are often referred to as **genomic fingerprinting**. Any microorganism that is identified solely on its nucleic acid sequence is called a **phylotype**. ◀◀ *Restriction enzymes; Southern blotting* (section 17.1) 🔗 *Restriction Fragment Length Polymorphisms*

1. DNA amplified from different microbial isolates are digested with the same endonuclease (e.g., BamHI).

2. Digested DNA is separated and visualized by gel electrophoresis.

Figure 19.4 Examination of SSU rRNA Genes from Three Different Microbial Isolates Using RFLP Analysis.

MICRO INQUIRY Why does isolate #2 yield only one DNA fragment (band)?

So far we have discussed methods that generally resolve identity only to the genus level. To identify a microbial species, genes that evolve more quickly than those that encode rRNA must be analyzed. In fact, rather than using a single gene, five to seven conserved housekeeping genes can be sequenced and compared in a technique called **multilocus sequence analysis (MLSA)**. Multiple genes are examined to avoid misleading results that can arise through horizontal gene transfer. MLSA compares orthologous genes from a number of strains that may not belong to the same genus. Because many different versions, or alleles, of each gene can exist, the finding that two microbial isolates share the same alleles for multiple genes is very strong evidence that the two strains are closely related, perhaps even the same strain. MLSA was derived from **multilocus sequence typing (MLST)**, which is used to discriminate among strains belonging

to the same pathogenic species. MLSA differs from MLST because its broad application to microbial taxonomy often requires the comparison of genes from more than one microbial species.

Highly conserved and repetitive DNA sequences present in many copies in the genomes of most Gram-negative and some Gram-positive bacteria can also be used to help identify microbes. There are three families of repetitive sequences: the 154 bp BOX elements, the 124–127 bp enterobacterial repetitive intergenic consensus (ERIC) sequence, and 35–40 bp repetitive extragenic palindromic (REP) sequences. These sequences are typically found at distinct sites between genes; that is, they are intergenic. Because they are conserved among genera, oligonucleotide primers can be used to specifically amplify the repetitive sequences by PCR. Different primers are used for each type of repetitive element, and the results are classified as arising from BOX-PCR, ERIC-PCR, or REP-PCR. In each case, the amplified fragments from many microbial samples can be resolved and visualized on an agarose gel. Each lane of the gel corresponds to a single bacterial isolate, and the pattern created by many samples resembles a UPC bar code. The “bar code” is then computer analyzed using pattern recognition software as well as software that calculates phylogenetic relationships. Because DNA fingerprinting enables identification to the level of species, subspecies, and often strain, it is valuable not only in the study of microbial diversity but in the identification of human, animal, and plant pathogens as well.

In comparing the molecular methodological requirements for species definition, we see that with the exception of DNA-DNA hybridization, only a small region of the genome is sampled. As shown in **figure 19.5**, 16S rRNA analysis focuses on one specific gene, whereas MLSA and MLST sample multiple housekeeping genes. While much information is gained using these approaches, several disadvantages have been noted. Novel species of bacteria

Figure 19.5 Genome Coverage of Genetic Taxonomic Approaches.

A typical bacterial or archaeal genome contains at least one locus encoding 16S rRNA. MLSA samples multiple genes throughout the genome. SNP analysis compares more, but shorter, nucleotide sequences that span the entire genome.

| Family | Genus | Species | Subspecies | Strain |
|----------------------------|-------|---------|------------|--------|
| Genome sequencing | | | | |
| 16S rDNA sequencing | | | | |
| Mol% G+C | | | | |
| DNA-DNA hybridization | | | | |
| Multilocus sequence typing | | | | |
| Genomic fingerprinting | | | | |

Figure 19.6 Relative Taxonomic Resolution of Various Molecular Techniques.

and archaea can be missed when using so-called universal primers to amplify 16S rRNA sequences from natural samples. Evolutionary changes in housekeeping genes of certain bacteria, particularly pathogens and other microbes that live in association with other organisms, can be driven by interactions with the host. These changes are not necessarily correlated with housekeeping functions and therefore may not be good candidates for MLSA or MLST.

An alternate technique, **single nucleotide polymorphisms** (SNP, pronounced “snip”), samples a larger fraction of the genome than either 16S rRNA analysis or MLSA (figure 19.5). Originally designed for use in humans, SNP analysis looks at single nucleotide changes, or polymorphisms, in specific genes, intergenic regions, or other noncoding regions. These particular regions are targeted because they are normally conserved, so single changes in a base pair reveal evolutionary change. Recall that some intergenic and noncoding regions are important for gene regulation and thus are also conserved. SNP analysis has been used to distinguish between strains of *Bacillus anthracis* and strains of *Mycobacterium tuberculosis*. **Figure 19.6** shows the taxonomic utility of the molecular methods discussed here with the caveat that a combination of approaches is always best.

Retrieve, Infer, Apply

1. What are the advantages of using each major group of characteristics (morphological, physiological and metabolic, biochemical, ecological, and molecular) in classification and identification? How is each group related to the nature and expression of the genome? Give examples of each type of characteristic.
2. What is the G + C content of DNA, and how can it be determined through melting temperature studies?
3. Why is it not safe to assume that two microorganisms with the same G + C content belong to the same species? In what ways are G + C content data taxonomically valuable?
4. What are the drawbacks of DDH?
5. Why is rRNA so suitable for determining relatedness?
6. How is ribotyping similar to rRNA sequence analysis? How do the two techniques differ? Do you think one is more accurate than the other?

19.4 Phylogenetic Trees

After reading this section, you should be able to:

- Paraphrase the rationale underpinning the construction of phylogenetic trees
- Compare and contrast rooted and unrooted trees
- Outline the general considerations used in building a phylogenetic tree
- Characterize the challenges horizontal gene transfer introduces in the study of microbial evolution

Microbial taxa within *Bacteria* and *Archaea* form discrete, genealogically clustered groups that can be illustrated in phylogenetic trees. **Phylogenetic trees** show inferred evolutionary relationships in the form of multiple branching lineages connected by nodes (figure 19.7). The organism whose nucleotide sequences have been analyzed is identified at the tip of each branch. Each node (branchpoint) represents a divergence event, and the length of the branches represents the number of molecular changes that have taken place between the two nodes.

(a) Sequence alignment and analysis

| Microbe | 1 | 2 | 3 | 4 |
|---------|-----|------|------|------|
| 1 | 1.0 | 0.27 | 0.27 | 0.33 |
| 2 | | 1.0 | 0.27 | 0.33 |
| 3 | | | 1.0 | 0.20 |
| 4 | | | | 1.0 |

(b) Calculated evolutionary distance

| Microbe | 1 | 2 | 3 | 4 |
|---------|-----|------|------|------|
| 1 | 1.0 | 0.32 | 0.32 | 0.44 |
| 2 | | 1.0 | 0.32 | 0.44 |
| 3 | | | 1.0 | 0.26 |
| 4 | | | | 1.0 |

(c) Corrected evolutionary distance

(d) Phylogenetic tree

Often sequences are obtained from well classified microbes that have been grown in pure culture; however, this is not always the case. SSU rRNA sequences have become particularly important in both identifying microbes in nature and constructing phylogenetic trees to describe their evolutionary relationships. An inclusive term for the organism at each branch tip is the **operational taxonomic unit (OTU)**. We now briefly describe how phylogenetic trees can be built with the intention of increasing an understanding of what they represent.

There are five steps in building a phylogenetic tree. First, the nucleotide or amino acid sequence must be aligned. Alignment is usually done using an online resource such as CLUSTAL, although manual inspection of the alignment is also important (figure 19.7a). In addition to SSU rRNA gene sequences, protein-coding genes may also be analyzed, in which case the alignment of amino acids is preferred. This is because the genetic code is degenerate, so even if a nucleotide sequence is not conserved, the amino acid sequence may be. Next the alignment must be examined for a phylogenetic signal; this will determine if it is appropriate to continue with tree building (figure 19.7b). There

are two extremes in this regard: at one end of the spectrum, the sequences align perfectly; the other extreme is the absence of any matches whatsoever. Phylogenetic analysis can only be performed on those sequences that fall in the middle, with a mixture of random and matched positions. The third step is the hardest: one must choose which tree-building method to use. We briefly review some of the more popular methods next. The last two steps involve the application of the method, which is performed by a computer, followed by manual examination of the resulting tree to make sure it makes sense. For example, a tree that places a mammal and an archaeon on the same branch would inspire very little confidence.

The different approaches to building a phylogenetic tree can be divided into two broad categories: a distance-based (phenetic) approach and a character-based (cladistic) approach.

Figure 19.7 Constructing a Phylogenetic Tree Using a Distance Method. (a) Nucleotide sequences are aligned and pairwise comparison is made. The number of nonidentical nucleotides is then scored. For instance, when sequences from microbes 1 and 2 are compared, there are 4 mismatches out of 15 total nucleotides, yielding a calculated evolutionary distance (E_D) of 0.27. (b) The calculated E_D values are corrected to account for back mutation to the original genotype or other forward mutations that could have occurred at the same site before generating the observed genotype. (c) A tree-building method is then selected (in this case, a distance method is used), and computer analysis of the values generates a phylogenetic tree as shown in (d). E_D values are indicated for each branch.

Distance-based approaches are the most intuitive. Here the differences between the aligned sequences are counted for each pair and summarized into a single statistic, which is roughly the percent difference between the two sequences (figure 19.7b,c). A tree is then generated by serially linking pairs that are ever more distantly related (i.e., start with those with the least number of sequence differences and move to those with the most). This is called cluster analysis and should be carefully applied as it has the unattractive capability of generating trees even in the absence of evolutionary relationships. Neighbor joining is another distance-based method that uses a slightly different matrix that attempts to avoid this problem by modifying the distance between each pair of nodes based on the average divergence from all other nodes.

Character-based methods for phylogenetic tree building are more complicated but generate more robust trees. These methods start with assumptions about the pathway of evolution, infer the ancestor at each node, and choose the best tree according to a specific model of evolutionary change. These methods include maximum parsimony, which assumes that the fewest number of changes occurred between ancestor and extant (living) organisms. Another approach is called maximum likelihood. This requires a large data set because for each possible tree that can be built, its probability (i.e., the likelihood) based on certain evolutionary and molecular information is evaluated. All tree building methods have their advantages and disadvantages, so it is usually advisable to use several methods to analyze the same data set. Similar trees generated by different approaches is the best outcome.

Importantly, a tree may be unrooted or rooted. An unrooted tree (figure 19.8a) simply represents phylogenetic relationships but does not provide an evolutionary path. Figure 19.8a shows that A is more closely related to C than it is to either B or D, but it does not specify the common ancestor for the four species or the direction of change. In contrast, the rooted tree (figure 19.8b) gives a node that serves as the common ancestor and shows the development of the four species from this root. It is much more difficult to develop a rooted tree. For example, there are 15 possible rooted trees that connect four species but only three possible unrooted trees.

An unrooted tree can be rooted by adding data from an outgroup—a species known to be very distantly related to all the species in the tree (figure 19.8c). The root is determined by the point of the tree where the outgroup joins. This provides a point of reference to identify the oldest node on the tree, which is the node closest to the outgroup.

Once a tree is constructed, it is important to get a sense of whether the placement of its branches and nodes is legitimate. There are a variety of methods to assess the “strength” of a tree, but the most common is bootstrapping. Bootstrapping involves phylogenetic analysis of a randomly selected subset of the data presented on the tree. A bootstrap value is the percent of analyses in which that particular branch was found. Typically bootstrap values of 70% or greater are thought to support a tree. Another approach, called Bayesian inference, may also be used. Rather than looking at a single tree, Bayesian inference analyzes multiple potential trees and calculates the probability that each branch would

appear based on this comparison. Although these values are also reported as percentages, they are not directly comparable to bootstrap values. Only values greater than 95% are acceptable when Bayesian inference is used.

An important feature in phylogenetic trees is the scale. Just as a scale bar on a road map indicates distance in number of kilometers per centimeter, the scale bar on a phylogenetic tree illustrates the evolutionary distance. This is usually measured in number of mutations per 1,000 nucleotides or amino acid substitutions per 1,000 amino acid residues. This may be expressed as a number without units, e.g., 0.02 (2 per 1,000). To continue our analogy with a road map, just as a map does not reveal how long it takes to get from one point to another (due to traffic, weather,

Figure 19.8 Phylogenetic Tree Topologies. (a) Unrooted tree joining four taxonomic units. (b) Rooted tree. (c) The tree shown in (a) can be rooted by adding an outgroup, represented by Z.

variable road conditions), the branches on a phylogenetic tree do not indicate the length of time it took for an ancestral microbe to give rise to an extant form. As discussed in section 19.5, the theory of punctuated equilibria is one important reason evolutionary distance, as measured by the similarity of genes or proteins in living organisms, provides little or no information regarding how long ago evolutionary divergence occurred.

One of the biggest challenges in constructing a satisfactory tree is widespread, frequent horizontal gene transfer (HGT). Although microbiologists are careful to exclude from their analysis genes and proteins known to have been subject to HGT, the influence of HGT on phylogeny and evolution cannot be ignored. Indeed, eukaryotes possess genes from both bacteria and archaea, and there has been frequent gene swapping between the bacterial and archaeal domains. Some bacteria even have acquired eukaryotic genes. Clearly, the pattern of microbial evolution is not truly linear and treelike.

Assessing the impact HGT has had on microbial evolution has been guided by genome sequence analysis. Comparisons of the genomes of strains within a species and among species within a phylum have revealed that microbial genomes consist of an older core genome and a more recently acquired pan-genome (figure 19.9). The **core genome** is that set of genes found in all members of a species (or other monophyletic group). Thus it is thought to represent the minimal number of genes needed for the microbes to survive. In general, these genes encode “informational” proteins involved in replication, transcription, and translation (e.g., the rRNA genes).

These genes are thought to have been present in the group’s common ancestor. By contrast, the **pan-genome** is the combination of all the different genes found among all taxa being compared but not in each taxon. These are more recently acquired genes that enable microbial colonization of new niches. A comparison of the core genome size with the actual genome size of a particular strain thus indicates the evolution of new traits. For instance, current values of the core genome and pan-genome of *Bacillus anthracis* differ by only roughly 200 genes (about 3,600 versus 3,800, respectively), whereas the same estimate for *E. coli* is over 3,000 genes (about 2,800 for the core genome and 6,000 for the pan-genome). The limited genetic diversity among *B. anthracis* strains reflects the fact that its growth is restricted to only a few habitats. The enormous diversity among strains of *E. coli* has allowed this species to radiate to numerous habitats. Obviously for any given species, the accuracy with which the core and pan-genome can be compared will depend on the number of strains with sequenced genomes. ❖❖ *Mechanisms of genetic variation* (chapter 16)

1. Could a phylotype be considered an OTU? What about a species?
2. List the differences between distance-based and character-based methods for constructing a phylogenetic tree. Which type is maximum parsimony? Explain your answer.
3. What is the difference between a rooted and unrooted tree? Which provides more information?
4. You are building a tree based on 16S rRNA sequence alignments of a group of spirochetes. Suggest a possible outgroup so that you can build a rooted tree. Refer to chapter 21 if you need more information about these bacteria.
5. Is HGT involved in movement of genes in the core or pan-genome? Explain.

Figure 19.9 Core and Pan-Genomes. The number of genes in each core genome is listed at each branch point (node). The size of the pan-genomes for *E. coli*, *Streptococcus agalactiae*, and *B. anthracis* are noted.

19.5 Evolutionary Processes and the Concept of a Microbial Species

After reading this section, you should be able to:

- Diagram the endosymbiotic theory of the origin of mitochondria and chloroplasts
- Compare and contrast the two theories that address the origin of the nucleus
- Explain why the concept of a microbial species is difficult to define
- List the “gold standard” taxonomic methods currently applied to species designation
- Explain the importance of adaptive mutations in giving rise to new ecotypes

It is our goal here to describe current models that seek to explain the evolution of new microbial species. Before we begin this discussion, however, it is helpful to consider the origin of all microbes—bacterial, archaeal, and eukaryotic. We then need to review the controversy that surrounds the word species as applied to bacteria and archaea. Only then will it be possible to understand and appreciate the evolutionary mechanisms that drive the development of new species of microorganisms.

Evolution of the Three Domains of Life

As we present in chapter 1, many scientists think that the first self-replicating entity was RNA. This is because RNA has the capacity to reproduce itself as well as catalyze chemical reactions. It is thought that when early RNA became enclosed in a lipid sphere, the first primitive cell-like forms were generated (see figures 1.5 and 1.6). Considerable evidence indicates that by at least 3.5 billion years ago, such proto-cells (Greek, *protos*, meaning first) had evolved to form the ancestors of our extant microbes. Moreover, by 2.5 billion years ago, bacteria and archaea not only abounded, but each had evolved distinct taxonomic lineages. For instance, *Archaea* had diverged into two major phyla, *Crenarchaeota* and *Euryarchaeota*. Similarly the Gram-positive bacterial phylum *Firmicutes* and Gram-negative phyla *Proteobacteria* and *Cyanobacteria* had developed. Indeed, the ancestors of modern *Cyanobacteria* performed the oxygenic photosynthesis responsible for converting our anoxic planet to an oxygenated one.

A reexamination of the tree of life based on SSU rRNA (see figure 1.2) shows that the root of the tree is on the earliest region of the bacterial branch. As we discuss in chapter 1, the root is considered the last universal common ancestor, or LUCA. The placement of LUCA indicates that although bacteria and archaea share similar cellular construction, they are not phylogenetically linked. Because LUCA maps to the bacterial branch of the tree, it is thought that *Archaea* and *Eukarya* evolved independently of *Bacteria*. Recall that this was first suggested by Carl Woese and George Fox in the 1970s. Since that time, the evolutionary distance they inferred from bacterial and archaeal SSU rRNA sequences has also been demonstrated by a number of biochemical

differences. These include membrane lipids, cell wall construction, and enzymes involved in gene transcription (table 19.4).

Notice that the placement of LUCA suggests that *Archaea* and *Eukarya* descended from the same ancestor but diverged to become separate domains. As seen in table 19.4, RNA polymerases and the regulation of gene transcription (“information processing”) in the archaea are more similar to that in eukaryotes than in bacteria. ◀◀ *Archaeal and eukaryotic genome replication and expression* (chapter 15)

Although *Archaea* and *Eukarya* share a recent common ancestor, eukaryotes possess both archaeal and bacterial traits. There are several hypotheses that account for genes of both archaeal and bacterial ancestry on the eukaryotic nuclear genome. One hypothesis asserts that an archaeon and a bacterium living in close association fused (figure 19.10a). Over time, archaeal genes involved in metabolism were lost while bacterial genes involved in information processing were also degraded. Another hypothesis involves a series of endosymbioses, rather than fusion (figure 19.10b). Here the archaeal cell is thought to have engulfed the bacterium, which then donated genes to the proto-nuclear genome by HGT. Others argue that eukaryotes evolved more slowly through numerous HGT events. Finally, structural and molecular similarities between some members of the *Planctomycetes* and eukaryotes have led to several hypotheses that suggest ancient relatives of these Gram-negative bacteria gave rise to the first eukaryotes. This scenario agrees well with the SSU tree of life (see figure 1.2), which suggests that archaea and eukaryotes are similar in age. ▶▶ *Phylum Planctomycetes* (section 21.5)

Unlike the uncertainty surrounding the origin of the first eukaryotic proto-cell, there is general agreement that mitochondria and chloroplasts arose by the incorporation of endosymbiotic bacteria. Like bacteria, most mitochondria and chloroplasts have a single, circular chromosome and undergo binary fission. In addition, mitochondria and chloroplasts have 70S, not 80S, ribosomes. These observations led to the development of the **endosymbiotic hypothesis** (figure 19.11). This theory posits the following series of events. An ancestral eukaryotic cell lost its rigid cell wall but had evolved actin (or its precursor) that enabled amoeboid motility. This nucleated cell was then able to develop endocytosis. These mobile proto-eukaryotes became predators of other cells, including bacteria. Predation imposed selection for cellular enlargement and increased motility. Engulfment without digestion of bacterial prey evolved because a smaller bacterial cell provided energy for the larger host cell, while the host protected and supplied nutrients to the bacterial cell. The energy supplied by the endosymbiont must have conferred a growth advantage to the proto-eukaryote, enabling its dominance over other cells that lacked both cell walls and endosymbionts.

As the endosymbiont became more dependent on its host for nutrients and protection, there was little selective pressure for the retention of genes involved in these processes. Conversely, because the endosymbiont was “permitted” to remain only if it captured and stored energy (presumably as ATP), there was strong selective pressure to retain the genes involved in energy conservation. Thus genes whose products were redundant

Table 19.4 Comparison of *Bacteria*, *Archaea*, and *Eukarya*

| Property | <i>Bacteria</i> | <i>Archaea</i> | <i>Eukarya</i> |
|--|---|--|---|
| Membrane-Enclosed Nucleus with Nucleolus | Absent | Absent | Present |
| Complex Internal Membranous Organelles | Absent | Absent | Present |
| Cell Wall | Almost always have peptidoglycan containing muramic acid | Variety of types, no muramic acid; some have pseudomurein | No muramic acid |
| Membrane Lipid | Have ester-linked, straight-chained fatty acids | Have ether-linked, branched isoprene-derived chains | Have ester-linked, straight-chained fatty acids |
| Gas Vesicles | Present | Present | Absent |
| Transfer RNA | Thymine present in most tRNAs <i>N</i> -formylmethionine carried by initiator tRNA | No thymine in T or TΨC arm of tRNA Methionine carried by initiator tRNA | Thymine present Methionine carried by initiator tRNA |
| Polycistronic mRNA | Present | Present | Present in some protists |
| mRNA Introns | Rare | Rare | Present |
| mRNA Splicing, Capping, and Poly-A Tailing | Absent | Absent | Present |
| Ribosomes | | | |
| Size | 70S | 70S | 80S (cytoplasmic ribosomes) |
| Elongation factor 2 reaction with diphtheria toxin | Does not react | Reacts | Reacts |
| Sensitivity to chloramphenicol and kanamycin | Sensitive | Insensitive | Insensitive |

to the host eroded and were eventually lost. In fact, such genome reduction is the rule, rather than the exception, among obligate intracellular microbes (*see figure 18.18*).

Finally, as genome reduction continued, the endosymbiont was so dependent on its host, it had evolved into an energy-providing organelle. It was originally postulated that the endosymbiont was capable of oxidative phosphorylation and so gave rise to the mitochondrion. However, more recent evidence suggests that the endosymbiont was an anaerobic bacterium with a fermentative metabolism. These endosymbionts then evolved into either hydrogenosomes or mitochondria. Hydrogenosomes are found in some extant protists where, like mitochondria, they take up pyruvate that results from glycolysis within the host cytoplasm. Unlike mitochondria, however, pyruvate in the hydrogenosome is reduced to acetate, H_2 , and CO_2 with an additional ATP generated

Figure 19.11 The Endosymbiotic Theory. (a) According to this hypothesis, mitochondria were derived from an α -proteobacterium. (b) A similar phenomenon occurred for chloroplasts, which were derived from cyanobacteria.

MICRO INQUIRY On what evidence is this hypothesis based?

(see figure 5.16). The similarity between certain key genes (and thus their protein products) supports the notion that hydro-genosomes and mitochondria evolved from a single common ancestor, probably related to the α -proteobacterium *Rickettsia prowazekii* (see p. 513). Mitochondria appear to be more highly derived (i.e., continued to evolve), since these organelles are the site of oxidative phosphorylation.

Chloroplasts arose when these new aerobic eukaryotes engulfed a cyanobacterium—probably an ancestor of *Prochlorococcus* (see p. 500). Again, this led to the development of a mutualistic relationship that evolved into our extant green plants and algae—organisms that possess both mitochondria and chloroplasts. Such endosymbioses exist today in certain protists that retain living cyanobacteria or the functional chloroplasts of their algal prey. However, this picture is a bit complicated by a secondary endosymbiotic event that gave rise to the red algae (e.g., the heterokonts, haptophytes, and cryptomonads; see chapter 25). Here it is thought a eukaryotic cell with a mitochondrion-like organelle engulfed a eukaryotic-like cell that possessed both a mitochondrion and chloroplast. ◀◀ *Microbial Diversity & Ecology 5.1*

The Concept and Definition of a Microbial Species

The term “species concept” describes a theoretical framework used to understand how and why certain organisms can be sorted into discrete taxonomic groups. We have already discussed “species definition” in sections 19.2 and 19.3, when we reviewed the criteria used to identify a microbial genus, species, or strain. From this, we can see that species definition is the application of the species concept.

Both species concept and definition have changed over time and continue to be difficult for microbiologists to agree upon. Historically, microbiologists used taxonomic systems designed to identify and classify plants and animals. However, bacteria and archaea lack sexual reproduction, extensive morphological features, and a fossil record. Thus when applied to microbes, the phenetic system has always been considered limited, even when a polyphasic approach is employed. The development of chromosome-based approaches, including G + C ratios and DNA-DNA hybridization, was considered a breakthrough when introduced about 50 years ago. Biochemical methods also gained popularity, and characterization of the cell wall components, lipids (e.g., FAME analysis), and other chemotaxonomic indicators were used. Although Carl Woese introduced SSU rRNA gene sequencing about 30 years ago and its validity has been intensively studied, it was not until 2002 that those charged with determining the necessary criteria for microbial species definition, the International Committee on Systematics of Prokaryotes (ICSP), recommended its use. Importantly, unlike whole genome hybridization, SSU rRNA gene comparisons can be performed on microorganisms that are not in pure culture.

Historically, the application of different criteria in making species assignments has led to microbial taxonomic confusion. In some cases, a single microbial species is so metabolically and genetically

diverse that it seems probable that the group represents multiple species. On the other hand, some species are very narrowly defined, such that two species differ very little. For instance, *Bacillus anthracis* strains are so similar to *B. cereus*, many believe that all *B. anthracis* strains are really members of the *B. cereus* species. It is argued that only because *B. anthracis* causes anthrax does it have its own species designation.

In an effort to clarify and standardize microbial taxonomy, the ICSP recommends a “gold standard” for species assignment: phenotypic or morphological similarity to others in the group, whole genome similarity as determined by DNA-DNA hybridization of at least 70%, the melting temperature of the DNA (a reflection of the G + C content) within 5°C, and less than 3% divergence in rRNA gene sequence. Some remain uncomfortable with these criteria, pointing out that two microorganisms with, for instance, only 75% similarity in DNA and 98% rRNA gene sequence identity can be considered the same species. However, if these criteria were applied to eukaryotes, all primates (monkey, apes, you) would be lumped together as a single species! Indeed, it remains unresolved whether or not the species concept can be applied to microbes.

Microbial Evolutionary Processes

While the debate regarding the operational definition of a microbial species continues, most microbiologists agree that the microbial species concept is grounded in natural selection and evolution. As the most ancient life forms on Earth, bacteria and archaea have had the opportunity to evolve and adapt to virtually every habitat. While their diverse metabolic strategies and ability to tolerate extreme conditions explain *why* microbes display such enormous diversity, natural selection explains *how* this diversity came to be.

Recall that genetic diversity in members of the *Archaea* and *Bacteria* must occur asexually. Thus heritable genetic changes in these organisms are introduced principally by two mechanisms: mutation and HGT, both of which are subject to natural selection. Because diverse individuals arise from a genetically homogeneous population, HGT is not relevant when considering the initial evolution of diversity within a given taxon. That is to say, even if HGT does occur, very little (if any) genetic diversity is introduced because the individuals are so similar. Rather, genetic variation must arise within a homogeneous population by mutation, gene loss and gain, and intragenomic recombination (figure 19.12a).

Anagenesis, also known as **genetic drift**, refers to small, random genetic changes that occur over generations. It might seem that very small genetic differences within a microbial population would be of little evolutionary significance. However, model studies designed to assess competition between microbial populations has led to some surprising observations. When selection is applied, very small genetic differences can result in one population overtaking another. How does this happen when individuals within a population have similar mutation rates and most of these

(a) Mechanisms of genetic variation within a homogeneous population

(b) Stable ecotype model

Figure 19.12 Evolution of Microbial Diversity. (a) Mechanisms by which a single, genetically homogeneous population of microbes can develop genetic variation include mutation, gene loss and duplication, and recombination. (b) Genetic changes within a population can lead to the development of new ecotypes. Each ecotype is subject to periodic selection events (indicated by stars) that enable cells with adaptive mutations to outcompete other lineages, which are eventually driven to extinction (dotted lines). The solid lines represent successful populations or lineages; those at the top are extant.

MICRO INQUIRY Construct a scenario in which each of the following factors lead to the establishment of two ecotypes from a single common ancestor, as shown in (b): the availability of carbon and nitrogen sources; terminal electron acceptor; and mean local temperature.

mutations are neutral and have no phenotypic effect? Only those rare mutations that confer a growth advantage, called **adaptive mutations**, are retained and passed from one generation to the next; that is, the mutation is fixed. The descendants of that individual continue to evolve through mutation and other intraspecific mechanisms.

Adaptive mutation is key to the ecotype model of microbial evolution. An **ecotype** is a population of microbes that is

genetically similar (usually determined by 16S rRNA sequencing) but ecologically distinct. Ecotypes arise when members of a microbial population living in a specific ecosystem undergo a genetic event (or series of events) that enables them to outcompete the remainder of the population. According to the ecotype model, the acquisition of adaptive mutations ultimately drives the remaining members of the population into extinction and reduces the amount of genetic diversity within the surviving population (figure 19.12b). The fossil record shows that the pace of evolution does not always occur at a constant rate but is periodically interrupted by rapid bursts of speciation driven by abrupt changes in the environment. Niles Eldredge and Steven Jay Gould coined the term **punctuated equilibria** to describe this phenomenon. Certainly, the 3.5-billion-year history of microbial life on Earth affords the accumulation of many, many mutations; that in turn has resulted in speciation. ◀◀ *Mechanisms of genetic variation (chapter 16); Comparative genomics (section 18.7)*

In considering microbial evolution and diversity, we cannot completely ignore horizontal transfer of genetic material. Recall that the pan-genome is the complete gene repertoire of a taxon, so it includes the core genome plus housekeeping and dispensable genes. Housekeeping genes are generally defined as those genes whose products are required for normal metabolism and growth. In general, genes within the pan-genome are considered to have been acquired by HGT (figure 19.13).

Unlike the variation introduced in the ecotype model, HGT-driven genetic variation requires a genetically heterogeneous group of microbes. This is because HGT does not rely on replication but rather on the exchange of genetic material within the same generation. The rate of HGT is extremely variable. Some microbes have very reduced genomes with no evidence of HGT. These microbes are generally highly adapted to a specific, stable ecological niche. The most extreme examples are obligate intracellular symbionts that can only grow within their host cells. By contrast, some microbes appear to have a high rate of HGT with almost a third of their genome acquired from genetic exchange. In these bacteria and archaea, genes acquired by horizontal transfer frequently expand metabolic capabilities. It is thought that in general, speciation is driven by mutation, while the rapid adaptation to new environmental challenges is mediated by HGT.

Finally, we pose the question: How many bacterial and archaeal species are there? There are two major obstacles to formulating an answer. First, most microbial species resist growth in the laboratory, so they can only be detected by metagenomic or other culture-independent approaches. Second, as we have seen, microbiologists cannot agree on a biological species concept. So we must resort to the operational definition of a species in terms of G + C content and percent SSU rRNA and DNA homologies, as well as similarities in physiology, morphology, and ecology. Based on these considerations, there are over 7,000 accepted species. But estimates range from 100,000 to 1,000,000 species in nature, with about 10^{30} individual cells. These estimates reveal

Figure 19.13 Horizontal Gene Transfer (HGT) and the Pan-Genome. (a) The acquisition of genes from other populations of microbes is mediated by phage infection, conjugation, and transformation. During conjugation and transformation, transferred genes can be integrated directly into the chromosome or encoded on a plasmid, as shown here. (b) The prevalence of genes that have been horizontally transferred has given rise to the concept of a core genome—genes found in all members of a taxon, and a pan-genome—the combination of the core genome and all additional genes acquired principally by HGT within the taxon.

MICRO INQUIRY Which do you think would have a pan-genome more closely related to its core genome: a microbial species whose strains are obligate intracellular symbionts, or a species whose strains are part of the normal flora of the mammalian gut? Explain your answer.

that there are probably about a billion more microbes on Earth than stars in the universe.

Retrieve, Infer, Apply

1. Define ecotype. Do you think it is necessary to obtain microbes in pure culture before assigning different ecotypes?
2. What is the difference between the core genome and pan-genome? What might you infer if you compare two genera, one in which the size of the core genome and pan-genome are very similar, and one in which the core genome is much smaller than the pan-genome?
3. Of the following genes, which do you think are part of the pan-genome and which are part of the core genome: the genes for lactose catabolism in *E. coli*; the genes for heat-stable DNA polymerase in *Thermus aquaticus*; the genes for proteorhodopsin in marine bacteria; the genes for toxin production in *Vibrio cholerae*?
4. Would a protein encoded on the core genome or one encoded only on the pan-genome be best to use in constructing a phylogenetic tree? Explain your answer.

19.6 Bergey's Manual of Systematic Bacteriology

After reading this section, you should be able to:

- Employ *Bergey's Manual* to investigate the defining taxonomic elements used for a bacterium or archaeon that is unfamiliar to you

In 1923 David Bergey, professor of bacteriology at the University of Pennsylvania, and four colleagues published *Bergey's Manual of Determinative Bacteriology*, a classification of bacteria that could be used for the identification of many bacterial species. The ninth edition of this single-volume manual was published in 1994. Despite its age, this text continues to serve as a relatively brief reference guide in the identification of bacteria based on physiological and morphological traits.

In 1984 the first edition of *Bergey's Manual of Systematic Bacteriology* was published. It contained descriptions of all bacterial and archaeal species then identified (**Microbial Diversity & Ecology 19.1**). A more recent second edition consists of five volumes published over a number of years, starting in 2001. Each volume covers a specific group of microbes and is written by experts in that particular field. The morphology, physiology, growth conditions, ecology, and other information is provided, making this a valuable reference for microbiologists.

The second edition of *Bergey's Manual of Systematic Bacteriology* reflects the enormous progress that has been made in microbial taxonomy since the first edition was published. This is particularly true of the molecular approaches to phylogenetic analysis. Whereas microbial classification in the first edition was phenetic (based on phenotypic characterization), classification in the second edition of *Bergey's Manual* is largely phylogenetic. Although Gram-staining properties are generally considered phenetic characteristics, they also play a role in the phylogenetic classification of microbes.

In addition to the reorganization based on phylogeny, the second edition has more ecological information about individual taxa. It does not group all the clinically important bacteria together as the

Microbial Diversity & Ecology

19.1 "Official" Nomenclature Lists—A Letter from Bergey's

On a number of occasions lately, the impression has been given that the status of a bacterial taxon in *Bergey's Manual of Systematic Bacteriology* or *Bergey's Manual of Determinative Bacteriology* is in some sense official. Similar impressions are frequently given about the status of names in the Approved List of Bacterial Names and in the Validation Lists of newly proposed names that appear regularly in the *International Journal of Systematic Bacteriology*. It is therefore important to clarify these matters.

There is no such thing as an official classification. *Bergey's Manual* is not "official"—it is merely the best consensus at the time, and although great care has always been taken to obtain a sound and balanced view, there are always regions in which data are lacking or confusing, resulting in differing opinions and taxonomic instability. When *Bergey's Manual* disavows that it is an official classification, many bacteriologists may feel that the solid earth is trembling. But many areas are in fact reasonably well established. Yet taxonomy is partly a matter of judgment and opinion, as is all science, and until new information is available, different bacteriologists may legitimately hold different views. They cannot be forced to agree to any "official classification." It must be remembered that, as yet, we know only a small percentage of the bacterial species in nature. Advances in technique also shed new light on bacterial relationships. Thus we must expect that existing boundaries of groups will have to be redrawn in the future, and it is expected that molecular biology, in particular, will experience a good deal of change over the next few decades.

The position with the Approved Lists and the Validation Lists is rather similar. When bacteriologists agreed to make a new start in bacteriological nomenclature, they were faced

with tens of thousands of names in the literature of the past. The great majority were useless, because, except for about 2,500 names, it was impossible to tell exactly what bacteria they referred to. These 2,500 were therefore retained in the Approved Lists. The names are only approved in the sense that they were approved for retention in the new bacteriological nomenclature. The remainder lost standing in the nomenclature, which means they do not have to be considered when proposing new bacterial names (although names can be individually revived for good cause under special provisions).

The new International Code of Nomenclature of Bacteria requires all new names to be validly published to gain standing in the nomenclature, either by being published in papers in the *International Journal of Systematic Bacteriology* or, if published elsewhere, by being announced in the Validation Lists. The names in the Validation Lists are therefore valid only in the sense of being validly published (and therefore they must be taken account of in bacterial nomenclature). The names do not have to be adopted in all circumstances; if users believe the scientific case for the new taxa and validly published names is not strong enough, they need not adopt the names. For example, *Helicobacter pylori* was immediately accepted as a replacement for *Campylobacter pylori* by the scientific community, whereas *Tatlockia micdadei* had not generally been accepted as a replacement for *Legionella micdadei*. Taxonomy remains a matter of scientific judgment and general agreement.

first edition did. Instead, pathogenic species are placed phylogenetically and thus scattered throughout the five volumes:

- Volume 1, *The Archaea and the Deeply Branching and Phototrophic Bacteria*
- Volume 2, *The Proteobacteria*
- Volume 3, *The Firmicutes*
- Volume 4, *The Bacteroidetes, Spirochaetes, Tenericutes (Mollicutes), Acidobacteria, Fibrobacteres, Fusobacteria, Dictyoglomi, Gemmatimonadetes, Lentisphaerae, Verrucomicrobia, Chlamydiae, and Planctomycetes*
- Volume 5, *The Actinobacteria*

Figure 19.14 illustrates most of the groups covered in *Bergey's Manual* and in chapters 20–24.

Retrieve, Infer, Apply

1. Why is the second edition of *Bergey's Manual* no longer based on phenetic classification?
2. Describe two different situations in which it would be essential to identify the genus and species of a bacterium or archaeon.

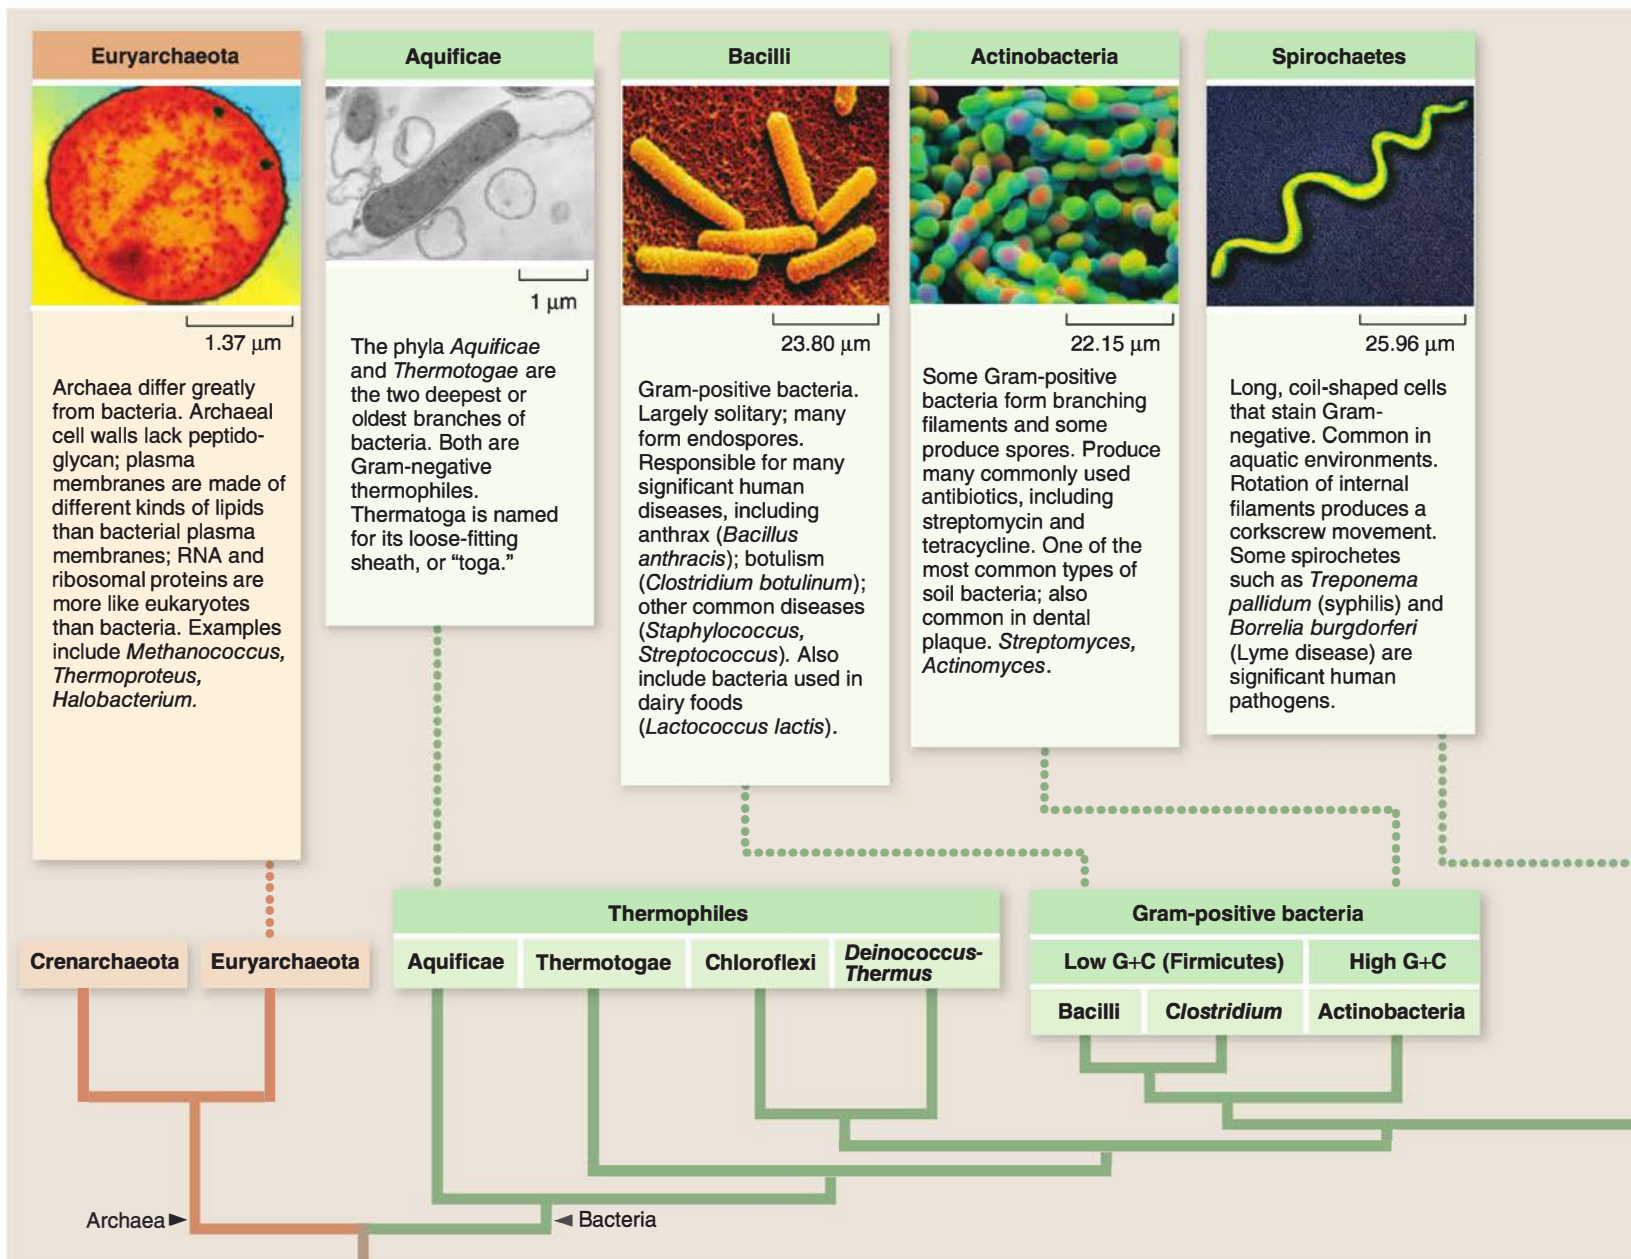

Figure 19.14 Some Major Clades of *Bacteria* and *Archaea*. This classification scheme is based on *Bergey's Manual of Systematic Bacteriology*, 2nd ed.

Key Concepts

19.1 Introduction to Microbial Taxonomy

- Taxonomy, the science of biological classification, is composed of three parts: classification, nomenclature, and identification.
- A polyphasic approach is used to classify microbes. This incorporates information gleaned from genetic, phenotypic, and phylogenetic analysis.

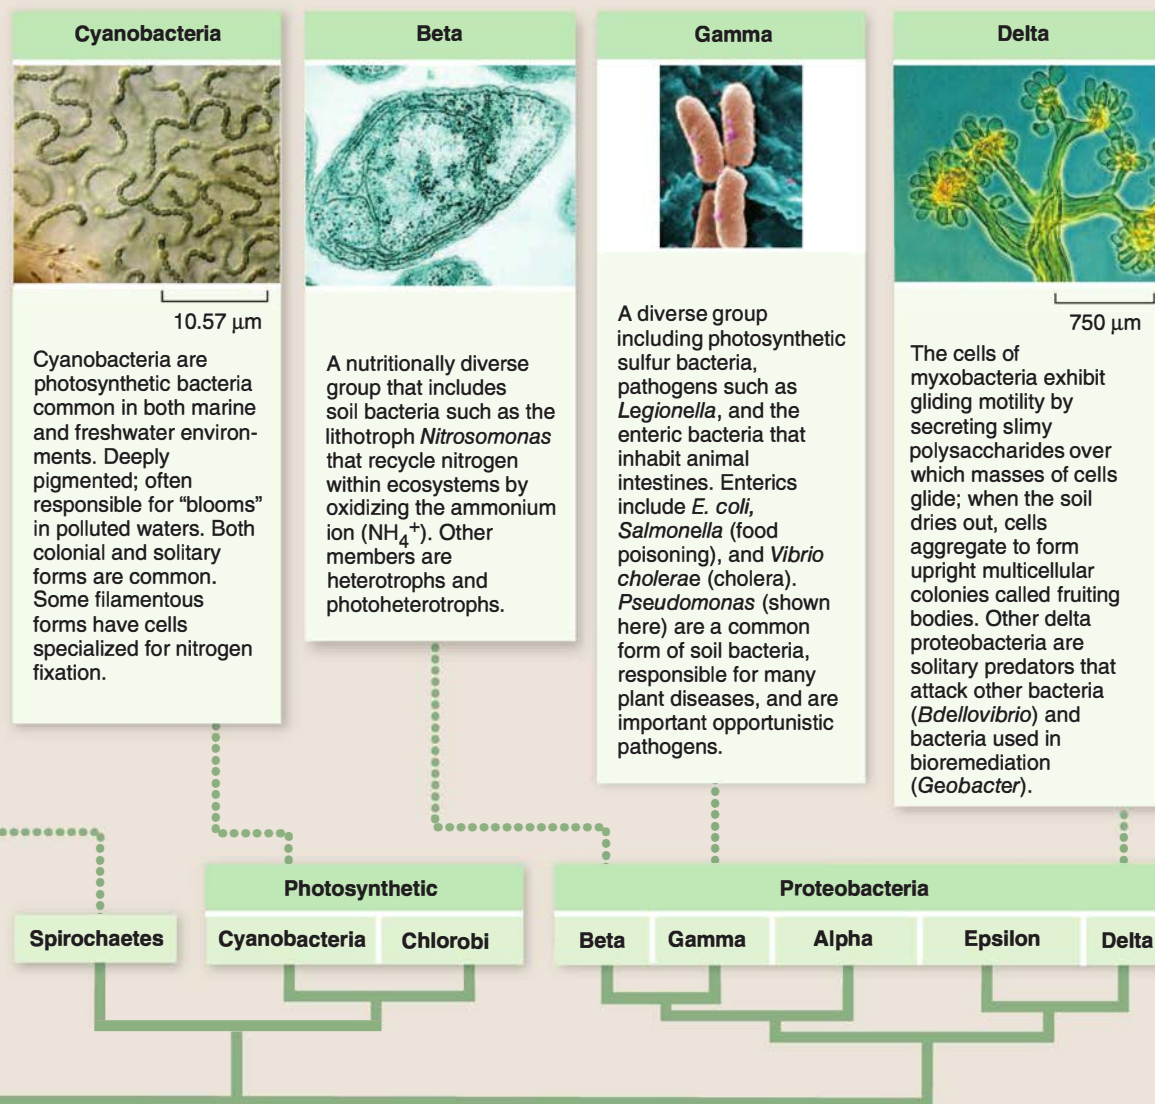

19.2 Taxonomic Ranks

- Taxonomic ranks are arranged in a nonoverlapping hierarchy (figure 19.1).
- A bacterial or archaeal species is a collection of strains that have many stable properties in common and differ significantly from other groups of strains.

- Microorganisms are named according to the binomial system.

19.3 Exploring Microbial Taxonomy and Phylogeny

- Historically, microbial taxonomic and phylogenetic analysis used morphological, physiological, and ecological characteristics. These remain important in building a complete picture that also includes molecular information.
- The G + C content of DNA is taxonomically valuable because it is an indirect reflection of the base sequence.
- Nucleic acid hybridization studies are used to compare DNA or RNA sequences and thus determine genetic relatedness.
- Nucleic acid sequencing is the most powerful and direct method for comparing genomes. The sequences of SSU rRNA

are used most often in phylogenetic studies of microbes (figure 19.3). Alternatively, SSU rRNA genes can be analyzed by phylotyping, which does not require PCR amplification or nucleotide sequencing (figure 19.4).

- Additional techniques must be applied to identify a microbe at the species or strain level. They include restriction fragment length polymorphism (RFLP) analysis, multilocus sequence typing (MLST), the study of repetitive sequences, and single nucleotide polymorphism analysis (figures 19.5 and 19.6).

19.4 Phylogenetic Trees

- Phylogenetic relationships often are shown in the form of branched diagrams called phylogenetic trees. Trees are based on pairwise comparison of amino acid or nucleotide sequences, followed by computer analysis (figure 19.7).

- Trees may be either rooted or unrooted and are created in several different ways. Unrooted trees can be rooted by including an outgroup when the tree is constructed (figure 19.8).
- Microbes have a long history of horizontal gene transfer, which confuses taxonomic analysis. Complete genome analysis has revealed a set of core genes found in all members of a given taxon and a pan-genome, which is the sum of all genes outside the core genome of that taxon. The pan-genome is the result of horizontal gene transfer (figure 19.9).

19.5 Evolutionary Processes and the Concept of a Microbial Species

- The origin of eukaryotic cells is thought either to have involved the fusion of an archaeal cell with a bacterium or to have been the result of a bacterial endosymbiont within an archaeon (figure 19.10). Most biologists agree that

endosymbioses of a bacterium and a cyanobacterium gave rise to mitochondria and chloroplasts, respectively (figure 19.11).

- The operational definition of a microbial species is based on criteria approved by the International Committee on the Systematics of Prokaryotes. This includes at least 70% whole genome similarity as determined by DNA-DNA hybridization, at least 97% 16S rRNA homology, no more than a 5°C difference in % G + C, and physiological, morphological, and ecological similarity.
- The concept of a microbial species is based on evolution. The ecotype model describes the outcome of a periodic natural selection on a genetically homogeneous microbial population. Individuals that acquire adaptive mutations are the source of microbial diversity (figure 19.12).

- Horizontal gene transfer is also important in microbial evolution. However, speciation is thought to be the outcome of mutation, while rapid adaptation to new niches is mediated by horizontal gene transfer (figure 19.13).

19.6 Bergey's Manual of Systematic Bacteriology

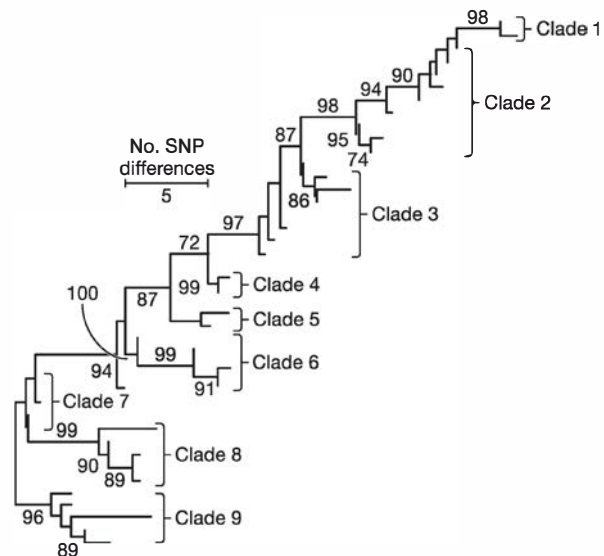

- *Bergey's Manual of Systematic Bacteriology* is based on the accepted system of prokaryotic taxonomy.
- The second edition of *Bergey's Manual* provides phylogenetic classifications. Bacteria are classified among 26 phyla and archaea are divided between two phyla. Comparisons of nucleic acid sequences, particularly 16S rRNA sequences, are the foundation of this classification.

Compare, Hypothesize, Invent

1. Consider the fact that the use of 16S rRNA sequencing as a taxonomic and phylogenetic tool has resulted in tripling the number of bacterial phyla. Why has the advent of this genetic technique expanded the currently accepted number of microbial phyla?
2. *Bacteria* and *Archaea* were classified phenetically in the first edition of *Bergey's Manual of Systematic Bacteriology*. What are the advantages and disadvantages of the phylogenetic classification used in the second edition?
3. You have recently established a pure culture of a new archaeon from soil. Describe the approaches you would use to identify your new microbe to the species level.
4. Discuss the problems in developing an accurate phylogenetic tree. Do you think it is possible to create a completely accurate universal phylogenetic tree? Explain your answer.
5. Why is the current classification system for *Bacteria* and *Archaea* likely to change considerably? How would one select the best features to use in the identification of unknown microbes and determination of relatedness?
6. In 2007 a severe food-borne outbreak of enterohemorrhagic *E. coli* (EHEC) O157:H7 occurred in the United States. The strain that caused this outbreak seemed to be more virulent, causing more severe illness, than previous outbreaks. To test if new, more virulent strains of EHEC might be evolving, SNP analysis was performed on 500 clinical isolates of the bacterium that were collected before, during, and after the 2007 outbreak. SNPs were detected in 96 loci, and 39 discrete SNP genotypes were identified. These could be separated into nine different clades, as shown in this phylogenetic tree. The amount of toxin produced and the severity of disease differed among clades. It was

discovered that members of clade 8 caused the 2007 outbreak and this clade was associated with high levels of toxin production. Discuss the evolution of this pathogen. Specifically consider each of these mechanisms of genetic variation: horizontal gene transfer, mutation, gene amplification, gene deletion, and intragenic recombination. Which do you think is (or are) the most important? Explain your answer.

Read the original paper: Manning, S. D., et al. 2008. Variation in virulence among clades of *Escherichia coli* O157:H7 associated with disease outbreaks. *Proc. Natl. Acad. Sci. USA*. 105:4868.

The Archaea

The recovery of natural gas (methane, produced by archaea) could be a boon to the U.S. energy economy, but the method by which it is extracted—hydraulic fracturing—is not without controversy.

Methanogenic Archaea Fuel Domestic Energy Debate

Long before gas prices surged and politicians began to argue about energy security, archaea were busy generating methane, otherwise known as natural gas. Although methane deposits are billions of years old, only recently have geologists recognized that at least 2,000 trillion cubic feet (Tcf) of natural gas could be recovered within the United States. This upward revision is largely due to the inclusion 750 Tcf of methane trapped in underground shale. This domestic source of gas, much of it under Appalachian and Rocky Mountain states, could provide over 20% of the total U.S. gas supply by 2020. This should be good news as the United States consumes about 25 Tcf annually. But there is a hitch. The methane has to be extracted from the earth.

Before we tackle the extraction problem, let's discuss how all that natural gas got there in the first place. There are two sources of methane: abiotic and biotic. Abiotic methane results principally from thermal decomposition of sedimentary rocks and is almost negligible compared to that produced by microbes. All biologically produced methane is generated by methanogenic archaea from either $\text{CO}_2 + \text{H}_2$ or acetate (section 20.3). Evidently, shale beneath the United States has been home to a vast and productive archaeal community for eons.

Although this has been known for a long time, methane recovery was not cost effective. The price of extracting the gas trapped within the soft, porous shale far exceeded any later profits. But the recent development of horizontal drilling and hydraulic fracturing ("fracking") technologies changed the economic equation. Now a typical well can be drilled vertically about 3,000 meters and then extended just as far horizontally. Fracking involves high-pressure pumping of up to 9 million liters of water, sand, and chemicals into the well. This cracks the shale, while a "propping agent" keeps the pores open so the gas can be recovered.

However, some citizens in communities where fracking takes place report three specific problems: groundwater contamination, the escape of contaminated drilling fluids at the well surface, and methane leaking from the wells, thereby increasing the carbon footprint of natural gas usage. Federal regulations mandate that recovered drilling fluids be treated before they are discharged back into the environment. In some cases, drillers have used municipal wastewater treatment facilities for this, creating a tremendous burden on local infrastructure. Escaping methane is considered problematic because methane is a harmful greenhouse gas (see section 28.2). If the United States is to use this tremendous natural resource, these concerns must be addressed to the satisfaction of producers and consumers.

In this chapter, we review archaea, which were once considered almost exclusively "extremophiles"—organisms that thrive in extreme conditions, where they do unusual things, such as make methane. However, we know now that they are physiologically and ecologically diverse, found in both mundane and challenging environments. Indeed, the third domain of life deserves our respect, especially if they are to provide us with energy to fuel our power grid.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Draw the basic structure of the phylogenetic tree of life based on SSU rRNA sequences and explain the placement of *Archaea* (section 1.2)
- ✓ Describe an archaeal cell wall, including its component parts (section 4.2)
- ✓ Distinguish the lipids typically found in archaeal membranes from those found in bacteria (section 4.2)
- ✓ List environmental factors that influence microbial growth, including oxygen (section 7.3)
- ✓ Summarize rhodopsin-based phototrophy (section 11.11)
- ✓ Review archaeal DNA replication, gene transcription, and protein synthesis and secretion (chapter 15)

20.1 Overview of the Archaea

After reading this section, you should be able to:

- List some common habitats in which archaea reside
- Describe the debate that surrounds archaeal taxonomy
- Compare at least three key metabolic pathways that are central to archaeal physiology with those used by bacteria

Archaea have many features in common with eukaryotes, others in common with bacteria, and still other elements that are uniquely archaeal. In general, archaeal informational genes—those that encode proteins involved in replication, transcription, and translation—share homology with those of eukaryotes, whereas genes involved in metabolism are similar to bacterial genes. Like all generalizations, this is not uniformly the case; for instance, archaea have a unique tRNA structure and only archaea are capable of methanogenesis. Like bacteria, archaea are quite diverse, both in morphology and physiology. They may be spherical, rod-shaped, spiral, lobed, cuboidal, triangular, plate-shaped, irregularly shaped, or pleomorphic. Some are single cells, whereas others form filaments or aggregates. They range in diameter from 0.3 to over 15 μm , and some filaments can grow up to 200 μm in length. Although they stain either Gram positive or Gram negative, they have unique cell walls—different from that of bacteria. Multiplication is usually by binary fission but may be by budding, fragmentation, or other mechanisms. Archaea are just as diverse physiologically. They can be aerobic, facultatively anaerobic, or strictly anaerobic. Nutritionally, they range from chemolithoautotrophs to organotrophs. They include psychrophiles, mesophiles, and hyperthermophiles that can grow above 100°C.

Archaea inhabit a wide variety of habitats, but for many years they were considered microbes of “extreme environments,” or “extremophiles.” Indeed, many, but by no means all, archaea inhabit niches that have very high or low temperatures or pH, concentrated salts, or are completely anoxic. However, we should remember that most of Earth (the oceans) is an “extreme environment” where it is very cold (about 4°C), dark, and under high pressure. Many archaea evolved to live in these environments, so from their perspective, such habitats are not extreme. For instance, in some hypersaline environments, their populations become so dense that the brine is red with archaeal pigments. By contrast, archaea also make up about 20% of the prokaryotic biomass of marine plankton and are important members of some soil communities—environments that cannot be considered extreme. In addition, some are symbionts in the digestive tracts of animals, but to date, no pathogenic archaea have been described. Thus the notion that archaea are exclusively “extremophiles” is no longer valid as archaea are known to inhabit temperate and tropical soils and waters.

Archaeal Taxonomy

As shown in **table 20.1**, well-characterized archaea can be divided into five major groups based on physiological and morphological differences. However, we present these microbes as

they are phylogenetically classified, as defined by *Bergey's Manual of Systematic Bacteriology*. Thus, we divide Archaea into the phyla *Euryarchaeota* (Greek *eurus*, wide, and *archaios*, ancient or primitive) and *Crenarchaeota* (Greek *crene*, spring or fount, and *archaios*) (**figure 20.1**). The euryarchaeotes are given this name because they occupy many different ecological niches and have a variety of metabolic patterns. The methanogens, extreme halophiles, sulfate reducers, and many extreme thermophiles with sulfur-dependent metabolism are placed in the *Euryarchaeota*. The crenarchaeotes are thought to resemble the ancestral archaea, and almost all the well-characterized species are thermophiles or hyperthermophiles.

Whereas all archaea currently in pure culture belong to either *Crenarchaeota* or *Euryarchaeota*, an ever-growing collection of 16S rRNA nucleotide sequences cloned directly from the environment suggests that archaeal phylogeny is more complicated. Indeed, metagenomic analysis has detected many mesophilic and psychrophilic archaea. These archaeal sequences were originally placed into two groups: group I became known as the “mesophilic crenarchaeota,” thereby distinguishing them from the majority of crenarchaeotes in pure culture, which are thermophilic; and group II are members of *Euryarchaeota*.

It has been particularly difficult to resolve the phylogeny of several groups of archaea. Analysis of the complete genomes of about half a dozen archaea, most of which have not yet been grown in pure culture, has led some to suggest that three additional phyla exist: *Korarchaeota*, *Thaumarchaeota*, and *Aigarchaeota*. Complete genome analysis enables the comparison of the amino acid sequences of all ribosomal proteins found among the archaea for which such data exists. Because ribosomal proteins are under the same natural selection constraints as rRNA, they are good phylogenetic markers.

The phylum *Korarchaeota* (from the Greek word for “young man”) was proposed over a decade ago, based solely on the SSU rRNA data of uncultured microbes. Members of this lineage are hyperthermophilic anaerobes. Recent genome analysis of *Candidatus* (*Ca.*) *Korarchaeum cryptofilum* reveals ribosomal proteins similar to those in crenarchaeotes and tRNA maturation proteins that resemble those of euryarchaeotes. It is argued that this helps support the notion that *Korarchaeota* represent a unique lineage, separate from *Crenarchaeota*, where *Bergey's* places these microbes (**figure 20.2**). Genomic analysis of *K. cryptofilum* also reveals that this archaeon lacks genes for many biosynthetic pathways, which may help explain why it has not yet been grown in pure culture. Because this archaeon has not been grown axenically, it has candidate (*Candidatus*) species status and its name is not italicized.

The group I mesophilic archaea are placed by some taxonomists in the phylum *Thaumarchaeota* (Greek *thaumas*, wonder); others feel these microbes are true crenarchaeotes (**figure 20.2**). The phylum was initially proposed based on 16S rRNA data from uncultured archaea and genomic sequences of *Crenarchaeum symbiosum*, a marine sponge symbiont. More recently the genomes of *Nitrosopumilus aritmus* and *Ca. Nitrososphaera gargensis* have been analyzed. Both of these archaea are aerobic ammonia-oxidizing archaea; all such nitrifying archaea belong to this lineage.

Table 20.1 Characteristics of the Major Archaeal Physiological Groups

| Group | General Characteristics | Representative Genera |
|---|--|---|
| Methanogenic archaea | Strict anaerobes. Methane is the major metabolic end product. S^0 may be reduced to H_2S without yielding energy. Cells possess coenzyme M, factors 420 and 430, and methanopterin. | <i>Methanobacterium</i> (E) ¹ <i>Methanococcus</i> (E) <i>Methanomicrobium</i> (E) <i>Methanosarcina</i> (E) |
| Archaeal sulfate reducers | Irregular Gram-negative staining coccoid cells. H_2S formed from thiosulfate and sulfate. Autotrophic growth with thiosulfate and H_2 . Can grow heterotrophically. Traces of methane also formed. Extremely thermophilic and strictly anaerobic. Possess factor 420 and methanopterin but not coenzyme M or factor 430. | <i>Archaeoglobus</i> (E) |
| Extremely halophilic archaea | Rods, cocci, or irregular shaped cells that may include pyramids or cubes. Primarily chemoorganoheterotrophs. Most species require sodium chloride ≥ 1.5 M, but some survive in as little as 0.5 M. Most produce characteristic bright-red colonies; some are unpigmented. Neutrophilic to alkalophilic. Generally mesophilic; however, at least one species is known to grow at 55°C. Possess either archaerhodopsin or halorhodopsin and can use light energy to produce ATP. | <i>Halobacterium</i> (E) <i>Halococcus</i> (E) <i>Natronobacterium</i> (E) |
| Cell wall-less archaea | Pleomorphic cells lacking a cell wall. Thermoacidophilic and chemoorganotrophic. Facultatively anaerobic. Plasma membrane contains a mannose-rich glycoprotein and a lipoglycan. | <i>Thermoplasma</i> (E) |
| Extremely thermophilic S^{6-} -metabolizers | Gram-negative staining rods, filaments, or cocci. Obligately thermophilic (optimum growth temperature between 70–100°C). Usually strict anaerobes but may be aerobic or facultative. Acidophilic or neutrophilic. Autotrophic or heterotrophic. Most are sulfur metabolizers. S^0 reduced to H_2S anaerobically; H_2S or S^{6-} oxidized to H_2SO_4 aerobically. | <i>Desulfurococcus</i> (C) <i>Pyrodictium</i> (C) <i>Pyrococcus</i> (E) <i>Sulfolobus</i> (C) <i>Thermococcus</i> (E) <i>Thermoproteus</i> (C) |

¹ Indicates phylum; E, *Euryarchaeota*, C, *Crenarchaeota*

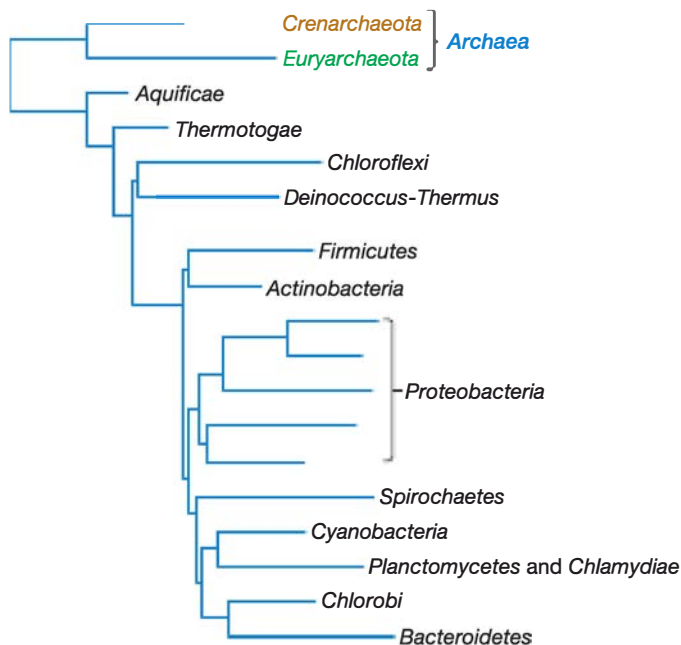

Figure 20.1 Phylogenetic Relationships Among Members of Bacteria and Archaea. Archaeal lineages are highlighted.

The third proposed phylum, *Aigarchaeota*, is based largely on the genome sequence of the archaeon *Ca. Caldiarchaeum subterraneum*, which was found in a subsurface geothermal stream. This is very controversial, with some taxonomists arguing that *C. subterraneum* and related taxa are members of *Thaumarchaeota*, while others feel that neither *Thaumarchaeota* or *Aigarchaeota* are valid phyla and all their proposed taxa belong in *Crenarchaeota*. ◀◀ *Comparative genomics* (section 18.7); *Phylogenetic trees* (section 19.4)

Thus although *Bergey's* currently accepts only two archaeal phyla, new phyla may eventually be recognized. This state of flux in archaeal phylogeny demonstrates how dynamic microbial taxonomy can be. The use of molecular probes to dissect microbial communities, combined with innovative culture techniques, ensures that phylogenetic analysis will continue to evolve.

Metabolism

In view of the diversity of archaeal lifestyles, it is not surprising that archaeal metabolism varies greatly among members of different groups. Some archaea are heterotrophs; others are autotrophic. Here we review the pathways by which archaea fix carbon and catabolize carbohydrates.

Like all anabolic processes, carbon fixation requires reducing power and energy. In this case, inorganic carbon (CO_2 or HCO_3^-)

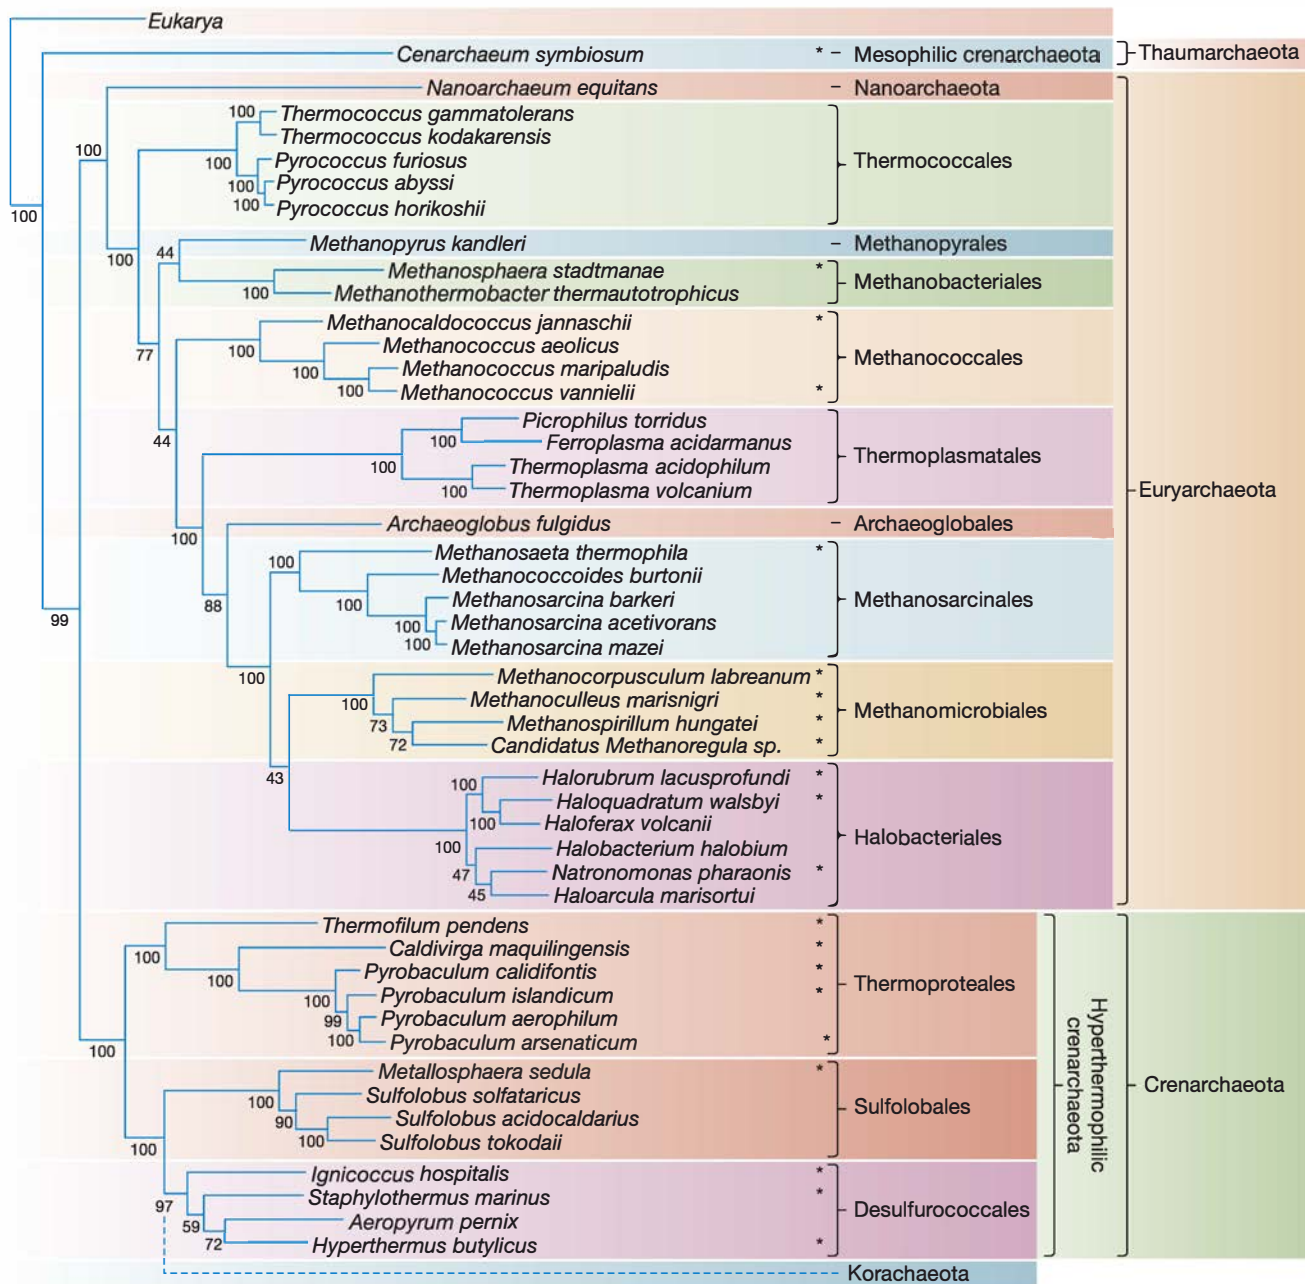

Figure 20.2 Maximum Likelihood Phylogenetic Tree of Archaea. This phylogenetic tree was constructed by comparing ribosomal proteins. Note that the newly proposed phylum *Thaumarchaeota* has not been adopted by *Bergey's Manual*. The hypothesized phylum *Korarchaeota* is displayed with a dashed line because its placement is not based on the data used to construct this tree. Numbers at nodes represent bootstrap values. The scale bar represents the number of amino acid substitutions per site.

Source: Brochier-Armanet, C., et al. 2008. Mesophilic crenarchaeota: Proposal for a third archaeal phylum, the *Thaumarchaeota*. *Nature Rev. Microbiol.* 6:245.

has an oxidation state of +4, so it requires four reducing equivalents for its assimilation into cellular carbon (oxidation state of 0). Most known autotrophic archaea are either anaerobic or live in low oxygen conditions. These microbes tend to use ferredoxin (Fd) instead of NADPH as their source of electrons. Because reduced Fd has a standard reduction potential (E'_0) of -400 mV, it bears more energy than NADPH (E'_0 of -320 mV), and most

anaerobic pathways require less ATP than aerobic carbon fixation pathways (e.g., the Calvin cycle). This is important as some autotrophic archaea, particularly methanogens, live close to their thermodynamic limit. ◀◀ *Redox reactions* (section 10.3); *CO₂ fixation* (section 12.3)

Three different carbon fixation pathways have been characterized in archaea: the reductive acetyl-CoA pathway, the

Figure 20.3 The Reductive Acetyl-CoA Pathway. Methanogens reduce two molecules of CO_2 , each by a different mechanism, and combine them to form acetyl and then acetyl-CoA.

3-hydroxypropionate/4-hydroxybutyrate (HP/HB) cycle, and the dicarboxylate/4-hydroxybutyrate (DC/HB) cycle. Recently it has been shown that the euryarchaeotes *Archaeoglobus* and *Ferroglobus* spp. use the reductive acetyl-CoA pathway (figure 20.3). By contrast, it has long been known that methanogens (also euryarchaeotes) use this pathway, as it is the most energetically favorable route. It requires only about one ATP per pyruvate synthesized, compared to seven for the Calvin cycle. As the pathway's name reflects, two CO_2 molecules are incorporated into one acetyl-CoA. One CO_2 is reduced to carbon monoxide (CO) by a CO dehydrogenase that also functions as an acetyl-CoA synthase. Another CO_2 is reduced to the level of CH_3 and bound to a tetrahydropterin coenzyme. Methanogens withdraw this from the pathway and reduce it to methane, as discussed in section 20.3. Thus methanogens use the acetyl-CoA pathway for both carbon assimilation and energy conservation. *Archaeoglobus* and *Ferroglobus* spp. capture energy using anaerobic respiration with sulfate as the terminal electron acceptor, so this pathway is used only for carbon fixation. Likewise, several anaerobic bacteria, including some planctomycetes, proteobacteria, and spirochetes, use the reductive acetyl-CoA pathway to fix CO_2 .

The HP/HB cycle is found in members of the crenarchaeote genus *Sulfolobales* and in *Thaumarchaeota* (figure 20.4). It requires more energy than any other CO_2 fixation pathway (9 ATP/pyruvate synthesized) but has other advantages. It has a low demand for metal cofactors, and unlike either the acetyl-CoA pathway or the DC/HB cycle, it can operate under aerobic conditions. The key carboxylase enzyme, a biotin-dependent acetyl-CoA/propionyl-CoA carboxylase, accepts two bicarbonate ions (HCO_3^-) in a series of steps that yields succinyl-CoA; there is net synthesis of one acetyl-CoA. Interestingly, bacteria and eukaryotes use acetyl-CoA carboxylase as the first step in fatty acid biosynthesis, but because archaea do not make fatty acids, this enzyme can be dedicated to carbon assimilation.

The last autotrophic pathway known to occur in archaea is the anaerobic DC/HB pathway (figure 20.4). It is found in the anaerobic and microaerobic members of *Thermoproteales* and *Desulfurococcales*, which are both crenarchaeotes. The DC/HB

pathway starts when an acetyl-CoA and a CO_2 molecule are condensed to form pyruvate, which is then converted to phosphoenolpyruvate (PEP). PEP carboxylase then adds a HCO_3^- molecule to PEP to form oxaloacetate (OAA). Through a series of reductive tricarboxylic acid cycle steps (i.e., backward TCA cycle steps), OAA is converted to succinyl-CoA, which is transformed through 4-hydroxybutyrate into two molecules of acetyl-CoA. As in the HP/HB pathway, one acetyl-CoA is then used for biosynthesis, and the other is used as a CO_2 acceptor in the next round of the cycle. The DC/HB cycle uses only five ATP per pyruvate made, but some of its enzymes are oxygen sensitive. Thus while the conversion of succinyl-CoA to acetyl-CoA is the same in both the HP/HB and DC/HB pathways, aerobes must perform the more expensive HP/HB pathway.

Inspection of figures 20.3 and 20.4 reveals that autotrophic pathways used by archaea result in the production of the 2-carbon compound (C2) acetyl-CoA, which must be converted to the central metabolite pyruvate (C3) for anabolic purposes. The most common means by which this is accomplished is through the glyoxylate cycle (figure 20.5). Here the enzyme isocitrate lyase splits isocitrate (C6) into glyoxylate (C2) and succinate (C4); glyoxylate is then condensed with acetyl-CoA to form malate (C4). While autotrophic archaea and haloarchaea such as *Haloferax volcanii* use the glyoxylate cycle, other haloarchaea that must assimilate acetyl-CoA do not. These microbes use the methylaspartate pathway. This pathway also yields malate and succinate but requires many more steps. In the methylaspartate pathway (figure 20.5), α -ketoglutarate (C5) is converted to the amino acid glutamate, which is then rearranged to form the nonstandard amino acid methylaspartate. The ammonia is next removed, and several steps are required before the cleavage of a C5 intermediate into propionyl-CoA (C3) and glyoxylate (C2). Just as in the glyoxylate pathway, acetyl-CoA condenses with glyoxylate to form malate, which is used for biosynthesis. Unlike the glyoxylate pathway, another CO_2 (as HCO_3^-) is accepted by propionyl-CoA to form succinate, which is also converted to malate. All this begs the question, why use a more complicated (and therefore costly) mechanism? The answer may be linked to the fact that so far, the methylaspartate pathway is found only among haloarchaea. These

Figure 20.4 The 3-Hydroxypropionate/4-Hydroxybutyrate (HP/HB) and Dicarboxylate/4-Hydroxybutyrate (DC/HB) Cycles. Aerobic crenarchaea such as *Sulfolobus* and some thaumarchaea use the HP/HB pathway (left) to convert two bicarbonate ions into acetyl-CoA. Some crenarchaea fix one molecule of CO_2 and one HCO_3^- using the anaerobic DC/HB pathway (right). The reactions shown with red arrows are also used in the reductive tricarboxylic acid cycle.

MICRO INQUIRY Given that the DC/HB pathway uses far less ATP per pyruvate synthesized than the HP/HB pathway, why do some archaea use the HP/HB pathway instead?

microbes are under constant osmotic stress in the high-salt environments they inhabit. Glutamate is used as an osmoprotectant, so it is hypothesized that haloarchaea may use the accumulation of intracellular glutamate as a signal to activate the methylaspartate pathway when growing on acetate or compounds that produce acetate as an intermediate.

Very little is known in detail about other archaeal biosynthetic pathways. Evidence suggests that pathways for amino acid, purine, and pyrimidine biosynthesis are similar to those in other organisms. Some methanogens can fix atmospheric dinitrogen,

and this pathway also seems to be well conserved among bacteria and archaea. **◀◀ Synthesis of amino acids (section 12.5)**

Among chemoorganotrophic archaea, a least three novel carbohydrate catabolic pathways have been identified: a modified Embden-Meyerhof (EM) pathway and two variations of the Entner-Doudoroff pathway. The modified EM pathway used by hyperthermophilic euryarchaeotes involves several novel enzymes, including an ADP-dependent glucokinase and phosphofructokinase (figure 20.6). These kinases each result in the production of AMP; in fact, unlike the classical EM

Figure 20.5 Glyoxylate and Methylaspartate Pathways Are Used for Acetyl-CoA Assimilation. Autotrophic archaea and some haloarchaea use the glyoxylate pathway (red and dashed arrows) to incorporate acetyl-CoA. Other haloarchaea lack the key enzyme isocitrate lyase (ICL) and assimilate acetyl-CoA via the longer methylaspartate pathway instead (black and dashed arrows).

MICRO INQUIRY Why might the production of glutamate as an intermediate be beneficial for some haloarchaea?

pathway, there is no net ATP produced. Another unique step in this modified EM pathway is the conversion of glyceraldehyde 3-phosphate directly to 3-phosphoglycerate, with the use of ferredoxin as the electron acceptor, rather than NAD^+ . By contrast, members of the thermophilic crenarchaeote genus *Thermoproteus* employs NAD^+ as the electron acceptor when it uses the modified EM pathway.

Extreme halophiles and *Thermoproteus* spp. catabolize glucose using a phosphorylative form of the Entner-Doudoroff pathway (ED). As shown in **figure 20.7**, glucose is oxidized to gluconate and then dehydrated to 2-keto-3-deoxy-gluconate (KDG). KDG is phosphorylated at the expense of ATP to KDPG, and the remainder of the ED pathway is like that of bacteria. This results in a net yield of one ATP. A second, nonphosphorylative version of the ED pathway has been discovered in *Sulfolobus*, *Thermoplasma*, and *Thermoproteus* spp. (note that thermoprotei can utilize all three archaeal-specific pathways). This pathway begins like that of the halophiles, but KDG is cleaved by KDG aldolase to pyruvate and glyceraldehyde. Glyceraldehyde is oxidized to glycerate, which is then phosphorylated to 2-phosphoglycerate. Pyruvate is then generated as in the classical and halophilic ED pathway. Because these microbes bypass the energy-conserving step in which 1,3-bisphosphoglycerate is converted to 3-phosphoglycerate, there is no net yield of ATP.

◀◀ From glucose to pyruvate (section 11.4)

Figure 20.6 Modified Embden-Meyerhof Pathway. The pathway used by some archaea compared to that of bacteria. The only difference between the pathway used by *Thermoproteus* spp. and the other archaea shown is the use of NAD^+ as the electron acceptor rather than ferredoxin when glyceraldehyde 3-phosphate is oxidized to 3-phosphoglycerate. There is no net ATP produced in the archaeal pathway.

All archaea that have been studied can oxidize pyruvate to acetyl-CoA. However, they lack the pyruvate dehydrogenase complex present in eukaryotes and respiratory bacteria, and use the enzyme pyruvate oxidoreductase instead. Halophiles and the extreme thermophiles *Thermoplasma* spp. appear to have a functional tricarboxylic acid cycle. Methanogens do not catabolize glucose to any significant extent, so it is not surprising that they lack a complete tricarboxylic acid cycle. However, some store glycogen, which is catabolized via a modified EM pathway (figure 20.6). ◀◀ Tricarboxylic acid cycle (section 11.5)

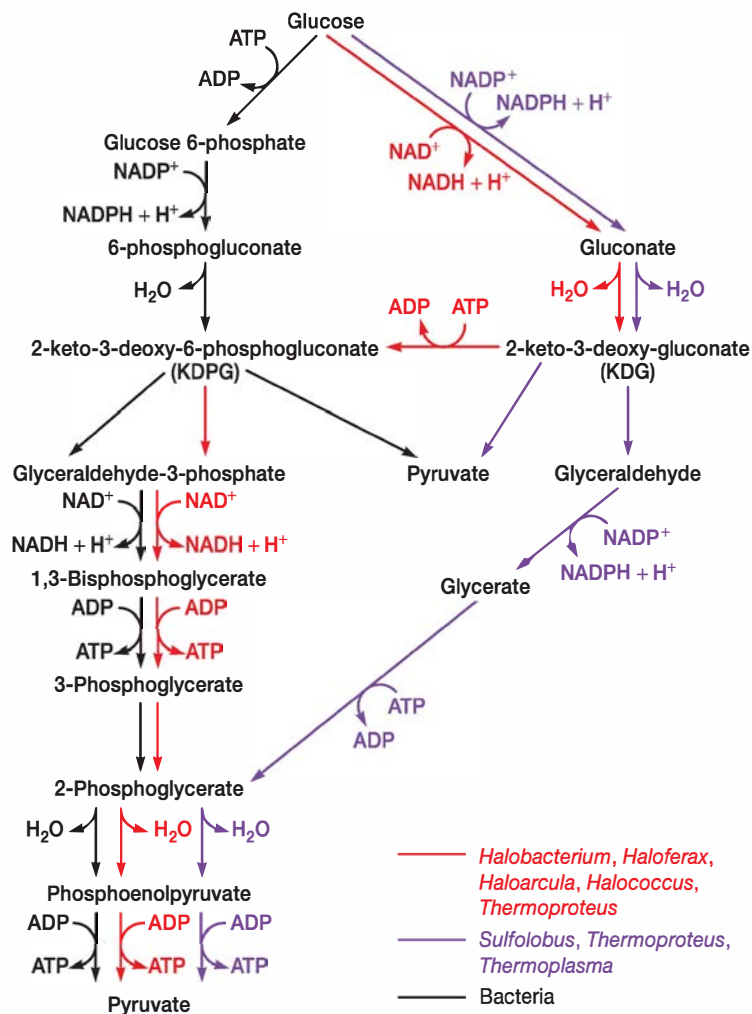

Figure 20.7 Two Alternate Versions of the Entner-Doudoroff Pathway.

The phosphorylative pathway used by halophilic archaea involves the ATP-dependent phosphorylation of KDG to KDPG; the remainder of the pathway is like that of bacteria and an ATP is gained. The nonphosphorylative pathway used by *Sulfolobus* spp. and others joins the bacterial ED pathway when glyceraldehyde is converted to 2-phosphoglycerate, so no net ATP is produced.

4. Why do haloarchaea use the methylaspartate rather than the glyoxylate cycle for the incorporation of acetate?
5. Compare the ATP and NADH yield of each of the archaeal glycolytic pathways with that used by bacteria.

20.2 Phylum Crenarchaeota

After reading this section, you should be able to:

- List the major physiological types among crenarchaea
- Evaluate the importance of crenarchaeol in the discovery of new crenarchaeotes
- Discuss hyperthermophilic and thermoacidophilic growth

Bergey's Manual lists only the well-characterized thermophilic members of the phylum *Crenarchaeota*; we also discuss mesophilic archaea in this section. All thermophilic crenarchaeotes belong to a single class, *Thermoprotei*, which is divided into four orders. The order *Thermoproteales* contains two families. The family *Thermoproteaceae* includes anaerobic to facultative hyperthermophilic rods. The family *Thermophilaceae* has only one representative, *Thermophilum pendens*, an anaerobic thermoacidophile that is filamentous with cells extending more than 100 μm . The order *Sulfolobales* has a single family, the *Sulfolobaceae*, whose members are coccus-shaped thermoacidophiles. The two families within the order *Desulfurococcales* contain coccoid or disk-shaped hyperthermophiles. They grow chemolithotrophically by hydrogen oxidation or organotrophically by fermentation or respiration with sulfur as the electron acceptor. Members of the family *Desulfurococcaceae* are also capable of chemoorganotrophic growth using sulfur as the electron acceptor. The family *Pyrodictiaceae* includes the genus *Pyrodicticum*, whose members form tubelike structures that connect cells, thereby forming a network called cannulae (see figure 4.10). Also included in this family is the genus *Pyrolobus*. *P. fumarii* is one of the most thermophilic microbes isolated to date. Its optimum growth temperature is 106°C and its maximum is 113°C. The order *Caldisphaerales* has only one genus, *Caldisphaera*, whose members are thermoacidophilic, aerobic, and heterotrophic cocci.

Many of these thermophiles are sulfur dependent. The sulfur may be used either as an electron acceptor in anaerobic respiration or as an electron donor by lithotrophs. Many are strict anaerobes. They grow in geothermally heated water or soils that contain elemental sulfur. These environments are scattered all over the world. Familiar terrestrial examples are the sulfur-rich hot springs in Yellowstone National Park (figure 20.8). Such habitats are sometimes called solfatara. Many hyperthermophiles have also been isolated from the waters surrounding areas of submarine volcanoes (see figure 32.4). These archaea often are classified as **hyperthermophiles**. The most extreme example was isolated from an active hydrothermal vent in the northeast Pacific Ocean. This is one of three novel isolates that constitute a new genus in the *Pyrodictiaceae* family. Its optimum growth temperature is about 105°C, but even autoclaving this microbe at 121°C for 1 hour fails to kill it. It is strictly anaerobic, using Fe(III) as a terminal electron acceptor and H_2 or formate as electron donors and energy sources (figure 20.9).

Figure 20.8 Habitat for Thermophilic Archaea. The Sulfur Cauldron in Yellowstone National Park. The water is at its boiling point and very rich in sulfur. *Sulfolobus* spp. grow well in such habitats.

Hydrothermal vents are also home to the only parasitic archaeon, *Nanoarchaeum equitans* (a euryarchaeote), which relies on its crenarchaeal host, *Ignicoccus hospitalis*, for replication (figure 20.10). *I. hospitalis* is an anaerobic, chemolithoautotrophic hyperthermophile that uses H_2 as an electron donor and elemental sulfur as its electron acceptor. It uses the DC/HB pathway for carbon fixation (figure 20.4). Its cell envelope is unique as it lacks an S layer and is the only archaeon to possess a double membrane. The inner membrane is composed of di- and tetraethers that frequently give rise to small, bleblike vesicles. The outer membrane surrounds a wide periplasm-like compartment between the two membranes. This membrane lacks the typical caldarchaeol lipids found in other thermophilic archaea. Caldarchaeol lipids are extremely thermostable tetraethers found in many hyperthermophilic archaea. They consist of two C40 isoprenoid units linked to glycerol at both ends (i.e., it has four ether bonds), thus generating a monolayer rather than the more familiar lipid bilayer seen in bacteria and eukaryotes

(a)

(b)

Figure 20.9 An Extremely Hyperthermophilic Crenarchaeote.

(a) A member of the family *Pyrodictiaceae* (tube on left) grows following autoclaving at 121°C , as shown by its ability to reduce Fe(III) to magnetite when incubated anaerobically (tube on right is sterile control). (b) A transmission electron micrograph shows the S-layer cell envelope (S) and plasma membrane (CM). Scale bar = $1\ \mu\text{m}$.

Figure 20.10 Parasitic Cells of *Nanoarchaeum equitans* Attached to the Surface of Its Host, *Ignicoccus hospitalis*. The crenarchaeote *I. hospitalis* is the only archaeon known to have an outer membrane, which may be important for *N. equitans* attachment. In this confocal laser scanning micrograph, *I. hospitalis* is stained green and *N. equitans* is red.

(see figures 4.4 and 4.6). Remarkably, the outer membrane of *I. hospitalis* houses H_2 :sulfur oxidoreductase and ATP synthase complexes, making it the only organism known to have an energized outer membrane. Its parasitic partner *N. equitans* is also quite interesting. It cannot be grown without its host and forms tiny cells of only 350 to 500 nm that attach to the *I. hospitalis* outer membrane. Very little is known about the physiology of *N. equitans*, although genome analysis reveals that it lacks the capacity to synthesize most lipids, amino acids, nucleotides, and cofactors. At 490,000 bp, it seems *N. equitans* has taken genome reduction to the extreme. ◀◀ *Comparative genomics* (section 18.7)

Two of the best-studied members of *Crenarchaeota* belong to the genera *Sulfolobus* and *Thermoproteus*. Members of the *Sulfolobus* are aerobic, irregularly lobed, and spherical, with a temperature optimum around 80°C and a pH optimum of 2 to 3. For this reason, they are **thermoacidophiles**. Their cell walls contain carbohydrate and an archaeal-specific lipoprotein. They grow chemoorganotrophically under oxic conditions, but they can also grow chemolithoautotrophically, oxidizing H_2 , H_2S , and FeS_2 with oxygen as the terminal electron acceptor, although the use of ferric iron has been reported. When growing chemolithoautotrophically, they use the HP/HB cycle, and when growing chemoorganotrophically, they employ the phosphorylative version of the Entner-Doudoroff pathway (figure 20.7) and a complete TCA cycle. Unlike most organisms, *S. solfataricus* rarely uses NAD^+ as an electron acceptor; instead, it uses $NADP^+$ and ferredoxin-dependent oxidoreductases. In fact, archaea in general seem to lack NADH dehydrogenase, whereas it is integral to the function of bacterial and mitochondrial electron transport chains. The genomes of *Sulfolobus* spp. show a high level of plasticity; indeed, the *S. solfataricus* genome has 200 integrated insertion sequences. Although *S. solfataricus* grows at pH 2 to 4, it maintains a cytoplasmic pH of about 6.5, thereby generating a large pH gradient across the plasma membrane. This energy is conserved in the formation of ATP by membrane-bound ATP synthases and at least 15 secondary transport systems that couple the transport of organic solutes

(e.g., sugars, amino acids) with the movement of protons (figure 20.11). The ABC transporters also used for nutrient uptake have high substrate affinity, an important adaptation in low nutrient environments. ◀◀ *Electron transport and oxidative phosphorylation* (section 11.6)

Thermoproteus spp. are long, thin rods that can be bent or branched, with cell walls composed of glycoprotein. Members of this genus are anaerobic and grow at temperatures from 75 to 100°C. Some species are acidophiles, with optimum pH values between 3 and 4, while others are neutrophiles. They are found in hot springs and other hot aquatic habitats rich in sulfur. *Thermoproteus* spp. can grow organotrophically and oxidize glucose, amino acids, alcohols, and organic acids with elemental sulfur as the electron acceptor during anaerobic respiration. Like *Sulfolobus* spp., they use the phosphorylative Entner-Doudoroff pathway to catabolize sugars. They also grow chemolithotrophically, oxidizing H_2 with S^0 as the electron acceptor. CO_2 is incorporated through the DC/HB cycle (figure 20.4).

The detection of the crenarchaeote-specific lipid **crenarchaeol** and sequence analysis of DNA fragments derived directly from environmental samples reveal that crenarchaeol-containing archaea are widespread in nature (figure 20.12). Recall that only a small fraction of microbes have been grown in culture, so the ability to analyze microbial communities using molecular techniques is an important way to truly understand microbial diversity. Such studies demonstrate that significant populations of these archaea dwell in marine plankton from polar, temperate, and tropical waters. They also inhabit rice paddies, soils, and freshwater lake sediments, and at least two symbiotic species have been isolated, one from a cold-water sea cucumber and the other from a marine sponge. Collectively, these microbes are often called the group I archaea or mesophilic *Crenarchaeota*, but as discussed in section 20.1, comparative genome analysis suggests that these microbes may belong to the phylum *Thaumarchaeota* (figure 20.2). ◀◀ *Metagenomics* (section 18.8)

The purification and growth of one of these mesophilic archaea, the marine crenarchaeote *Nitrosopumilus maritimus*, confirms that archaea are capable of nitrification. *N. maritimus* grows chemolithoautotrophically, fixing carbon via the HP/HB cycle and capturing energy through the oxidation of ammonia to nitrite using oxygen as the terminal electron acceptor. The first step in ammonia oxidation is its conversion to hydroxylamine (NH_2OH), a reaction catalyzed by ammonia monooxygenase (AMO; see figure 22.15). AMO is composed of three subunits, AmoA, AmoB, and AmoC; the archaeal versions of the genes encoding these proteins are phylogenetically distinct from bacterial *amo* genes. This has made it possible to assess the presence and, through reverse transcription PCR studies, the activity of archaeal nitrification in soils and waters. While it had long been thought that α - and β -proteobacteria were solely responsible for nitrification, it appears that mesophilic archaea capable of ammonia oxidation may be numerically dominant in many terrestrial and marine environments. ▶▶ *Nitrifying bacteria* (section 22.1)

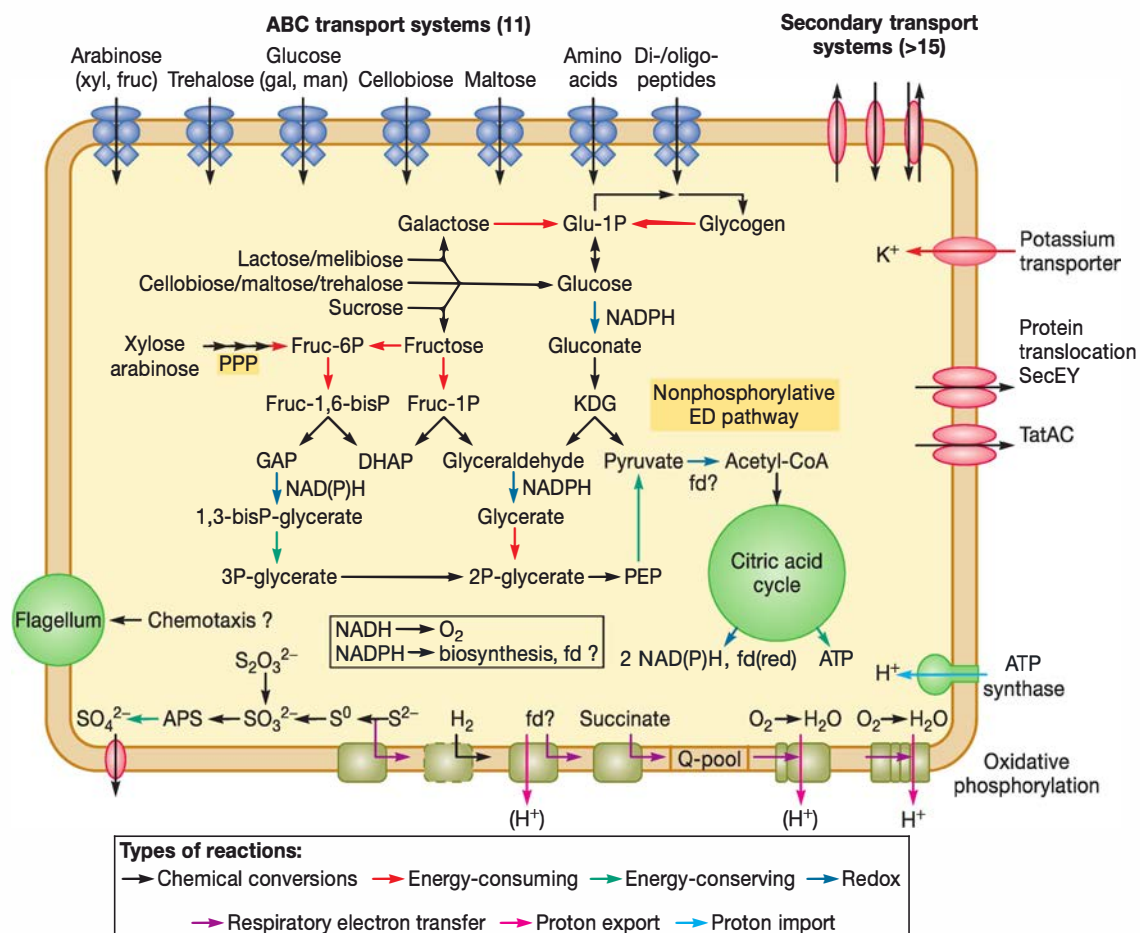

Figure 20.11 Genomic Reconstruction of *Sulfolobus solfataricus*. Each type of reaction is denoted by a different color arrow, as shown in the key. Components of the aerobic respiratory network include the reduction of a quinone (Q) pool, a putative ferredoxin dehydrogenase (Fd?), and succinate dehydrogenase. Alternative electron donors include hydrogen and sulfide, which reduce the quinone pool through hydrogenase and sulfide reductase, respectively. Elemental sulfur and thiosulfate are converted to sulfate. The ABC transport systems import xylose (xyl), fructose (fruc), glucose (glu), galactose (gal), and mannose (man). Transporters for carbohydrates that support growth are listed in blue. The flagellar apparatus more closely resembles type IV pili, as is the case with other archaea, and a gene encoding a methyl-accepting chemotaxis protein is present.

MICRO INQUIRY Identify the potential electron donors to the electron transport chain. What is the source of energy for the potassium transporter shown on the right-hand side of the cell? Hint: Examine the arrow color code box.

20.3 Phylum Euryarchaeota

After reading this section, you should be able to:

- Outline the process of methanogenesis and discuss its importance in the flow of carbon through the biosphere as well as in the production of energy
- Discuss the physiology and ecology of anaerobic methane oxidation
- Explain the strategies halophiles have evolved to cope with osmotic stress and why these strategies are needed
- Outline rhodopsin-based phototrophy as used by halophiles
- Describe the habitats in which methanogens and halophiles reside
- List one unique feature of *Thermoplasma*, *Pyrococcus*, and *Archaeoglobus* spp.

Euryarchaeota is a very diverse phylum with many genera (figure 20.2). We discuss five major physiologic groups within the euryarchaeotes.

Methanogens and Methanotrophs

Late in the eighteenth century, Italian physicist Alessandro Volta discovered that he could ignite gas from anoxic marshes. In this way, Volta discovered the biological production of methane and demonstrated the industrial importance of natural gas. The production of methane—**methanogenesis**—is the last step in the anaerobic degradation of organic compounds. Because the ΔG of methanogenesis compares unfavorably to other forms of respiration, methanogenesis occurs only when O_2 and most other electron acceptors are unavailable, making it a strictly anaerobic

Figure 20.13 Methanogens. (a) *Methanobrevibacter smithii*. (b) *Methanosarcina mazei*; SEM. Scale bar = 5 μm .

process (see figure 28.1). All methanogenic microbes belong to *Euryarchaeota* and are called **methanogens**. They use H_2 and CO_2 or short-chain organic compounds, such as formate, acetate, and methanol, as substrates. These compounds are usually the fermentation products of other microbes that live in the same community. When using H_2 and CO_2 , their growth is autotrophic. As discussed in section 20.1, these archaea use the acetyl-CoA pathway to incorporate CO_2 (figure 20.3).

Methanogens are the largest group of cultured archaea. There are five orders (*Methanobacteriales*, *Methanococcales*, *Methanomicrobiales*, *Methanosarcinales*, and *Methanopyrales*) that differ greatly in overall shape, 16S rRNA sequence, cell wall chemistry and structure, membrane lipids, and other features. For example, methanogens construct three different types of cell walls. Several genera have walls with pseudomurein; other walls contain either proteins or heteropolysaccharides (see figure 4.6). The morphology of two representative methanogens is shown in figure 20.13, and selected properties of representative genera are presented in table 20.2.

Table 20.2 Selected Characteristics of Representative Genera of Methanogens

| Genus | Morphology | % G + C | Wall Composition | Motility | Methanogenic Substrates Used |
|--|----------------------------------|---------|--|----------|--|
| Order <i>Methanobacteriales</i> <i>Methanobacterium</i> | Long rods or filaments | 32–61 | Pseudomurein | — | H_2 + CO_2 , formate |
| <i>Methanothermus</i> | Straight to slightly curved rods | 33 | Pseudomurein with an outer protein S-layer | + | H_2 + CO_2 |
| Order <i>Methanococcales</i> <i>Methanococcus</i> | Irregular cocci | 29–34 | Protein | + | H_2 + CO_2 , formate |
| Order <i>Methanomicrobiales</i> <i>Methanomicrobium</i> | Short curved rods | 45–49 | Protein | + | H_2 + CO_2 , formate |
| <i>Methanogenium</i> | Irregular cocci | 52–61 | Protein or glycoprotein | — | H_2 + CO_2 , formate |
| <i>Methanospirillum</i> | Curved rods or spirilla | 47–52 | Protein | + | H_2 + CO_2 , formate |
| Order <i>Methanosarcinales</i> <i>Methanosarcina</i> | Irregular cocci, packets | 36–43 | Protein sometimes with polysaccharide | — | H_2 + CO_2 , methanol, methylamines, acetate |

As might be inferred from the methanogens' ability to produce methane anaerobically, their metabolism is unusual. These euryarchaeotes contain several unique cofactors: tetrahydromethanopterin (H_4MPT), methanofuran (MFR), coenzyme M (2-mercaptoethanesulfonic acid), coenzyme F_{420} , and coenzyme F_{430} (figure 20.14). These cofactors are used in the following series of reactions (figure 20.15). (1) Gaseous CO_2 is bound to MFR, and as such, it is now activated and part of a formyl group ($-HC=O$). (2) The formyl group is transferred to H_4MPT

and dehydrated. (3) Using F_{420} as the electron donor, the dehydrated formyl group ($=HC-$) is reduced to the methyl level ($-CH_3$) in a two-step process. (4) The methyl group is transferred to CoM. This reaction releases energy. (5) The methyl group is now ready for final reduction to methane (CH_4). This is catalyzed by the F_{430} -containing methyl-coenzyme M reductase (MCR). H_2 is the electron donor and protons are released.

It appears that ATP synthesis is linked with methanogenesis by electron transport, proton pumping, and a chemiosmotic

Figure 20.14 Methanogen Coenzymes. (a) Coenzyme MFR, (b) H_4MPT , and (c) coenzyme M are used to carry 1-carbon units during methanogenesis. MFR and a simpler form of H_4MPT called methanopterin (MPT; not shown) also participate in the synthesis of acetyl-CoA. The portions of the coenzymes that carry the 1-carbon units are highlighted. H_4MPT carries carbon units on nitrogens 5 and 10, like the more common enzyme tetrahydrofolate. (d) Coenzyme F_{420} participates in redox reactions. The part of the molecule that is reversibly oxidized and reduced is highlighted. (e) Coenzyme F_{430} participates in reactions catalyzed by the enzyme methyl-CoM methylreductase.

Figure 20.15 Methane Synthesis. Pathway for CH_4 synthesis from CO_2 in *M. thermoautotrophicus*. Cofactor abbreviations: methanopterin (MPT), methanofuran (MFR), and 2-mercaptoethanesulfonic acid or coenzyme M (CoM). The nature of the carbon-containing intermediates leading from CO_2 to CH_4 is indicated in parentheses. Stars indicate sites of energy conservation. The circled numbers correspond to steps described in text.

MICRO INQUIRY What are the mechanisms by which methanogens are thought to couple CO_2 reduction to ATP generation? Why do you think this has been so hard to demonstrate?

mechanism. The precise means by which a proton motive force is generated is not known but may involve the oxidation of H_2 on the outer surface of the membrane (figure 20.15, step 5). In addition, the transfer of the methyl groups from methyl- H_4MPT to HS-CoM releases sufficient energy for the uptake of sodium ions (step 4). This results in a sodium motive force that could also drive ATP synthesis. This may explain why methanogens require about 1 mM Na^+ for growth. **Electron transport and oxidative phosphorylation (section 11.6)**

It can be useful to compare methanogens that possess cytochromes with those that lack them. Among the five orders of methanogens, only members of the least ancient order, the *Methanosarcinales*, have cytochromes and methanophenazine, a menaquinone-like molecule. This is the only order with a broad substrate range and the capacity to grow on acetate, methanol, and methylamines, with a few species of *Methanosarcina* also growing on H_2 and CO_2 . These archaea tend to have relatively high growth yields of around 7 grams of dried cellular material per mole of CH_4 produced. By contrast, most members of the other four orders convert only H_2 and CO_2 to methane; a few can also use formate as a methanogenic substrate. These archaea have growth yields of between 1.5 to 3 grams per mole CH_4 .

Methanogenic archaea are potentially of great practical importance, as discussed in the chapter opening story. Anaerobic digester microbes degrade particulate wastes such as sewage sludge to H_2 , CO_2 , and acetate (see figure 43.7). CO_2 -reducing methanogens then form CH_4 from CO_2 and H_2 , while acetoclastic methanogens

cleave acetate to CO_2 and CH_4 (about two-thirds of the methane produced by an anaerobic digester comes from acetate). There is a tight thermodynamic relationship between the H_2 -producing microbes and the methanogens, as discussed in chapter 32. A kilogram of organic matter can yield up to 600 liters of methane. It is quite likely that future innovation will greatly increase the efficiency of methane production and make methanogenesis an important source of pollution-free energy.

Methanogenic archaea are estimated to produce about 1 billion tons of methane annually. The rate of methane production can be so great that bubbles of methane sometimes rise to the surface of a lake or pond. Rumen methanogens are so active that a cow can belch 200 to 400 liters of methane a day. Methanogenesis can be considered an environmental problem. Methane absorbs infrared radiation and is a more potent greenhouse gas than CO_2 . Atmospheric methane concentrations have been rising over the last 200 years. Methane production may significantly promote global warming; this subject is discussed in chapter 28. **The rumen ecosystem (section 32.1); Global climate change (section 28.2)**

No doubt the levels of archaeal-generated methane would render this planet uninhabitable were it not for the oxidation of methane by microbes capable of methanotrophy. For many decades, it was thought that this process—the capacity to oxidize methane and use it as a carbon source—was restricted only to strictly aerobic proteobacteria. However, it is now recognized that about 80% of methane produced in marine sediments is oxidized anaerobically by archaea. The use of fluorescent probes for specific DNA sequences has revealed assemblages of archaea and sulfate-reducing bacteria inhabiting anoxic, methane-rich sediments. These clusters of cells contain a core of about 100 cells from the order *Methanosarcinales* surrounded by a layer of bacteria related to the proteobacterial genus *Desulfosarcina* (figure 20.16). Although no anaerobic methane-oxidizing archaeon has yet been grown in pure culture, additional assemblages have since been identified and grouped into three distinct lineages called ANME-I, ANME-II and ANME-III. Those in ANME-I are related to members in the order *Methanomicrobiales*, while those in ANME-II and ANME-III are related to *Methanosarcinales*. These microbes are found in regions of the seafloor where methane seeps into the surrounding cold water. Interestingly, some members of ANME-I are found in the absence of a bacterial partner.

The precise nature of the *Methanosarcinales/Desulfosarcina* consortium has been difficult to study. Recent advances support the hypothesis that anaerobic methane oxidation proceeds as reverse methanogenesis. These microbes appear to possess all the genes needed for methanogenesis, implying that anaerobic methane oxidation is accomplished by running methanogenesis backward. The recent demonstration that purified enzyme methyl-coenzyme M reductase can catalyze the energetically unfavorable conversion of

Figure 20.16 Methanotrophic Archaea Grow in Association with Sulfate-Reducing Bacteria. A cluster of methanotrophic archaea, stained red by an archaeal fluorescent 16S rRNA probe, surrounded by a layer of sulfate-reducing bacteria labeled by a green bacterial 16S rRNA fluorescent probe.

methane to methyl-coenzyme M (denoted with a red star in figure 20.15) supports the notion that methane is an electron donor while sulfate is the terminal electron acceptor:

It is not clear how electrons are transferred from the archaeon to the bacterium. The archaea provide the bacteria with much of their organic carbon. In addition, anaerobic methane-oxidizing archaea also fix N_2 gas and provide the bacteria with organic nitrogen. Finally, a freshwater archaeon has been reported that couples the anaerobic oxidation of methane with denitrification—the reduction of nitrate to N_2 during anaerobic respiration by a bacterium. These archaeal-bacterial associations are important in the global carbon, nitrogen, and sulfur cycles.

Haloarchaea

The **extreme halophiles** include some bacteria, eukaryotic microorganisms and **haloarchaea**, which belong to the order *Halobacteriales*. This euryarchaeal group currently has 17 genera in one family, the *Halobacteriaceae*. These microbes received this unfortunate name before the *Archaea* and *Bacteria* were recognized as different taxa. Most are aerobic chemoorganotrophs with respiratory metabolism. Extreme halophiles demonstrate a wide variety of nutritional capabilities. When grown in defined media, these archaea use carbohydrates or simple compounds such as glycerol, acetate, or pyruvate as their carbon source. Halophiles are found in a variety of cell shapes, including cubes and pyramids in addition to rods and cocci (figure 20.17a). Some are motile.

The most obvious distinguishing trait of this family is its absolute dependence on a high concentration of NaCl, requiring at least 1.5 M NaCl (about 8%, wt/vol). Growth optima are usually 3 to 4 M NaCl (17 to 23%), but some will grow at salt concentrations approaching saturation (about 36%). The cell walls of most halophiles are so dependent on the presence of NaCl that they disintegrate when the NaCl concentration drops below 1.5 M. Thus they only grow in high-salinity habitats such as marine salterns and salt lakes such as the Dead Sea between Israel and Jordan, and the Great Salt Lake in Utah. Haloarchaea often have red-to-yellow pigmentation from carotenoids that are probably used as protection against strong sunlight. They can reach such high population levels that salt lakes, salterns, and salted fish actually turn red (figure 20.17b). In fact, halophiles are used in the production of many salted food products.

Halophiles use two strategies to cope with osmotic stress. The first approach is to increase cytoplasmic osmolarity by accumulating small organic molecules called **compatible solutes**. These include glycine, betaine, polyols, ectoine, and amino acids. When this strategy is used, salt adaptation of cytoplasmic proteins is not necessary. Compatible solutes are found in extremely halophilic

(a)

(b)

Figure 20.17 Halophilic Archaea. (a) A sample taken from a saltern in Australia viewed by fluorescence microscopy. Note the range of cell shapes includes cocci, rods, and cubes. (b) A solar evaporation pond in Owen's Lake, California, is extremely high in salt and mineral content. The archaea that dominate this hot, saline habitat produce brilliant red pigments.

methanogenic archaea, as well as halophilic bacteria. Members of the order *Halobacteriales*, *Haloanaerobiales*, and *Salinibacter* employ a “salt-in” approach. These archaea use Na^+/H^+ antiporters and K^+ symporters to concentrate KCl and NaCl to levels equivalent to the external environment. Thus proteins need to be protected from salt denaturation and dehydration. Proteins from these microbes have evolved to possess a limited number of hydrophobic amino acids and a greater number of acidic residues. The acidic amino acids tend to be located on the surface of the folded protein, where they attract cations, which form a hydrated shell around the protein, thereby maintaining its solubility.

Probably the best-studied member of the family is *Halobacterium salinarum*. This archaeon is unusual because it produces a protein called **archaerhodopsin** (originally termed **bacteriorhodopsin**) that can harvest light energy without the presence of chlorophyll. Structurally similar to the rhodopsin found in the mammalian eye, archaerhodopsin functions as a light-driven proton pump. Like all members of the rhodopsin family, archaerhodopsin has two distinct features: (1) a chromophore that is a derivative of retinal (an aldehyde of vitamin A), which is covalently attached to the protein by a Schiff base with the amino group of lysine (**figure 20.18**); and (2) seven

Figure 20.18 The Photocycle of Archaerhodopsin.

membrane-spanning domains connected by loops on either side of the membrane with the retinal resting within the membrane. Archaerhodopsin molecules form aggregates in a modified region of the plasma membrane called the **purple membrane**. As shown in [figure 20.19](#), this light-driven proton pumping generates a pH gradient independent of an electron transport chain. Nonetheless, this gradient can be used to power the synthesis of ATP by a chemiosmotic mechanism.  *Electron transport and oxidative phosphorylation (section 11.6); Rhodopsin-based phototrophy (section 11.11)*

H. salinarum has three additional rhodopsins, each with a different function. Halorhodopsin uses light energy to transport chloride ions into the cell and maintain a 4 to 5 M intracellular KCl concentration. The two additional rhodopsins are called sensory rhodopsin I (SRI) and SRII. **Sensory rhodopsins** act as photoreceptors; in this case, one for red light and one for blue. They control flagellar activity to position the organism optimally in the water column. *Halobacterium* moves to a location of high light intensity that lacks the ultraviolet light that would be lethal.

Surprisingly, rhodopsin is widely distributed among bacteria and archaea. DNA sequence analysis of uncultivated marine bacterioplankton reveals the presence of rhodopsin genes among some α - and β -proteobacteria and bacteroidetes. This rhodopsin is called **proteorhodopsin**. Cyanobacteria also have sensory rhodopsin proteins, which like SRI and SRII of the haloarchaea, sense the spectral quality of light. All these bacterial and archaeal rhodopsins conserve the seven transmembrane helices through the cell membrane and the lysine residue that forms the Schiff base linkage with retinal.

Genomic analysis of *Halobacterium* NRC-1 illustrates many of these physiologic strategies ([figure 20.19](#)). The use of both archaerhodopsin-mediated proton motive force and oxidative phosphorylation to drive ATP synthesis is shown, as is the import of cations to increase cytoplasmic osmolarity. The signals from sensory rhodopsins converge on the flagellar apparatus, along with input from 17 methyl-accepting chemotactic proteins. *Halobacterium* NRC-1 uses a variety of ATP transporters for the uptake of cationic amino acids, peptides, and sugars. Carbohydrates are oxidized via the phosphorylative variant of the Entner-Doudoroff pathway ([figure 20.7](#)) and the TCA cycle. Interestingly, genes for exporting the toxic heavy metals arsenite and cadmium are present, as well as genes homologous to the nonspecific multidrug-resistance exporters.

Thermoplasmas

Archaea in the class *Thermoplasmata* are thermoacidophiles that lack cell walls. At present, three genera—*Thermoplasma*, *Picrophilus*, and *Ferroplasma*—are known. They are sufficiently different from one another to be placed in separate families: *Thermoplasmataceae*, *Picrophilaceae*, and *Ferroplasmataceae*.

Members of the genus *Thermoplasma* grow in refuse piles of coal mines. These piles contain large amounts of pyrite (FeS), which is oxidized to sulfuric acid by chemolithotrophic bacteria. As a result, the piles become very hot and acidic. This is an

ideal habitat for these archaea because they grow best at 55 to 59°C and pH 1 to 2. Although they lack cell walls, their plasma membranes are strengthened by large quantities of caldarchaeol, lipid-containing polysaccharides, and glycoproteins. Their DNA is stabilized by association with archaeal histones that condense the DNA into structures resembling eukaryotic nucleosomes. At 59°C, *Thermoplasma* spp. take the form of irregular filaments, whereas at lower temperatures, they are spherical. The cells may be flagellated and motile.

Picrophilus spp. are even more unusual than *Thermoplasma*. They have an S-layer outside the plasma membrane. The cells grow as irregularly shaped cocci, around 1 to 1.5 μm in diameter, and have large cytoplasmic cavities that are not surrounded by a membrane. They are aerobic and grow between 47 and 65°C with an optimum of 60°C. They have remarkable pH requirements, growing only below pH 3.5 with a growth optimum at pH 0.7. Growth even occurs at about pH 0.

Extremely Thermophilic S^0 -Reducers

This physiological group contains the class *Thermococci*, with one order, *Thermococcales*. These archaea are strictly anaerobic and can reduce sulfur to sulfide. They are motile by flagella and have optimum growth temperatures around 88 to 100°C. The order contains one family and three genera, *Thermococcus*, *Paleococcus*, and *Pyrococcus*.

Sulfate-Reducing Euryarchaeota

Euryarchaeal sulfate reducers are found in the class *Archaeoglobi* and the order *Archaeoglobales*. This order has only one family and three genera. *Archaeoglobus* spp. contain irregular coccoid cells with cell walls consisting of glycoprotein subunits. They can extract electrons from a variety of electron donors (e.g., H_2 , lactate, glucose) and reduce sulfate, sulfite, or thiosulfate to sulfide. Elemental sulfur is not used as an acceptor. They are thermophilic (optimum growth is about 83°C) and have been isolated from marine hydrothermal vents. Their capacity to reduce sulfate distinguishes it from other archaea, as does its use of methanogen coenzymes F_{420} and methanopterin. In fact, they produce tiny amounts of methane. However, genome sequencing reveals that they lack the critical enzyme methyl-CoM reductase ([figure 20.15](#), step 5), so the mechanism by which methane is made remains unclear. Some species are autotrophic and, like methanogens, use the reductive acetyl-CoA pathway to assimilate CO_2 .

A recently characterized thermophilic euryarchaeote that is not yet listed in *Bergey's Manual* bears mention. The isolated *Aciduliprofundum* strain, *Candidatus Aciduliprofundum boonei* is an acidophile that requires a pH of 3.3 to 5.8 and a temperature between 60 and 75°C for growth. Culture-independent analysis shows that members of this genus are often abundant in microbial communities growing at hydrothermal vents with actively venting sulfide deposits. It follows that *A. boonei* is a sulfur- and iron-reducing heterotroph. Its significance is twofold. It is the first thermoacidophile (as opposed to acid-tolerant) microbe to be isolated from environments rich

Figure 20.19 Genomic Reconstruction of *Halobacterium* NRC-1. ATP synthesis occurs through respiratory-dependent chemiosmosis and the ATP synthase, light-driven proton pumping by archaerhodopsin (AR, pink oval), and chloride transport by halorhodopsin (HR, blue oval). Nutrient uptake systems are shown in brown and yellow; names of transporters correspond with the gene(s) encoding them; the substrates transported are shown in the inside of the transporter. Cation transporters are shown in purple and anion transporters in red. Sensory rhodopsins (orange) and 17 light, oxygen, and amino acid receptors (Htr proteins) regulate chemotaxis and are thus shown linked to the flagellar motor through the chemotaxis protein CheY.

in sulfide deposits. Also, its abundance at such sites implies that it is important in sulfur and iron cycling in these ecosystems.

►► Sulfur cycle (section 28.1)

Retrieve, Infer, Apply

1. Why are the growth yields of most methanogens much lower than those of microbes that grow aerobically?
2. Why do you think methanogenesis requires so many cofactors? (Hint: What would happen to CO_2 and CH_4 if they were not bound to larger molecules?)
3. What is the ecological and practical importance of methanogens?
4. Where are extreme halophiles found, and what is unusual about their cell walls and growth requirements?
5. What is the difference between sensory rhodopsin and archaeorhodopsin? Find examples of each in figure 20.19.
6. How is *Thermoplasma* able to live in acidic, very hot coal refuse piles when it lacks a cell wall?
7. In what way are members of the genus *Archaeoglobus* similar to methanogens, and how do they differ from other extreme thermophiles?

Key Concepts

20.1 Overview of the Archaea

- Archaea contains a highly diverse group of microbes with respect to morphology, reproduction, physiology, and ecology. Although best known for their growth in anoxic, hypersaline, and high-temperature habitats, they also inhabit marine Arctic, temperate, and tropical waters.
- Archaea may be divided into five physiological groups: methanogenic archaea, sulfate reducers, extreme halophiles, cell wall-less archaea, and extremely thermophilic S^0 -metabolizers (table 20.1).
- The second edition of *Bergey's Manual* divides Archaea into two phyla, *Crenarchaeota* and *Euryarchaeota*; however, this may eventually be revised to include additional phyla (figure 20.2).
- Autotrophic archaea generally use one of three pathways for CO_2 assimilation: the reductive acetyl-CoA pathway, the 3-hydroxypropionate/4-hydroxybutyrate (HP/HB) cycle, or the dicarboxylate/4-hydroxybutyrate (DC/HB) cycle. Acetate is incorporated either by the glyoxylate or methylaspartate cycle. Most other anabolic pathways appear to be similar to those found in bacteria (figures 20.3 and 20.4).
- Although much of archaeal catabolism appears similar to that of bacteria, archaea differ with respect to glucose catabolism, using modified versions of the Embden-Meyerhof and Entner-Doudoroff pathways (figures 20.6 and 20.7).

20.2 Phylum Crenarchaeota

- The extremely thermophilic S^0 -metabolizers in the phylum *Crenarchaeota* depend on sulfur for growth and are frequently acidophiles. The sulfur may be used as an electron acceptor in anaerobic respiration or as an electron donor by chemolithotrophs. Many are strict anaerobes and grow in geothermally heated soil and water that is rich in sulfur.

- More recent metagenomic evidence suggests that group I mesophilic crenarchaeotes are not confined to extreme environments. These microbes may represent a new phylum and include ammonia-oxidizing archaea (figure 20.2).

20.3 Phylum Euryarchaeota

- The phylum *Euryarchaeota* contains five major physiological groups: methanogens, haloarchaea, thermoplasmas, extremely thermophilic S^0 -reducers, and sulfate-reducing archaea.
- Methanogenic archaea are strict anaerobes that obtain energy through the synthesis of methane. They have several unusual cofactors that are involved in methanogenesis (figures 20.14 and 20.15).
- Anaerobic methane-oxidizing archaea belong to the *Methanomicrobiales* and *Methanosarcinales*, with members of the latter found in association with sulfate-reducing bacteria. These methanotrophs oxidize methane apparently by reversing the methanogenic pathway (figure 20.16).
- Extreme halophilic archaea are aerobic chemoorganotrophs that require at least 1.5 M NaCl for growth. They are found in habitats such as salterns and salt lakes.
- *Halobacterium salinarum* can carry out phototrophy without chlorophyll or bacteriochlorophyll by using archaeorhodopsin, which employs retinal to pump protons across the plasma membrane (figures 20.18 and 20.19).
- The thermophilic *Thermoplasma* spp. grow in hot, acidic coal refuse piles and survive despite the lack of a cell wall. Another thermoplasm, *Picrophilus* spp. grow at pH 0.
- The class *Thermococci* contains extremely thermophilic organisms that can reduce sulfur to sulfide.
- Sulfate-reducing archaea are placed in the class *Archaeoglobi*. The extreme thermophiles in the genus *Archaeoglobus* differ from other archaea in using a variety of electron donors to reduce sulfate. They also contain methanogen cofactors F_{420} and methanopterin.

Compare, Hypothesize, Invent

1. Some believe that archaea should not be separate from bacteria because both groups are prokaryotic. Do you agree or disagree? Explain your reasoning.
2. Explain why the fixation of CO₂ by *Thermoproteus* spp. using the DC/HB cycle is not photosynthesis.
3. When the temperature increases, some archaea change their shapes from elongated rods into spheres. Suggest one reason for this change.
4. Why would ether linkages be more stable in membranes than ester lipids? How would the presence of tetraether linkages stabilize a thermophile's membrane?
5. Suppose you wished to isolate an archaeon from a hot spring in Yellowstone National Park. How would you go about it?
6. Thermophilic archaea capable of ammonia oxidation to nitrite were discovered in enrichment cultures derived from microbial mats from the Siberian Garga hot spring. To demonstrate the presence of these microbes and their ability to oxidize ammonia, the authors did the following:
 - Screened for α - and β -proteobacterial 16S rRNA genes and the bacterial gene that encodes the key enzyme in ammonia oxidation (see chapter 22).

- Screened for crenarchaeal specific 16S rRNA and crenarchaeal specific genes that encode the ammonia oxidation subunits AmoA and AmoB.
- Constructed two phylogenetic trees—one based on the crenarchaeal 16S rRNA genes and one based on the AmoA and AmoB amino acid sequences as compared to other archaeal AmoA and AmoB sequences.
- Performed reverse-transcriptase PCR using mRNA extracted from the enrichment cultures. Primers were specifically targeted crenarchaeal *amoA* nucleotide sequences.

What was the rationale (i.e., what were the authors testing) for each procedure? Since the authors concluded that a thermophilic ammonia-oxidizing crenarchaeote was responsible for the conversion of ammonia to nitrite in this system, what was the likely result of each test?

Read the original paper: Hatzenpichler, R., et al. 2008. A moderately thermophilic ammonia-oxidizing crenarchaeote from a hot spring. *Proc. Natl. Acad. Sci. USA*. 105:2134–39.

The Deinococci, Mollicutes, and Nonproteobacterial Gram-Negative Bacteria

Cyanobacteria Stimulate Broad Appeal for Biofuel Production

Biofuels could be part of a comprehensive, global energy solution. They are renewable and can be produced domestically. But there is a downside. In the United States, most biofuel is made from corn, thereby co-opting thousands of acres of land for producing energy rather than food. This has the unintended consequence of driving food prices higher. Given that about 14% of the world's population is undernourished, this is not the best use of arable land.

Some scientists have turned from corn to cyanobacteria for an answer. Globally, there are a number of projects that seek to turn these bacteria, once known as blue-green algae, into a source of biofuel. One approach, used by Hyun Woo Kim and Raveender Vannela at Arizona State University's Biodesign Institute, involves harvesting lipids from the cyanobacteria that belong to the genus *Synechocystis*. These microbes can be genetically engineered to increase production of the kinds of lipids used in biodiesel. Their growth requirements are simple: CO₂, phosphorus, and minor elements. Because *Synechocystis* spp. fix atmospheric N₂, there is no need for petroleum-based nitrogenous fertilizer. And it gets even better: it may be possible to meet the microbe's carbon requirements by feeding it CO₂ generated by power plants. Lastly, cyanobacterial lipid production is more than 100 times more efficient per acre than plants, and their growth need not eliminate land from food production.

Not far from Arizona, Malcolm Brown and David Nobles at the University of Texas are using a different approach to capitalize on the benefits of cyanobacteria. They, like others, would like to replace corn as a biofuel source. The use of corn is expensive, involving enzymatic, chemical, and mechanical methods to break down cellulose into its glucose monomers, which is then fermented to ethanol (see section 42.2).

Biofuel production is an active area of microbiological research.

They have developed a strain of the cyanobacterium *Oscillatoria* that secretes high levels of glucose, sucrose, and cellulose. Importantly, unlike plant cellulose, cyanobacterial cellulose is not mixed with lignin and other compounds, making it more easily fermented. Thus these cyanobacteria can easily provide the starting materials for biofuel fermentation. Like other cyanobacterial researchers, Brown and Nobles are keen to avoid the sacrifice of thousands of acres to the growth of a food product for biofuel generation.

These projects are only two of many under development around the world that aim to harness cyanobacteria for biofuel generation. In this chapter, we cover these microbes as well as nine other phyla of Gram-negative bacteria (figure 21.1). This includes a variety of morphologically and physiologically amazing microbes. From deinococci, which can withstand levels of ionizing radiation that would kill a human, to the spirochetes that cause syphilis, this chapter truly illustrates the depth of microbial diversity.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✓ Draw a Gram-negative bacterial cell wall and list its constituent parts (section 3.4)
- ✓ Differentiate between swimming and gliding motility (section 3.8)
- ✓ List environmental factors that influence microbial growth (section 7.3)
- ✓ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.3)
- ✓ Describe the difference between heterotrophy and autotrophy (section 11.1)
- ✓ Define chemolithotrophy and identify an example of an electron donor and an acceptor (section 11.10)
- ✓ Compare and contrast oxygenic and anoxygenic phototrophy (section 11.11)

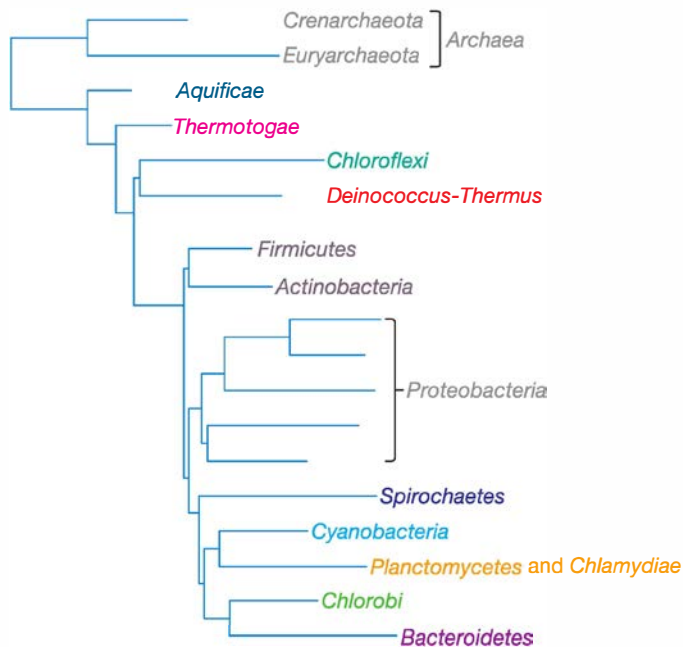

Figure 21.1 Phylogenetic Relationships Among *Bacteria* and *Archaea*. The *Deinococcus-Thermus* group and other nonproteobacterial, Gram-negative bacteria are highlighted.

21.1 *Aquificae* and *Thermotogae*

After reading this section, you should be able to:

- Compare and contrast the physiological and structural differences between members of the phyla *Aquificae* and *Thermotogae*

Thermophilic microbes are found in both the bacterial and archaeal domains, but to date, most hyperthermophilic microbes (those with optimum growth temperatures above 80°C) belong to *Archaea*. The phyla *Aquificae* and *Thermotoga* are two examples of bacterial hyperthermophiles.

The phylum *Aquificae* is thought to represent the deepest, oldest branch of *Bacteria*. Two of the best-studied genera are *Aquifex* and *Hydrogenobacter*. *Aquifex* spp. are chemolithoautotrophs that capture energy by oxidizing hydrogen, thiosulfate, and sulfur with oxygen as the terminal electron acceptor. The reductive citric acid cycle is used to fix CO₂ (see figure 12.5). *Aquifex pyrophilus* is a microaerophilic rod that has been shown to grow with a temperature optimum of 85°C and a maximum of 95°C. Because the genera *Aquifex* and *Hydrogenobacter* contain thermophilic chemolithoautotrophic species, it has been suggested that the original bacterial ancestor was probably thermophilic and chemolithoautotrophic. ◀◀ *Chemolithotrophy* (section 11.10)

The second deepest branch is the phylum *Thermotogae*. Members of the genus *Thermotoga* (Greek *therme*, heat; Latin *toga*, outer garment), like *Aquifex*, are thermophiles with a growth optimum of 80°C and a maximum of 90°C. They are

Figure 21.2 *Thermotoga maritima*. Note the loose sheath extending from each end of the cell.

Gram-negative rods with an outer sheathlike envelope (like a toga) that can extend or balloon out from the ends of the cell (figure 21.2). They grow in active geothermal areas found in marine hydrothermal systems and terrestrial solfataric springs. In contrast to *Aquifex*, *Thermotoga* species are chemoorganotrophs with a functional glycolytic pathway that can grow anaerobically on carbohydrates and some proteins. About a quarter of the *Thermotoga* genome coding sequences are similar to archaeal genes; this proportion is greater than that of other bacteria, including *Aquifex* (16% similarity), and may be due to horizontal gene transfer. ◀◀ *Horizontal gene transfer in Bacteria and Archaea* (section 16.4)

21.2 *Deinococcus-Thermus*

After reading this section, you should be able to:

- Explain why members of *Deinococcus-Thermus* have erroneously been considered Gram positive
- Describe habitats in which deinococci can be isolated
- Discuss the unique capacity of the deinococci to tolerate desiccation and high doses of radiation

The phylum *Deinococcus-Thermus* contains the orders *Deinococcales* (Greek, *deinos*, unusual) and *Thermales*. There are only three genera in the phylum. Most are mesophilic, but *Deinococcus geothermalis* and *D. murrayai* are thermophiles with optimum growth between 45°C and 55°C. Deinococci are spherical or rod-shaped and nonmotile. They often are associated in pairs or tetrads (figure 21.3a) and are aerobic and catalase positive; usually they produce acid from only a few sugars. Although they stain Gram positive, their cell wall is layered with an outer membrane like Gram-negative bacteria (figure 21.3b). They also differ from Gram-positive cocci in having L-ornithine in their peptidoglycan, lacking teichoic acid, and having a plasma membrane with large amounts of palmitoleic acid rather than phosphatidylglycerol phospholipids. They also possess an

(a)

(b)

Figure 21.3 Deinococci. (a) A *Deinococcus radiodurans* tetracoccus, or cluster of four cells (average cell diameter 2.5 μm). (b) The cell wall of *D. radiodurans* with an S-layer (S), a peptidoglycan layer (PG), and an outer membrane (OM). Scale bar = 100 nm.

S-layer. Almost all strains are extraordinarily resistant to all sources of oxidative stress, including desiccation and radiation; they can survive as much as 3 to 5 million rad of radiation. By contrast, exposure to 100 rad can be lethal to humans.

Deinococci can be isolated from ground meat, feces, air, freshwater, and other sources, but their natural habitat is not yet known. Their resistance to radiation results from their ability to repair a severely damaged genome, which consists of a circular chromosome, a megaplasmid, and a small plasmid. When exposed to high levels of radiation, radical oxygen species are generated and the genome is broken into hundreds of fragments. Amazingly, within 12 to 24 hours, the genome is pieced back together, ensuring viability. It is unclear how this is accomplished. Evidence suggests that while *Deinococcus radiodurans* DNA is not especially radiation resistant, its proteins are. The ability to accumulate high levels of Mn(II) helps protect the microbe from damage caused by radiation-induced toxic oxygen species. Interestingly, manganese ions selectively protect proteins, rather than DNA. Thus, unlike other microbes, *D. radiodurans* DNA repair enzymes survive severe oxidative stress.

21.3 Class Mollicutes (Phylum Tenericutes)

After reading this section, you should be able to:

- Relate the structure of the mollicute cell envelope to their morphology
- Outline how arginine can be catabolized to yield ATP by substrate-level phosphorylation
- Draw the flux of protons that enables *Ureaplasma urealyticum* to generate a proton motive force despite the absence of an electron transport chain
- Illustrate how gliding motility is accomplished by mycoplasmas
- List several habitats in which mollicutes reside and relate this to their capacity to be pathogenic

Until recently the class *Mollicutes* was placed in the phylum *Firmicutes*. Although it is generally agreed that members of this class are related to certain clostridia (low G + C Gram-positive bacteria), the fourth volume of *Bergey's Manual of Systematic Bacteriology* lists *Mollicutes* as a separate phylum, the *Tenericutes* (Latin *tener*, tender, and *cutis*, skin). *Tenericutes* includes all bacteria that lack walls and do not synthesize peptidoglycan precursors. The *Mollicutes* are commonly called **mycoplasmas**; these bacteria are characterized by the absence of cell walls, their small genomes, and simplified metabolic pathways. Their small genome appears to be the result of genome reduction such that they now lack a variety of metabolic capabilities, including the ability to synthesize peptidoglycan precursors (see figure 18.18).

Some of the major characteristics of the best-studied genera are summarized in table 21.1. Because members of *Mollicutes* are bound only by a plasma membrane, these bacteria are pleomorphic, varying in shape from spherical or pear-shaped microbes from 0.3 to 0.8 μm in diameter, to slender branched or helical filaments (figure 21.4). Some mycoplasmas (e.g., *M. genitalium*) have a specialized terminal structure that projects from the cell and gives them a flask or pear shape. This structure aids in attachment to eukaryotic cells. They are among the smallest bacteria capable of self-reproduction. Most species are facultative anaerobes, but a few are obligate anaerobes. When grown on agar, most form colonies with a “fried egg” appearance because they grow into the agar surface at the center while spreading outward on the surface at the colony edges (figure 21.5).

Mollicute genomes are among the smallest found among bacteria, ranging from 0.7 to 1.7 Mb (table 21.1). The genomes of the human pathogens *Mycoplasma genitalium*, *M. pneumoniae*, and *Ureaplasma urealyticum* have fewer than 1,000 genes, suggesting a minimal genome size for a free-living existence. Their limited number of genes reflects their inability to synthesize a number of macromolecules. For instance, because *M. genitalium* relies so heavily on its host's biosynthetic capacity, it has lost the genes that encode the enzymes needed to synthesize amino acids, purines, pyrimidines, and fatty acids. In addition, most species require sterols for growth, which they obtain from the host as cholesterol.

Table 21.1 Properties of Some Members of the Class *Mollicutes*

| Genus | No. of Recognized Species | G + C Content (mol%) | Genome Size (Mb) | Sterol Requirement | Habitat | Other Distinctive Features |
|-----------------------|---------------------------|----------------------|------------------|--------------------|--------------------------------------|---|
| <i>Acholeplasma</i> | 13 | 26–36 | 1.50–1.65 | No | Vertebrates, some plants and insects | Optimum growth 30–37°C |
| <i>Anaeroplasma</i> | 4 | 29–34 | 1.50–1.60 | Yes | Bovine or ovine rumen | Oxygen-sensitive anaerobes |
| <i>Asteroleplasma</i> | 1 | 40 | 1.50 | No | Bovine or ovine rumen | Oxygen-sensitive anaerobes |
| <i>Entomoplasma</i> | 5 | 27–29 | 0.79–1.14 | Yes | Insects, plants | Optimum growth 30°C |
| <i>Mesoplasma</i> | 12 | 27–30 | 0.87–1.10 | No | Insects, plants | Optimum growth 30°C; sustained growth in serum-free medium only with 0.04% detergent (Tween 80) |
| <i>Mycoplasma</i> | 104 | 23–40 | 0.60–1.35 | Yes | Humans, animals | Optimum growth usually 37°C |
| <i>Spiroplasma</i> | 22 | 25–30 | 0.94–2.20 | Yes | Insects, plants | Helical filaments; optimum growth at 30–37°C |
| <i>Ureaplasma</i> | 6 | 27–30 | 0.75–1.20 | Yes | Humans, animals | Urea hydrolysis |

Figure 21.4 Mycoplasmas. A scanning electron micrograph of *Mycoplasma pneumoniae* shows its pleomorphic nature ($\times 26,000$).

Figure 21.5 Mycoplasma Colonies. Note the “fried egg” appearance; colonies stained before photographing ($\times 100$).

Sterols are an essential component of the mycoplasma plasma membrane, where they may facilitate osmotic stability in the absence of a cell wall. Some produce ATP by the Embden-Meyerhof pathway and lactic acid fermentation. The pentose phosphate pathway seems to be functional in at least some mycoplasmas; none appears to have the complete tricarboxylic acid cycle. Arginine can be catabolized to generate ATP in the following series of reactions:

The first reaction is catalyzed by the enzyme arginine deaminase, which is found in several firmicutes, including *Bacillus* and *Clostridium* species.

The small size of the mycoplasma genome has made it the model organism for development of a “synthetic” bacterium. As discussed in chapters 17 and 18 (see p. 416 and p. 424, respectively), this has resulted in the construction of a bacterium with a genome that has been chemically synthesized. This work provides proof of principle that cells can be manufactured to encode only those products desired by the biotechnologist. **Techniques & Applications 17.2**

Ureaplasma urealyticum, a causative agent of urinary tract infections, has a unique means of conserving energy: it hydrolyzes urea to generate an electrochemical gradient via the accumulation of ammonia/ammonium ($\text{NH}_3/\text{NH}_4^+$). This gradient is responsible for the chemiosmotic potential that drives ATP synthesis (figure 21.6).

Figure 21.6 Energy Conservation in *Ureaplasma urealyticum*. To generate an electrochemical gradient through the accumulation of $\text{NH}_3/\text{NH}_4^+$, *U. urealyticum* is thought to import urea through specific transporters. Once inside the cell, urease (a nickel-binding enzyme) catalyzes the hydrolysis of urea to NH_3 and CO_2 . Ammonia accepts a proton to become NH_4^+ , which is exported through NH_4^+ uniporters (AMT). Once outside the cell, NH_4^+ is converted to NH_3 and H^+ , providing the protons to drive ATP synthesis via the membrane-bound ATP synthase.

Adapted from Glass, J. I., et al. 2000. The complete genome of the mucosal pathogen *Ureaplasma urealyticum*. *Nature*. 407:757–62.

Some mycoplasmas are capable of gliding motility. Recall that gliding motility enables movement across solid surfaces. *Mycoplasma mobile* moves at a steady pace of 2 to 5 μm per second. This appears to be mediated by cell surface proteins that surround the “neck” of the cell (figure 21.7). In *M. mobile*, these proteins are thought to attach to the cytoskeleton and function like microscopic legs. Unlike flagellar motility, gliding in this microbe is powered by ATP hydrolysis. By contrast, most other motile mycoplasmas move more like inchworms, at a tenth of the speed of *M. mobile*. For instance the terminal structure of *M. pneumoniae* is covered with cytoskeletal proteins that may function as motors to cause the contraction and extension of the cell. **◀◀ Twitching and gliding motility (section 3.8)**

Mycoplasmas are remarkably widespread and can be isolated from animals, plants, the soil, and even compost piles. Although their complex growth requirements can make their growth in pure (axenic) cultures difficult, at least 10% of the mammalian cell cultures in use are probably contaminated with mycoplasmas. This seriously interferes with tissue culture experiments and has resulted in the development of commercially available rapid tests for the detection of mycoplasmas in cell culture.

In animals, mycoplasmas colonize mucous membranes and joints, and often are associated with diseases of the respiratory and urogenital tracts. Mycoplasmas cause several major diseases in livestock; for example, contagious bovine pleuropneumonia in cattle (*M. mycoides*), chronic respiratory disease in chickens (*M. gallisepticum*), and pneumonia in swine (*M. hyopneumoniae*). Spiroplasmas have been isolated from insects, ticks, and a variety of plants. They cause disease in citrus plants, cabbage, broccoli, corn, honeybees, and other hosts. Arthropods often act as vectors and carry the spiroplasmas between plants. In humans, *U. urealyticum* and *M. hominis* are common parasitic microorganisms of the genital tract, and their transmission is related to sexual activity. Both mycoplasmas can opportunistically cause inflammation of the reproductive organs of males

and females. In addition, *Ureaplasma urealyticum* is associated with premature delivery of newborns, as well as neonatal meningitis and pneumonia. *M. pneumoniae* causes primary atypical pneumonia in humans. **▶▶ Direct contact diseases (section 39.3)**

1. In what ways are members of *Aquifex* and *Thermotoga* similar? How do they differ?
2. How do deinococci survive high doses of radiation?
3. Design an experiment designed to explore the role of sterols in mycoplasma structure and/or physiology.
4. Explain the relationship between genome size and growth requirements of mycoplasmas. Why is genome reduction common in intracellular microbes?

Figure 21.7 Two Forms of Gliding Motility in Mycoplasmas. (a) *M. mobile* uses cytoskeletal “leg” proteins to move the microbe at a constant speed. (b) *M. pneumoniae* has cytoplasmic motor proteins that cause the cell to expand and contract, so that it moves more slowly and at an uneven, inchwormlike pace.

21.4 Photosynthetic Bacteria

After reading this section, you should be able to:

- Assess the importance of photosynthetic pigments in the distribution of photosynthetic bacteria in nature
- Draw a generic chlorosome and identify the function of its structural elements
- Predict the habitat closest to your home where you might find members of the phyla *Chlorobi*, *Chloroflexi*, and *Cyanobacteria*
- Draw a generic cyanobacterial cell and label its intracellular structures
- List three types of specialized cells made by cyanobacteria and describe the function of each
- Compare and contrast the prochlorophytes with other cyanobacteria
- Draw a concept map describing the structure and physiology of the six types of photosynthetic bacteria listed in table 21.2

Historically, the term photosynthetic has been applied to both photoheterotrophic and photoautotrophic microbes. We continue to use this term in this way, but care should be taken not to assume that phototrophic capture of energy is always linked with CO₂ fixation. As we shall see, unlike plants, photosynthetic microbes often have more than one metabolic strategy.

Chlorophyll-based photosynthesis is well established in five bacterial phyla: the Gram-negative *Chlorobi*, *Chloroflexi*, *Cyanobacteria*, and *Proteobacteria*, and the Gram-positive *Firmicutes*. Other Gram-negative photosynthetic bacteria include the purple bacteria, aerobic anoxygenic phototrophs, and green bacteria (table 21.2). Cyanobacteria differ fundamentally from the other photosynthetic bacteria because they perform **oxygenic photosynthesis**: they have photosystems I and II, use water as an electron donor, and generate oxygen during photosynthesis. In contrast, purple bacteria, aerobic anoxygenic phototrophs (AAnPs), and green bacteria have only one photosystem and use **anoxygenic photosynthesis**. Because they are unable to use water as an electron source, they employ other reduced molecules as electron donors. AAnPs and purple nonsulfur bacteria are photoorganoheterotrophs, so they use electrons obtained during the oxidation of organic substrates. The purple and green sulfur bacteria use inorganic electron donors such as hydrogen sulfide, sulfur, and hydrogen, as well as organic matter, as an electron source for the reduction of NAD(P)⁺ to NAD(P)H. Consequently many of these bacteria form sulfur granules. Purple sulfur bacteria accumulate granules within their cells, whereas green sulfur bacteria deposit the sulfur granules outside their cells. ◀◀ *Phototrophy* (section 11.11)

Photosynthetic microbes contribute a significant amount of fixed carbon, termed primary productivity, in a variety of habitats. The differences in photosynthetic pigments and oxygen requirements among the photosynthetic bacteria have important ecological consequences. As shown in figure 21.8,

chlorophylls (Chl), bacteriochlorophylls (Bchl), and their associated accessory pigments have distinct absorption spectra. Accessory pigments collect light of different wavelengths and transfer it to Chl or Bchl, where it is converted to chemical energy. Oxygenic cyanobacteria and diatoms dominate the aerated upper layers of freshwater and marine microbial communities, where they absorb large amounts of red and blue light. Anoxygenic purple and green photosynthetic bacteria inhabit the deeper anoxic zones that are rich in hydrogen sulfide and other reduced compounds that can be used as electron donors. Their Bchl and accessory pigments enable their use of light in the far-red spectrum that is not used by other photosynthetic organisms. In addition, Bchl absorption peaks at about 350 to 550 nm, allowing them to grow at greater depths because shorter wavelength light can penetrate water farther.

AAnP bacteria make up less than 10% of marine and freshwater photosynthetic microbial populations and, as heterotrophs, do not contribute to primary productivity. An interesting, new chlorophyll-containing thermophilic bacterium in the phylum *Acidobacteria* has recently been discovered in Yellowstone National Park hot springs. This Gram-negative bacterium has not yet been grown in pure culture but is known to contain bacteriochlorophylls *a* and *c* under oxic conditions and to grow photoheterotrophically. The discovery of 16S rRNA sequences in Thailand and Tibet similar to those found at Yellowstone suggests a global distribution of this thermophile. The phylum *Acidobacteria* is small, but it may be far more diverse than previously imagined. Indeed, the number of photosynthetic microbes may exceed our long-held beliefs.

Bergey's Manual distributes photosynthetic bacteria between five bacterial phyla. The phylum *Chloroflexi* contains green nonsulfur bacteria, and the phylum *Chlorobi* includes green sulfur bacteria. Cyanobacteria are placed in their own phylum, *Cyanobacteria*. Purple bacteria are divided between three groups. Purple sulfur bacteria are placed in γ -proteobacteria (families *Chromatiaceae* and *Ectothiorhodospiraceae*). Purple nonsulfur bacteria are distributed between α -proteobacteria and the β -proteobacteria. Depending on species, AAnPs are divided among α -, β -, and γ -proteobacteria. Finally, Gram-positive heliobacteria in the phylum *Firmicutes* are also photosynthetic. There appears to have been considerable horizontal transfer of photosynthetic genes among the five phyla. At least 50 genes related to photosynthesis are common to all five. In this chapter, we describe the cyanobacteria and green bacteria; purple bacteria are discussed in chapter 22, while heliobacteria are discussed in chapter 23.

Phylum *Chlorobi*

The phylum *Chlorobi* includes **green sulfur bacteria**, which are a small group of obligately anaerobic photolithoautotrophs that use hydrogen sulfide, elemental sulfur, and hydrogen as electron sources. When sulfide is oxidized, elemental sulfur is deposited outside the cell. Their photosynthetic pigments are located in

| Table 21.2 Characteristics of the Major Groups of Gram-Negative Photosynthetic Bacteria | | | | | |
|---|--|---|--|--|---|
| Characteristic | Green Sulfur | Green Nonsulfur | Purple Sulfur | Purple Nonsulfur | Aerobic Anoxygenic Phototrophs |
| Major photosynthetic pigments | Bacteriochlorophylls <i>a</i> plus <i>c</i> , <i>d</i> , or <i>e</i> (the major pigment) | Bacteriochlorophylls <i>a</i> and <i>c</i> | Bacteriochlorophyll <i>a</i> or <i>b</i> | Bacteriochlorophyll <i>a</i> or <i>b</i> | Bacteriochlorophyll <i>a</i> |

² With the exception of *Ectothiorhodospira*.

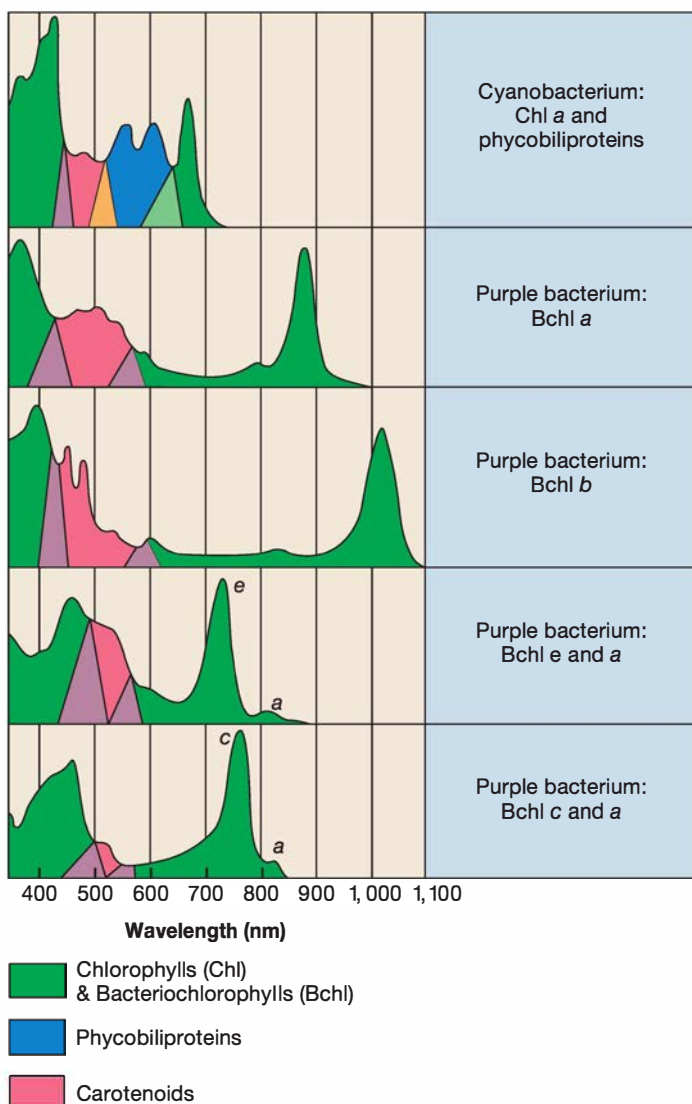

Figure 21.8 Photosynthetic Pigments. Absorption spectra of five photosynthetic bacteria showing the differences in absorption maxima and the contributions of various accessory pigments.

ellipsoidal vesicles called **chlorosomes** or chlorobium vesicles, which are attached to the plasma membrane by a proteinaceous baseplate that contains Bchl *a* molecules (figure 21.9). The chlorosome membrane is an unusual lipid monolayer, rather than bilayer. Within chlorosomes, bacteriochlorophyll molecules (Bchl *b*, *d*, or *e*) are grouped into rodlike structures held together by carotenoids and lipids. The light harvested by these pigments is transferred by baseplate Bchl *a* to reaction centers in the plasma membrane, which also contain Bchl *a*. The energy captured is used to fuel CO₂ fixation by the reductive citric acid cycle (see figure 12.5).

These bacteria flourish in the anoxic, sulfide-rich zones of lakes. Although they lack flagella and most are nonmotile, at least

one genus glides. Some species have gas vesicles to adjust their depth for optimal light and hydrogen sulfide (see figure 3.38). Those without gas vesicles are found in sulfide-rich muds at the bottom of lakes and ponds.

The green sulfur bacteria are very diverse morphologically. They may be rods, cocci, or vibrios; some grow singly, and others form chains and clusters. They are either grass-green or chocolate-brown in color. Representative genera are *Chlorobium*, *Prosthecochloris*, and *Pelodictyon*.

Phylum *Chloroflexi*

The phylum *Chloroflexi* is a deep and ancient branch of the bacterial tree. It has both photosynthetic and nonphotosynthetic members. Members of the genus *Chloroflexus* are the major representatives of the photosynthetic **green nonsulfur bacteria**. However, the term green nonsulfur is a misnomer because not all members of this group are green, and some can use sulfur. *Chloroflexus* spp. are filamentous, gliding, thermophilic bacteria often isolated from neutral to alkaline hot springs, where they grow in the form of orange-reddish mats, usually in association with cyanobacteria. They possess small chlorosomes with accessory Bchl *c*. The light-harvesting complexes contain Bchl *a* and are in the plasma membrane. *Chloroflexus* spp. are metabolically very diverse. They can carry out anoxygenic photosynthesis with organic compounds as carbon sources or fix CO₂ using the 3-hydroxypropionate cycle (see figure 12.6). They can also grow chemoheterotrophically, using aerobic respiration.

Members of the nonphotosynthetic, gliding, rod-shaped, or filamentous genus *Herpetosiphon* also are included in this phylum. They are aerobic chemoorganotrophs with respiratory metabolism. They can be isolated from freshwater and soil habitats.

Retrieve, Infer, Apply

1. Which of the phototrophs discussed perform anoxygenic photosynthesis? Which are also capable of chemoorganoheterotrophy?
2. What is the function of chlorosomes? How does their unique structure contribute to this function?
3. Compare the capacity of green nonsulfur (*Chloroflexi*) and green sulfur bacteria (*Chlorobi*) to position themselves in light of optimum wavelength.

Phylum *Cyanobacteria*

Cyanobacteria are the largest and most diverse group of photosynthetic bacteria. Originally studied by botanists, they were classified as *Chlorophyceae*, commonly known as blue-green algae. The discovery that these microbes are really Gram-negative bacteria did not resolve their taxonomic issues. Older classifications list as many as 2,000 or more species. *Bergey's Manual* describes 56 genera and divides cyanobacteria into five subsections (table 21.3). At present all taxonomic schemes must be considered tentative, and while many genera have been

Figure 21.9 Green Sulfur Bacterium (a) Light-harvesting chlorosomes surround the inside perimeter of the cytoplasmic membrane. Antenna bacteriochlorophylls (Bchl *c*, *d*, or *e*) transfer light energy to reaction center Bchl *a* in the plasma membrane. (b) A chlorosome is attached to the inner surface of the plasma membrane by a baseplate composed of a lipid monolayer and Bchl *a* molecules. The chlorosome absorbs light by Bchl *c*, *d*, or *e* molecules aligned in rod-shaped complexes (Bchl *c* is shown here). The reaction center (RC) is located in the plasma membrane and contains only Bchl *a*. The light-harvesting complex (LH) and ATP synthase are also located in the plasma membrane.

| V | Filamentous trichomes either with branches or composed of more than one row of cells | Binary fission in more than one plane, hormogonia formed | + | 42–44 | May produce akinetes; greatest morphological complexity and differentiation in cyanobacteria | <i>Fischerella</i> <i>Stigonema</i> <i>Geitleria</i> |

assigned, species names have not yet been designated in most cases.

The cyanobacterial photosynthetic apparatus closely resembles that of eukaryotes; cyanobacteria have chlorophyll *a* and photosystems I and II, and thereby perform oxygenic photosynthesis. Recall that endosymbiotic cyanobacteria are thought to have evolved into chloroplasts. Light-harvesting and electron transport chain components are located in thylakoid membranes to which particles called **phycobilisomes** are attached (figure 21.10). Phycobilisomes are protein complexes made up of **phycobiliprotein** pigments, particularly **phycocyanin** and **phycoerythrin**, held together by linker proteins (figure 21.10b). Each phycobilisome consists of a core phycobiliprotein pigment, allophycocyanin, to which other pigments are arranged in stack-like structures. This arrangement enables the efficient transfer energy to photosystem II. ◀◀ *Evolution of the three domains of life* (section 19.5)

Carbon dioxide is assimilated through the Calvin cycle (see figure 12.4). The enzymes needed for this process are found in internal structures (microcompartments) called **carboxysomes**. The reserve carbohydrate is glycogen. Some cyanobacteria store extra nitrogen as polymers of arginine and aspartic acid in **cyanophycin** granules. Phosphate is stored in polyphosphate granules. Because cyanobacteria lack the enzyme α -ketoglutarate dehydrogenase, it was long thought that they lack a fully functional TCA cycle. Recently two enzymes that bypass the need for this enzyme were identified in a unicellular cyanobacterium belonging to

the genus *Synechococcus*. In this microbe, and most cyanobacteria, the first enzyme converts α -ketoglutarate to succinic semi-aldehyde, which is then oxidized to succinate by the second enzyme; the intermediate succinyl-CoA is not produced (see figure 11.8). The pentose phosphate pathway plays a central role in their carbohydrate metabolism. Although most cyanobacteria are obligate photolithoautotrophs, a few can grow in the dark as chemoheterotrophs by oxidizing glucose and a few other sugars. Under anoxic conditions, *Oscillatoria limnetica* oxidizes hydrogen sulfide instead of water and carries out anoxygenic photosynthesis much like the green photosynthetic bacteria. *Oscillatoria* is one of several cyanobacterial genera whose members produce geosmins, volatile organic compounds that often have an earthy odor. When populations of these cyanobacteria become dominant in lakes and rivers, this can be a public nuisance, even changing the taste of drinking water. ◀◀ *Microcompartments* (section 3.6); ▶▶ *Microorganisms in marine and freshwater ecosystems* (chapter 30)

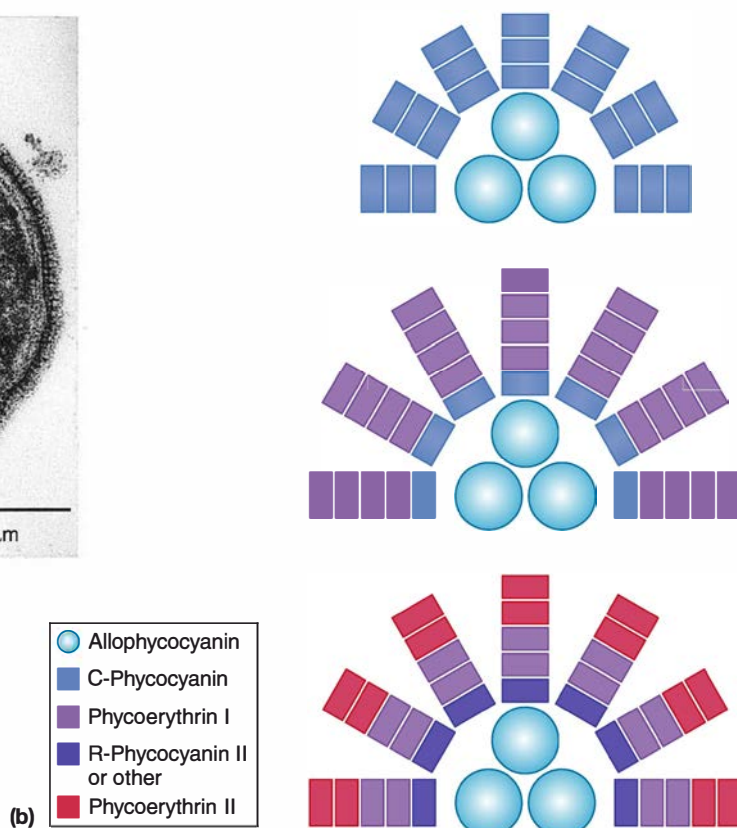

Cyanobacteria also vary greatly in shape and appearance. They range in diameter from about 1 to 10 μm and may be unicellular, exist as colonies of many shapes, or form filaments called trichomes (figure 21.11a). A **trichome** is a row of bacterial cells that are in close contact with one another over a large area. Although many cyanobacteria appear blue-green because of phycocyanin, isolates from the open ocean are red or brown because their phycobilisomes contain the pigment phycoerythrin (figure 21.10b). Cyanobacteria modulate the relative amounts of

these pigments in a process known as **chromatic adaptation**. When orange light is sensed, phycocyanin production is stimulated, whereas blue and blue-green light promote the production of phycoerythrin. Cyanobacteria use a variety of strategies to sense light, including sensory rhodopsins (see p. 485), plantlike proteins called phytochromes, and membrane-associated receptors that sense ultraviolet and blue light. Many cyanobacterial species use gas vacuoles to position themselves in optimum illumination in the water column—a form of **phototaxis**. Gliding motility is used by other cyanobacteria. Although cyanobacteria lack flagella, about one-third of the marine *Synechococcus* strains swim at rates up to 25 μm per second by an unknown mechanism. Swimming motility is not used for phototaxis; instead, it appears to be used for chemotaxis toward simple nitrogenous compounds such as urea. ◀◀ *Bacterial motility and chemotaxis* (section 3.8)

Cyanobacteria show great diversity with respect to reproduction and employ a variety of mechanisms: binary fission, budding, fragmentation, and multiple fission. In the last process, a cell enlarges and then divides several times to produce many smaller progeny, called **baeocytes** (see figure 7.2), which are released upon the rupture of the parental cell. Some baeocytes disperse through gliding motility. Fragmentation of filamentous

cyanobacteria can generate small, motile filaments called **hormogonia**. Some species develop **akinetes**, specialized, dormant, thick-walled resting cells that are resistant to desiccation (figure 21.12a). These later germinate to form new filaments.

Many filamentous cyanobacteria fix atmospheric nitrogen by means of special cells called **heterocysts** (figure 21.12a,b). Around 5 to 10% of the cells develop into heterocysts when these cyanobacteria are deprived of both nitrate and ammonia, their preferred nitrogen sources. Within these specialized cells, photosynthetic membranes are reorganized and the proteins that make up photosystem II and phycobilisomes are degraded. Photosystem I remains functional to produce ATP, but no oxygen is generated. Lack of O_2 production is critical because the N_2 -fixing enzyme nitrogenase is extremely oxygen sensitive. Heterocysts develop thick cell walls, which slow or prevent O_2 diffusion into the cell, and any O_2 present is consumed during respiration. Heterocyst structure and physiology ensure that these specialized cells remain anaerobic; the heterocyst is dedicated to nitrogen fixation, not reproduction. Nutrients are obtained from adjacent vegetative cells, while the heterocysts contribute fixed nitrogen in the form of amino acids. Nitrogen fixation also is carried out by some cyanobacteria that lack heterocysts. Some fix nitrogen under dark, anoxic

conditions in microbial mats. Planktonic forms such as belonging to the genus *Trichodesmium* fix nitrogen and contribute significantly to the marine nitrogen budget. ◀◀ Nitrogen fixation (section 12.5); ▶▶ Nitrogen cycle (section 28.1)

(c)

Figure 21.12 Cyanobacteria with Akinetes and Heterocysts.

(a) The filamentous cyanobacterium *Anabaena* with akinetes and heterocysts. (b) *Anabaena* heterocysts (arrow) and vegetative cells. (c) Heterocysts fix dinitrogen to form glutamate, which is exchanged with adjacent vegetative cells for carbohydrate. Heterocysts use only photosystem I, so photosynthesis is anoxygenic in these differentiated cells.

MICRO INQUIRY Why do you think NH_3 is converted to the amino acid glutamate in heterocysts before its transfer to neighboring vegetative cells?

One group of cyanobacteria is collectively referred to as **prochlorophytes** (genera *Prochloron*, *Prochlorococcus*, and *Prochlorothrix*). These microbes differ from other cyanobacteria by the presence of chlorophyll *a* and *b*, and the lack of phycobilins. This pigment arrangement imparts a grass-green color. As the only bacteria to possess chlorophyll *b*, the ancestors of unicellular prochlorophytes are considered to be the best candidates for the endosymbionts that gave rise to chloroplasts. ◀◀ Evolution of the three domains of life (section 19.5)

The three recognized prochlorophyte genera are quite different from one another. Members of the genus *Prochloron* were first discovered as extracellular symbionts growing either on the surface or within the cloacal cavity of marine colonial ascidian invertebrates (commonly called “sea squirts”). These bacteria are single-celled, spherical, and 8 to 30 μm in diameter. By contrast, those in the genus *Prochlorothrix* are free living, with cylindrical cells that form filaments growing in freshwater.

Prochlorococcus marinus, a tiny coccobacillus less than 1 μm in diameter, flourishes in marine plankton. It differs from other prochlorophytes in having divinyl chlorophyll *a* and *b*, and α -carotene, instead of chlorophyll *a* and β -carotene. Other cyanobacteria use monovinyl chlorophyll *a*; the difference between mono- and divinyl chlorophyll is the presence of a double bond between carbons attached to pyrrole ring II (see figure 11.29). During the summer, *P. marinus* reaches concentrations of 5×10^5 cells per milliliter. It is one of the most numerous of the marine plankton and is the most abundant photosynthetic organism on Earth.

Another indication of the vast diversity among cyanobacteria is the wide range of habitats they occupy. Many live in symbiotic association with protists and fungi. Thermophilic species may grow at temperatures up to 75°C in neutral to alkaline hot springs. Because these photoautotrophs are so hardy, they are primary colonizers of soils and surfaces that are devoid of plant growth. Some unicellular forms even grow in the fissures of desert rocks. In nutrient-rich warm ponds and lakes, filamentous cyanobacteria such as *Anacystis* and *Anabaena* spp. can reproduce rapidly to form blooms (figure 21.13). The release of large amounts of organic matter upon the death of the bloom microorganisms stimulates the growth of chemoheterotrophic bacteria. These microbes subsequently deplete available oxygen. This kills fish and other organisms. Some species can produce toxins that can kill animals that drink the water. Other cyanobacteria (e.g., *Oscillatoria* spp.) are so pollution resistant and characteristic of freshwater with high organic matter content that they are used as water pollution indicators. ▶▶ Microorganisms in coastal ecosystems (section 30.2)

Cyanobacteria have a profound effect on the global carbon cycle. Members of two marine genera in particular, *Synechococcus* and *Prochlorococcus*, account for about one-third of global CO_2 fixation. These microbes have coevolved to take maximum advantage of the incident light. *Synechococcus* spp. occupy the upper 25 meters of the open ocean, where white and blue-green light can be harvested. *Prochlorococcus* species are divided into two ecotypes (members of the same species that are adapted to different environmental conditions): the high-light ecotype grows between about 25 to 100 meters, while the low-light ecotype lives from 80 to 200 meters, where the waters are penetrated by blue-violet

Figure 21.13 Bloom of Cyanobacteria and Algae in a Eutrophic Pond.

light. Thus cyanobacteria in the two genera do not compete for the essential resource of light. ◀◀ *The concept of a microbial species* (section 19.5); ▶▶ *Microorganisms in the open ocean* (section 30.2)

Retrieve, Infer, Apply

1. What are the major characteristics that distinguish cyanobacteria from other photosynthetic organisms?
2. What is a trichome and how does it differ from a simple chain of cells?
3. Briefly discuss the ways in which cyanobacteria reproduce.
4. Describe how a vegetative cell, a heterocyst, and an akinete are different. How are heterocysts modified to carry out nitrogen fixation? Why must heterocysts use only photosystem I?
5. Compare the prochlorophytes with other cyanobacteria. Why do they occupy stratified layers in the ocean?
6. List some important positive and negative impacts cyanobacteria have on humans and the environment.

21.5 Phylum *Planctomycetes*

After reading this section, you should be able to:

- Draw the unusual structural features of planctomycetes
- Identify the electron donor and acceptor used in the anammox reaction
- Explain why the anammox reaction is important to the global flux of nitrogen

The phylum *Planctomycetes* was largely underappreciated until recently. Bacteria in this phylum are morphologically unique, having compartmentalized cells (figure 21.14). Although each species is unique, all follow a basic cellular organization that includes a plasma membrane closely surrounded by a proteinacious cell wall that lacks peptidoglycan. The intracytoplasmic membrane is separated from the plasma membrane by a peripheral, ribosome-free region called the paryphoplasm (sometimes

referred to as the pirellulosome). Some planctomycetes, such as *Gemmata obscuriglobus*, enclose their genome in a compartment called the nuclear body. Unlike a eukaryotic nucleus, the nuclear body contains ribosomes as well as nucleic acids. Members of the genus *Planctomyces* attach to surfaces through a stalk and holdfast; those belonging to other genera in the order lack stalks. Most of these bacteria have life cycles in which sessile cells bud to produce motile swarmer cells. The swarmer cells are flagellated and swim for a while before attaching to a substrate and beginning budding reproduction.

The genera *Brocadia*, *Kuenenia*, *Scalindua*, and *Anammoxoglobus* contain bacteria without a nuclear body but with another compartment, the **anammoxosome**. This is the site of anaerobic ammonia oxidation called the **anammox reaction**, or simply anammox. This unique form of chemolithoautotrophy employs ammonium ion (NH_4^+) as the electron donor and nitrite (NO_2^-) as the terminal electron acceptor—it is reduced to nitrogen gas (N_2) (figure 21.15). Hydrazine (N_2H_4) is normally a cellular toxin, but in this case, it is an important intermediate. This is because it has a very negative reduction potential so it can donate electrons to ferredoxin. The four high-energy electrons carried by reduced ferredoxin can then be used to produce a proton motive force (PMF) that is able to drive ATP synthesis by an ATP synthase embedded in the anammoxosome membrane. Reduced ferredoxin is also used in CO_2 fixation.

One interesting feature of the physiology of anammox bacteria is that they use nitrite not only as the electron acceptor for ammonium oxidation and generation of a PMF but also as an electron donor for CO_2 fixation, which is accomplished using the reductive acetyl-CoA pathway (see figure 20.3). Therefore nitrite acts in both anabolic and catabolic processes, as shown in the following reactions:

An anabolic reaction:

And a catabolic reaction:

The anammoxosome is bounded by a single bilayer membrane that contains ladderane lipids (see figure 3.34). These lipids are unique to planctomycetes. It is thought that they form an impermeable barrier, preventing the escape of toxic anammox intermediates into the riboplasm. Finally, the ecological consequence of the anammox reaction is significant. It is estimated that anammox may contribute as much as 70% to the cycling of nitrogen in the world's oceans. ▶▶ *Nitrogen cycle* (section 28.1)

21.6 Phylum *Chlamydiae*

After reading this section, you should be able to:

- Explain the term obligate intracellular parasite
- Diagram the chlamydial life cycle
- Deduce why chlamydia can survive despite significant metabolic limitations

Figure 21.14 Planctomycete Cellular Compartmentalization. (a) An electron micrograph of *Gemmata obscuriglobus* showing the nuclear body envelope (E), the intracytoplasmic membrane (ICM), and the paryphoplasm (P). (b) An electron micrograph of the anaerobic ammonia-oxidizing planctomycete *Candidatus Brocadia anammoxidans*. The anammoxosome is labeled AM. (c) Schematic drawings corresponding to (a) and (b): cell wall (CW), plasma membrane (PM).

Figure 21.15 The Anammox Reaction. Ammonium (NH_4^+) combines with nitric oxide (NO) to form hydrazine (N_2H_4) in a reaction catalyzed by hydrazine synthase (HZS). Oxidation of hydrazine by a hydrazine/hydroxylamine oxidoreductase (HZO/HAO) results in the formation of one N_2 and four protons. The electrons are passed to NO_2^- , which is reduced by nitrite:nitric oxide reductase (NirS) to form another molecule of NO and the cycle continues.

MICRO INQUIRY How does a planctomycete use the anammox reaction to generate a proton motive force?

Chlamydiae are Gram-negative obligate intracellular parasites. This means they must grow and reproduce within host cells. Although their ability to cause disease is widely recognized, many species grow within protists and animal cells without adverse effects. It is thought that these hosts represent a natural reservoir for the chlamydiae. In the human host, *C. trachomatis* is responsible for the most common sexually transmitted disease, known as nongonococcal urethritis. This microbe is also the most common cause of preventable blindness in the world. These diseases are discussed in chapter 39.

Members of the genus *Chlamydia* are nonmotile, coccoid bacteria, ranging in size from 0.2 to 1.5 μm . They reproduce only within cytoplasmic vesicles of host cells by a unique developmental cycle involving the formation of two cell types: elementary bodies and reticulate bodies. Although their envelope resembles that of other Gram-negative bacteria, the cell wall differs in lacking muramic acid and a peptidoglycan layer. Chlamydiae are extremely limited metabolically, relying on their host cells for key metabolites. This is reflected in the size of their genome, which is relatively small at 1.0 to 1.3 Mb. Comparative genomics reveals that some chlamydial genes were acquired by horizontal gene transfer (HGT) from free-living bacteria to a common chlamydial ancestor, and HGT accounts for the transfer of genes from chlamydiae to their protist hosts in the genera *Trypanosoma* and *Leishmania*. **Euglenozoa (section 25.2)**

Chlamydial reproduction is unique. Reproduction begins with the attachment of an **elementary body (EB)** to the host cell surface (**figure 21.16**). Elementary bodies are 0.2 to 0.6 μm in diameter, contain electron-dense nuclear material and a rigid cell wall, and are infectious. They achieve osmotic stability in the extracellular environment by cross-linking their outer membrane proteins, and pos-

sibly periplasmic proteins, with disulfide bonds. Host cells become infected with EBs by endocytosing them. An EB is held in an endosome that evades fusion with lysosomes. There the EB differentiates into a **reticulate body (RB)** and undergoes binary fission, which continues until the host cell dies. Reticulate bodies are 0.5 to 1.5 μm in diameter and have less dense nuclear material and more ribosomes than EBs; their walls are also more flexible. After 20 to 25 hours, RBs begin to differentiate into infectious EBs. The host cell lyses and releases EBs 48 to 72 hours after infection.

Chlamydial metabolism is very different from that of other bacteria. It had been thought that chlamydiae cannot catabolize carbohydrates or synthesize ATP. *Chlamydia psittaci*, one of the best-studied species, lacks both flavoprotein and cytochrome electron transport chain carriers but has a membrane translocase that acquires host ATP in exchange for ADP. The protist parasite *Chlamydia* UWE25 cannot synthesize NAD^+ but synthesizes a transport protein for the import of host NAD^+ . Thus some chlamydiae may be energy parasites that are completely dependent on their hosts for ATP. However, in addition to two genes for ATP/ADP translocases, the *C. trachomatis* genome also has genes for substrate-level phosphorylation, electron transport, and oxidative phosphorylation. When supplied with precursors from the host, RBs can synthesize DNA, RNA, glycogen, lipids, and proteins. They also can synthesize at least some amino acids and coenzymes. The EBs have minimal metabolic activity and cannot take in ATP or synthesize proteins. They are designed exclusively for transmission.

(b) Generalized life cycle of chlamydiae.

MICRO INQUIRY Why do you think RBs have been so difficult to study?

Retrieve, Infer, Apply

1. Describe planctomycetes and their distinctive morphological and metabolic properties.
2. Explain how some planctomycetes produce both NO_3^- and N_2 .
3. Briefly describe the steps in the chlamydial life cycle. Why do you think chlamydiae differentiate into specialized cell types for infection and reproduction?
4. How does chlamydial metabolism differ from that of other bacteria?

21.7 Phylum *Spirochaetes*

After reading this section, you should be able to:

- Draw a spirochete cell as it would be observed in a scanning electron micrograph and in cross section by transmission electron microscopy
- Describe how the unusual flagellar arrangement is well suited for motility in common spirochete habitats

The phylum *Spirochaetes* (Greek *spira*, a coil, and *chaete*, hair) contains Gram-negative, chemoorganotrophic bacteria distinguished by their structure and mechanism of motility. Spirochetes can be anaerobic, facultatively anaerobic, or aerobic. Carbohydrates, amino acids, long-chain fatty acids, and long-chain fatty alcohols may serve as carbon and energy sources.

Table 21.4 summarizes some of the more distinctive properties of selected genera.
